the medical referees and those adopted by the panel doctors. It was clear that every person who was entitled to benefit under this scheme should get benefit, and there ought not to be a differentiation in treatment by any of the medical practitioners. It was a striking thing that the recovery from long illness seemed to take place more rapidly when the value of the benefit was reduced. The inquiry which the Minister contemplated would at least show to the medical profession that this subject was being closely watched, and that doctors had to do something more than merely certify; they had to certify with proper care and precaution. If that debate did nothing more than bring doctors to a realisation of their duties it would have done something. In his view, whatever else the inquiry might find out, they would discover that they had to get back to the old method of transfer from one doctor to another.

THE MEDICAL VIEW.

Dr. MORRIS-JONES said that he understood that the Minister of Health could not touch on many important aspects of administration of the Department, but he was sorry that he did not mention one important matter, the question of vaccination. That matter affected medical and lay circles in this country, and would have to be faced. There were also international obligations associated with it. They saw this a very short time ago, when there was an epidemic in this country, and when a neighbour across the Channel raised difficulties with regard to people arriving there from this country. He hoped that the Minister of Health would face this matter. At present the administration of the law with regard to vaccination was almost farcical. If it was the opinion of the Government that vaccination should be compulsory, it ought to be made compulsory. At any rate, if the Government did not agree in that sense, steps ought to be taken to abolish compulsory vaccination.

Voluntary Services on Public Bodies.

He wished to say a few words in regard to the effect of the Local Government Act of 1929 on a large number of men and women who had been giving voluntary services on some public bodies. He was rather sorry that the late Minister of Health, who initiated and carried out that very great Act, had prevented a large number of public-spirited citizens from giving their services to local bodies on account of the fact that they would have to resign appointments which they had held for many years and which financially brought them very little benefit, but which under the Act they would have to give up or give up their voluntary services on a public body. In his own municipality—he spoke about medical men because he happened to know them better—it affected men and women who gave their services to local bodies. They was the case of a parish doctor who had been on the County Council since the beginning of that authority. Under the Act he had to take the choice of resigning an appointment which he had held for 30 or 40 years or resign his membership of the local authority. It was a pity that the right hon. gentleman did not preserve this great tradition of public service. Not only had these people to make the choice now as to whether they would give up their appointments or resign their membership of a public authority, but they knew that if they gave up their appointments and continued to serve in a voluntary capacity on the public authorities they would lose all superannuation payments, towards which they had contributed over a series of years, as well as the State contribution. It was an injustice that these men and women, who had given services for a great proportion of their life time, should now, because they might choose to continue their voluntary services to the State, be deprived of the superannuation towards which they had contributed for a large number of years. He hoped that the Government would be able to find a way of redressing this anomaly.

Industrial Depression the Cause of Sickness.

A matter which had received public notice was that of the large number of claims under the National Health Insurance Act. The Minister of Health had referred to some of the causes of this increase, and Mr. Rhys Davies, who had had very considerable experience in these societies, also analysed some of the causes. He agreed with Mr. Rhys Davies that the main cause was the serious industrial depression since the war. There were amendments of the National Health Insurance Act whereby persons who were unemployed were still able to retain their rights to medical benefit. By going to the employment exchange and having their cards checked, they were able to continue to receive medical benefit. It was perfectly right that they should continue to receive medical benefit. Although the payment of that benefit might result in the depletion of the funds of the approved societies, it would not be fair at a time when the insured persons were the subjects

of enforced idleness, due to no fault of their own, that they should be deprived of medical benefit. From his experience as a medical man he found that enforced idleness, enforced unemployment, was bound to cause more sickness. The man who was working was much healthier than the man who was not working, and the same remark applied to a woman. A person who had nothing to do except to analyse his own slightest symptom was in such a frame of mind that a small symptom which would not receive any notice at a time when he was working was magnified when he had nothing to do but to think about it. This was a very potent cause of the increased number of claims for sickness benefit. There were, of course, other causes. There was the war, and the increased illness as a result of the war, even among those who did not participate as combatants. In the course of some years' experience under this Act, people had come to consult him or he had had to attend people who did not take any part in the war, but who, nevertheless, were suffering very seriously from having gone through that great catastrophe. Many insured persons had suffered from the bombing that took place in London. It was no exaggeration to say that there were hundreds of people in the County of London who, since the war, were directly or indirectly suffering as a result of the experiences which they went through at that time. There was another reason for the increased claims. He agreed with Mr. Rhys Davies when he said that 99 out of every 100 national health insured were honest, hard-working people, but that 1 per cent. were malingerers. He had had experience of persons who had come to him as a medical man under the Act, and had said: "We have been paying long enough." One person said to him: "We have been paying to Lloyd George for years, and it is time that we got something out of it."

The Difficulties of Certification.

He wished to say a few words in regard to the alleged laxity in giving medical certificates. The giving of medical certificates was a very difficult matter. Medical men were neither worse nor better than any other class of human creature, certainly no worse, and he did not suppose they were any better. They were confronted day by day with very great difficulties under this Act. One Member had mentioned in the debate that a young medical man, newly qualified and anxious to build up a practice, would be rather keen to please his patient, and therefore he would possibly give a certificate when it was not really required. Quite possibly that might be the case, but he thought that such cases were very rare. It was an extraordinarily difficult thing to tell when a man was or was not capable of work. One of the most difficult things in the world was to prove that a man was not ill. There was a story told of a medical man who dealt rather cleverly with a man whom he knew was very definitely malingering. The man was making a very substantial claim on a railway company as a result of a railway accident. He stated that the pain in his back was so great that he could not stand upright. He walked into the doctor's consulting room bent on two sticks but the doctor had no doubt on the question of the man's capacity. As the man was bent in front of him, the doctor said "I can see that you are unable to stand upright on account of the pain in your back. Would you mind showing me how you used to stand before you met with your accident?" At once the man stood upright. There were occasions when one was able to find out whether or not a man was really ill, but generally it was very difficult. There had been cases known of responsible medical men, of great experience, pronouncing a man fit, and that man had died the same day. Medical science was not an exact science. There were very grave doubts in regard to many ailments. Certain possibilities of a very grave character did not show on the surface as obviously as they did in other cases.

Increasing Standard of Treatment.

On the whole, they saw from the report of the Ministry of Health and the statements made by the chief medical officer to the Ministry that the general standard of treatment under the Act had improved, and that great blessings had been conferred on the community. The claims on the service were constantly increasing. He was certain that the steps taken by the Minister of Health to inquire searchingly into the cause of the alleged and definitely large claims under the Act would result in some more certain causes being found than had been elicited so far. It was only fair to the insured population to point out that the same thing was happening in other countries which had adopted the health insurance system. In Germany and, he understood, in Ireland, the same thing applied as in England and Wales. He hoped the Minister of Health would be able thoroughly to overhaul and reorganise if possible the whole scope of the national health insurance service in this country. He hoped that the Parliamentary Secretary would say that the Government contemplated

before long being able to bring before the House a scheme to enlarge the whole of the service of national health insurance, co-ordinating the numerous branches of it, and bringing within its scope women and children and dependents, thereby crowning an Act which had been a very beneficent Act for the people of this country.

(To be continued.)

THE SLUM CLEARANCE BILL.

The Housing (No. 2) Bill was considered by Standing Committee A of the House of Commons on Thursday, May 1st. Mr. SCURR was in the chair.

Insanitary Areas.

On Clause 1 (which gives a local authority power to declare an unhealthy area to be a clearance area,

Dr. VERNON DAVIES moved an amendment to provide that the local authority should act under the clause after consideration of an official representation from a medical officer of health. He said this was a slum clearance Bill and its basic object was the protection of the health of the people who lived in slums. A medical man was necessary in judging conditions relating to health, and there was a particular branch of medicine in which medical officers of health had to take a special diploma. Therefore the man to determine whether the condition of any property was likely to be injurious to health should be the medical officer of health. As the clause now stood, information might come from people who were absolutely incompetent to furnish information, or might be acting from improper motives.

Mr. GREENWOOD (Minister of Health) said he could not accept the amendment under which there could be no clearance scheme without the consent of the medical officer of health.

Lieut.-Colonel FREMANTLE: Oh, no!

Mr. GREENWOOD said that that was what it meant. There might well be cases in which a local authority would be doing right in going forward with a clearance scheme without having obtained what was virtually the consent of the medical officer of health.

Lieut.-Colonel FREMANTLE said he saw the point put forward by the Minister, but he did not think the position was quite what the right hon. gentleman had stated. Of course a local authority had other means of obtaining information in addition to receiving representations from their medical officer of health, but if the clause remained as it was they could proceed without any consultation with the medical officer of health, or any report from him. The medical officer was the official who was technically trained for this purpose, and if in certain cases he was inclined to be dilatory, the local authority could call upon him for a report and they had power to secure other information.

Sir TUDOR WALTERS said that a medical officer of health was not in all cases the best person to discover insanitary areas. He (Sir Tudor Walters) was not a doctor, but he would be a better judge of an insanitary area than the most distinguished medical man in the country, because it happened to be his business to know something about the laying out of buildings and their construction.

Administrative Effects.

Mr. NEVILLE CHAMBERLAIN said he looked at this matter chiefly from the point of view of administration, and he viewed this innovation with some considerable concern. It was quite true that under the Bill it was open to a medical officer of health to make an official representation to the local authority, but if they did not accept that representation, housing reform would be held up quite as much as by a default on the part of the medical officer of health. He thought it was desirable that the local authorities should have all the information from whatever source it might come, but the responsibility should rest on the medical officer of health, and not on anybody else. If the medical officer of health knew that without any representation received from him the local authority could act on information received from anybody, that must necessarily weaken his responsibility. He asked the Minister to give further consideration to the matter.

Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) said the normal way would be for the medical officer of health to make representations in the exercise of his statutory duties, but a local authority might well have recourse to other information and act upon it. The only point at issue was whether in the case where an authority could not convert its medical officer to its view it should be placed in the dilemma of having to dismiss him or to drop the scheme. The plan outlined in the clause had

worked perfectly satisfactorily under the Act of 1925, and she thought that the provision had been re-enacted from an earlier Act.

After further debate,

The amendment was rejected by 33 votes to 12.

Mr. HARRIS moved an amendment to make it clear that a clearance area might include buildings other than houses. He said he moved the amendment on behalf of the London County Council.

Mr. GREENWOOD accepted the amendment, which was agreed to.

"Bad Arrangement."

Mr. WOMERSLEY moved an amendment to leave out from Subsection (1) the words "their bad arrangement," and to insert instead the words "want of light, air, ventilation, or proper conveniences."

Mr. GREENWOOD said it would be a most retrograde step to cut out from their operations huddled groups of buildings and streets so narrow that they were really injurious to health.

Mr. WOMERSLEY: What does "bad arrangement" really mean?

Sir WILLIAM JOYNT, Attorney General, said that these words had found their place in housing statutes for the last sixty years, and as far as he knew there had never been any difficulty arising out of their vagueness.

Lieut.-Colonel FREMANTLE said he had been discussing with the Society of Medical Officers of Health the provisions of this Bill. The amendments which the Society desired were very few, but there was one which they put forward dealing with the difficulty in defining the provision as to "unfit for human habitation." Though it was true, as Sir William Joynt had said, that the term "bad arrangement" had been in the law for a number of years, the difficulty none the less remained. What had a medical officer got to decide as being "unfit for human habitation" other than sanitary defects, want of air, and so forth, which were included in the later definition clause? This was one of the reasons probably for the allegation that there had been slackness in certain areas. He did not think this amendment would get over the difficulty, but there was a real point of substance in trying to define the term "bad arrangement."

The amendment was negatived.

An Obscure Clause.

Mr. CHAMBERLAIN moved an amendment to confine a clearance area to houses only. He said that he had put this amendment down largely to clear up the real meaning of the clause, which he found extremely obscure.

Mr. GREENWOOD said that if this amendment were adopted it would prove utterly impracticable. It was obvious that once they were satisfied that an area was injurious to the health of the people all the buildings should go. The confusion appeared to arise because it was thought that the area must be a solid piece, but that was not so. It might be dotted with islands which were excluded from the clearance area because the buildings on those islands did not conform to the conditions laid down in the clause. If the buildings did not in any way contribute by their bad arrangement, and so on, to the injury of the health of the people, then clearly they did not form part of the clearance area.

The amendment was still under discussion when the Committee adjourned.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 30TH.

Sickness and Disablement Benefits.

Sir FREDERICK HALL asked the Minister of Health the numbers of insured men per 100 who claimed sickness benefit in 1921 and 1927, respectively; the respective amounts of expenditure in the same two years for sickness and disablement benefits and the State treatment of disease; the cost per head of the population of England and Wales in 1921 and 1927, respectively, for national health insurance; the cost per head of that population for the same years for State medical treatment; whether the tendency was for expenditure on sickness benefit to decrease as expenditure on preventive and curative treatment increased; and if he would consider setting up a suitable body to inquire into the working of the Health Insurance Acts.—Miss LAWRENCE, Parliamentary Secretary to the Ministry of Health, replied: The information desired by the hon. Member is as follows: (1) According to a report recently furnished by the Government Actuary of the sickness and disablement benefit experience of a representative sample of the whole body of insured persons, the number of insured men per 100 who

claimed sickness benefit in 1921 and 1927 was 14 and 23 respectively. (2) The amounts expended under the Health Insurance Acts in England and Wales in 1921 and 1927 in respect of (a) sickness benefit, were £7,176,800 and £11,818,000 respectively; (b) disablement benefit, were £2,689,600 and £3,368,000 respectively; (c) Medical benefit, were £9,394,800 and £3,772,500 respectively. In this connexion it is pointed out that the increase in the amounts expended on sickness and disablement benefits in 1927 as compared with the corresponding amounts expended in 1921 was to some extent due to the fact that in the later of those years there were larger increases in the benefit rates under the societies' schemes of additional benefits. (3) The cost per head of the population of England and Wales in 1921 and 1927 for National Health Insurance was 13s. 11d. and 18s. 8d., respectively, and of medical benefit provided under the Health Insurance Acts 4s. 11½d. and 4s. 5½d. respectively. As regards the last two parts of the question I would refer to the reply given on the 10th inst. The factors which have contributed to the increases above noted are numerous and complex, and without further and fuller consideration any reply to the question does not think it possible to make any general statement as to the relation between those facts and the increased provision of curative and preventive treatment to which the hon. Member refers.

Importation of Unsound Meat.

Mr. THORNE asked the Minister of Health if he was aware that 541 carcasses of mutton from the Patea district of New Zealand were recently examined at a Wapping cold store for carcasses, lymphadenitis and 27 carcasses condemned; that 40 bags of legs of mutton were recently examined at the Port of London refrigerator, Charterhouse-street, and out of 400 legs 31 were found to be badly affected with the disease and condemned; and that the 27 sheep from Patea, New Zealand, had each attached to the leg a certificate of a veterinary inspector of the New Zealand Government to the effect that they had been examined and found sound; and if he would approach the High Commissioner of New Zealand and issue instructions that in future a thorough examination must be made of all legs and shoulders imported in bags at all customs where such bags are landed.—Miss LAWRENCE replied: My right hon. friend has made inquiries and is informed that the facts are substantially as stated in the question. He is bringing the matter to the notice of the Governments of the exporting countries. It is recognised by the local authorities concerned that several parts of carcasses require special attention, and on the information before him my right hon. friend does not think it is necessary to take the course suggested in the last part of the question.

THURSDAY, MAY 1ST.

Food Tickets as Unemployment Relief.

Sir GEORGE PENNY asked the Minister of Labour whether, instead of paying the full amount of unemployment benefit in cash, she would consider the desirability of issuing food tickets for a proportion of the amount where the recipient had a family dependent upon him.—Miss BONDFIELD replied: This suggestion has been considered several times in the past. In my view, it would not be desirable to adopt it.

Coroners' Salaries.

Mr. TINKER asked the Home Secretary the salaries paid to the coroners for St. Helens and Leigh; and what other parts of the county they had charge of in addition to the above.—Mr. CLYNTS replied: St. Helens is in the West Derby Coroner's District, which includes the Petty Sessional Divisions of Kirkdale, Ormskirk, St. Helens, Southport, and Warrington, parts of the Petty Sessional Divisions of Leigh, Prescot, and Wigan, and the whole of the County Boroughs of Bootle, St. Helens, Southport, and Warrington. The salary, I understand, is £1145. Leigh is in the Bury District, which includes the Petty Sessional Division of Bolton and parts of the Petty Sessional Divisions of Bury, Leigh, and Wigan, and the whole of the Borough of Leigh and of the county borough of Bury. I understand that the salary is £925.

Milk for School-children.

Mr. HIRD asked the President of the Board of Education what educational authorities were participating in the campaign to increase the consumption of milk by school-children; and what extension of the campaign was in contemplation.—Sir CHARLES TREVELYAN replied: I understand from the National Milk Publicity Council that their Milk Service scheme in the schools is in operation in 82 areas, with the general approval and encouragement of the local education authorities concerned. A number of other authorities are providing milk meals under their arrangements for the

provision of meals. I am anxious to see an increase in the consumption of milk in the schools, and with this end in view I am keeping in close touch with the National Milk Publicity Council.

"Drink More Milk" Campaign.

Mr. HURD asked the Minister of Agriculture what steps were being taken to renew and extend the drink more milk campaign; and what evidences were available of the increased consumption of liquid milk as a result of such propaganda.—Dr. ADDISON (Parliamentary Secretary to the Ministry of Agriculture) replied: There is no special milk advertising campaign in progress in this country at the present time, but the National Milk Publicity Council is continuing its work in the formation of milk clubs in the elementary and secondary schools of this country, which it is estimated has increased the consumption of milk by about 4,000,000 gallons a year.

Disposal of London Refuse.

Lieut.-Colonel FREMANTLE asked the Minister of Health how soon the report of the Departmental Committee on the Disposal of London Refuse was to be published.—Mr. GREENWOOD replied: I am informed that the Report is likely to be signed in the course of the present month.

Smoke Abatement.

Lieut.-Colonel FREMANTLE asked the Minister of Health how many local authorities had made by-laws under Section 5 of the Public Health (Smoke Abatement) Act, 1926; whether model by-laws under this section had been issued from the Ministry of Health for the guidance of local authorities; and, if not, what was the reason.—Mr. GREENWOOD replied: No local authority has made by-laws or forwarded draft by-laws under this section. Model by-laws have not yet been issued, by reason of technical difficulties.

Psittacosis.

Mr. HACKING asked the Minister of Health how many cases of parrot disease had been reported to him during each of the past two months.—Mr. GREENWOOD replied: My department has received information of 24 cases of illness which commenced during March, and two during April, in which the patients had been associated with sick parrots. I am advised, however, that in the present state of knowledge of psittacosis, it is not possible to say definitely how many of these persons were in fact suffering from that disease.

MONDAY, MAY 5TH.

Medical Qualifications in India.

Mr. FREEMAN asked the Secretary of State for India whether the Government of India had received any proposals for the constitution of an inter-university medical board, consisting of representatives of the Government and of the university, pending the establishment of an All-India General Medical Council; and, if so, whether they proposed to take any steps in the matter.—Mr. WEDGWOOD BENN replied: This proposal was made by a Conference of Indian Universities last October. It was referred to the General Medical Council, whose executive Committee adopted on Feb. 24th a resolution stating that it was unable to accept the proposal as furnishing a satisfactory method of supplying the Council with authoritative information on medical qualifications and standards in India, and with the necessary guarantees of sufficiency.

Mr. FREEMAN also asked whether it was proposed to revive the competitive examinations for admission to the Indian Medical Service; and, if so, whether he would consider the desirability of ordering these examinations to be held in India only.—Mr. WEDGWOOD BENN replied: I am sending my hon. friend a copy of the report of a debate on this subject in the Indian Legislative Assembly on Jan. 28th last, in which the present position is explained. It will be seen that the Government of India propose to review the situation and send me their considered views, which I am expecting shortly.

Development Fund Grant.

Mr. RAMSBOTHAM asked the Secretary to the Treasury the exact use of the grant of £500,000 made by his department to the development fund.—Mr. PETHICK-LAWRENCE (Financial Secretary to the Treasury) replied: The grant of £500,000 to the Development Fund will be issued in instalments as and when required. The advances (grants and loans) already recommended by the Development Commissioners and approved by the Treasury, includes £65,000 (in addition to £35,000 sanctioned previously) for the rebuilding of the Royal Veterinary College, and £4250 for the extension of the laboratory at the Cambridge Department of Animal Pathology.

TUESDAY, MAY 7TH.

Nurses' Conditions at Larbert Asylum.

Miss LEE asked the Secretary of State for Scotland what steps he intended to take to improve the wages and working conditions of nurses in Larbert Asylum.—Mr. ADAMSON replied: The General Board of Control are at present making inquiries into the conditions of service generally in Scottish asylums and the Larbert Asylum will be included within the scope of the inquiries.

Health of the Mercantile Marine.

Sir BASIL PETO asked the President of the Board of Trade the names of those serving on the committee set up to consider and advise on the health of the mercantile marine; and whether their report on the hygiene of crew spaces on board ship might be expected shortly.—Mr. W. GRAHAM replied: The membership of the committee is as follows: Representing the Board of Trade—Mr. E. J. Foley (Chairman), Mr. G. E. Baker, Mr. A. S. Hoskin, and Mr. C. J. Ovey (Clerical Secretary); Representing the Ministry of Health—Sir George S. Buchanan, Dr. P. G. Stock, Mr. M. Heseltine, Mr. R. H. Crooke, and Dr. M. T. Morgan. (Medical Secretary). I cannot yet say when the committee will be in a position to report on the question of the improvement of the hygiene of crew spaces.

Surplus Funds of Approved Societies.

Mr. HAYDAY asked the Minister of Health (1) the total surplus funds standing to the credit of all approved societies under the Health Insurance Acts, at the nearest convenient date; and (2) the total amount set aside by approved societies for the last insurance year for additional benefits; and the nature of such additional benefits and the amounts, respectively, allocated.—Mr. GREENWOOD replied: The total of the surplus funds of approved societies and branches under the Health Insurance Acts is ascertained by quinquennial valuations. The results of the last completed valuations are summarised in the report of the Government Actuary dated Nov. 25th, 1926 (Cmd. 2785). The hon. Member will see from that report that the total surpluses amounted to £42,413,319, from which amounts totalling £26,619,161 were certified for distribution in additional benefits in the ensuing quinquennium. Out of the above distributable surplus, £13,345,000, or about one-half, was applied by the societies and branches concerned in providing increases of the statutory cash benefits, and the remainder was utilised for the provision of various treatment benefits. The most important of these benefits and the annual sums made available for them during the period of the schemes (including State grant) were as follows: Dental benefit, £2,900,000; ophthalmic benefit, £470,000; hospitals, £324,000; convalescent home treatment, £233,000; and medical and surgical appliances, £142,000. As regards the total reserve funds of approved societies, I would refer to the reply given on March 6th last.

National Health Insurance.

Mr. HAYDAY asked the Minister of Health the number of insured persons removed from health insurance on attaining the age of 65 years, and how many of these were transferred from sickness benefit to old age contributory pension for the year ending January, 1930.—Mr. GREENWOOD replied: The number of insured persons who, up to Dec. 31st, 1929, had ceased to be entitled to sickness and disablement benefits under the National Health Insurance Acts by reason of the reduction of the age limit from 70 to 65, is estimated to have been about 650,000. These persons have not been "removed from National Health Insurance," since they continue to be entitled to medical benefit, and to any additional benefits in the nature of treatment after attaining the age of 65. I regret that the information asked for in the second part of the question is not available.

First-Aid in Coal Mines.

Mr. THOMAS WILLIAMS asked the Secretary for Mines whether the new regulations regarding first-aid at coal mines were compulsory, and, if so, if he had received any complaints concerning collieries who had failed to carry them out.—Mr. BEN TURNER replied: The answer to the first part of the question is in the affirmative; and to the second part in the negative. These regulations, which only came into operation a month ago, involve big changes, amounting at some collieries to a complete reorganisation of first-aid work. In some instances it has not yet been possible for this reorganisation to be carried out in the full detail required by the regulations, but the matter is receiving the special attention of H.M. inspectors, who will see that there is no unnecessary delay.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lt. J. V. Williams to be Surg.-Lt. Comdr.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. to be Col.: Bt.-Col. (temp. Col.) J. S. Bostock from R.A.M.C.

Lt.-Col. D. S. Skelton to be temp. Col.

Maj. and temp. Lt.-Col. A. S. Littlejohns to be Lt.-Col., vice Lt.-Col. and Bt.-Col. (temp. Col.) J. S. Bostock.

Maj. C. R. M. Morris to be temp. Lt.-Col.

Maj. C. S. P. Hamilton retires, receiving a gratuity.

Capt. E. H. W. Elkington to be Maj.

Capt. to be Maj.: J. D'A. Champney and V. J. Perez.

ARMY DENTAL CORPS.

Lts., temp. Dental Surgs., Gen. List, to be Lts. (on prob.): W. O. Cook and S. G. Watson.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. P. R. Bolus having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

ROYAL AIR FORCE.

Flying Officer J. L. Groom is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE.

Maj. R. de S. B. Herrick to be Lt.-Col.

Medical News.

UNIVERSITY OF OXFORD.—On May 1st the following degrees were conferred:—

D.M.—R. A. Walsh.

B.M.—R. G. Macbeth and M. G. Pearson.

UNIVERSITY OF CAMBRIDGE.—On May 3rd the following degrees were conferred:—

M.B., and B.Chir.—John Foster, T. D. W. Fryer, and C. J. M. Dawkins.

B.Chir.—T. O. Garland.

* By proxy.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the final examination from March 31st to April 21th the following candidates were approved in the subjects indicated, but are not eligible for the diplomas of the Colleges:—

Medicine.—N. B. Bapat, Bombay and Birmingham; S. W. T. Bontell, London; A. C. Bhargava, Lahore and Guy's; I. Billie, St. Thomas's; J. D. Bright-Richards, Liverpool; G. F. Carey, St. Thomas's; P. Chandra, Punjab and St. George's; L. Charney and D. N. Chatterji, London; A. H. Clegg, Leeds; Jane A. Davies, Cardiff and Royal Free; V. S. H. Davies, Liverpool; C. A. V. De Candole, St. George's; L. H. Devin, St. Bart's; D. Divine, Guy's; D. Durbach, St. Bart's; D. G. Evans, Cardiff and Univ. Coll.; E. D. Fitzpatrick, Birmingham; P. I. Franks, St. Bart's; L. P. Friedman, Univ. Coll.; G. G. Glasco, McGill and St. Mary's; L. H. Griffin, Bristol; Florence McGill and St. Mary's; Carrie I. Hearn, Pennsylvania and Royal Free; H. R. Hovsha, King's Coll.; J. C. de V. Hutchinson, Cape and Guy's; E. H. Jackson, Univ. Coll.; F. J. Javeri, London; C. R. Kenchington, Birmingham; F. S. Krushin, Guy's; S. B. Ledger, King's Coll.; R. E. Lomax, Guy's; S. H. Lumbar, London; Marjorie N. Lunn, Royal Free; F. G. Matland, St. Thomas's; A. F. Merchant, Bombay; D. K. Mulvany, King's Coll.; P. B. Nair, Bombay and Royal Free; Ethelwyn M. Newham, Royal Free; P. W. Parkes, Birmingham; M. A. Parthasarathy, Bombay and Guy's; R. V. C. Richards, Cardiff and Bristol; L. Rose, St. George's; A. L. Rowson, Manchester and London; K. C. Sarkar, King's Coll.; Ida B. Saxby, Bristol; Ester C. Seifert, Westminster; M. Shorron, King's Coll.; A. Shufelder and M. I. Silverton, Leeds; C. H. Sims, Westminster; D. J. R. Steen, St. Thomas's; H. B. Swift, St. Mary's; C. J. Coll.; R. S. Wale, King's Coll.; J. C. S. Wells, Univ. Coll.; Mary J. Westall, Royal Free; R. Wilkinson, Birmingham; Anne E. Williams-James, Bristol; and D. Wilson, St. Mary's.

EUGENICS EDUCATION SOCIETY.—Mr. Henry Twitche, of Portland-place, London, and formerly of Western Australia, after other bequests has left his residual estate, estimated at about £100,000, to the Eugenics Education Society, of Upper Bedford-place, London.

CHADWICK PUBLIC LECTURES.—At the Royal Sanitary Institute, 90, Buckingham Palace-road, London, S.W., at 8 P.M., on Thursday, May 15th, Mr. Edward Willis will lecture on *The Collection and Disposal of Refuse*.—Sir William Collins will preside at a lecture entitled *Cabbages and Kings*, to be given by Mr. A. W. Hill, F.R.S., director of Kew Gardens, in the Chelsea Physic Garden, Swan Walk, Chelsea, at 5 P.M., on Thursday, May 29th.

GLASGOW UNIVERSITY CLUB, LONDON.—The annual summer dinner of this club will be held at the Trocadero Restaurant, Piccadilly, on Friday, May 30th, at 7.30 P.M., with Mr. Robert S. Rait, LL.D., Principal and Vice-Chancellor, presiding. Any Glasgow University men who, though not members of the club, desire to attend, are asked to communicate with the hon. secretaries at 62, Harley House, N.W.1.

SEROLOGICAL DIAGNOSIS OF CANCER.—As we have already announced, the Italian Anti-Cancer League (Lega Italiana per la lotta contro il cancro, via Triboniano, Piazza Cavour, Rome) offers a prize of 15,000 lire for a paper written from a critical and experimental standpoint, on the value of serological methods in the diagnosis of malignant tumours. The paper must be submitted in proper form before June 30th.

MEDICAL PRAYER UNION.—The annual medical missionary breakfast will be held at 8 A.M. on Wednesday, May 21st, at the Refectory, University College, Gower-street, London, W.C. An address will be given by Mr. John Kirk, F.R.C.S., of University College, London, late of Kwangtung, China. Those intending to be present should inform the hon. secretary, Dr. Tom Jays, Livingstone College, Leyton, E.10.

ROYAL INSTITUTION.—At the annual meeting of the members of this institution on May 1st the following officers were elected for the ensuing year. President: The Duke of Northumberland. Treasurer: Sir Robert Robertson. Secretary: Major C. E. S. Phillips. Among the managers elected were Mr. Ernest Clarke, F.R.C.S., Sir James Crichton-Browne, M.D., and Mr. V. Warren Low, F.R.C.S.; while among the visitors were Prof. G. E. Gask, F.R.C.S., Mr. David Heron, F.R.C.S., Mr. G. W. C. Kaye, D.Sc., and Dr. H. R. D. Spitta.

CRITICISM OF PANEL PRACTITIONERS.—At the fifty-first annual conference of the Friendly Societies' Medical Alliance, held at Buxton on Easter Monday, a discussion arose on the following paragraph in the report of the council:—

"We believe and confidently assert that our system of whole-time medical service is the most efficient and satisfactory that can be provided for workers and their dependents. It is certainly better adapted to the requirements of National Health Insurance and the Friendly Societies generally than the existing part-time service afforded by panel doctors who are mainly occupied and interested in private practice and fee-paying patients, to whom preferential treatment is usually afforded."

One of the delegates said that they were looking forward to a national medical institution where they would be able to feel assured that the health of the people was cared for by doctors who would come under State control. The paragraph quoted was eventually deleted from the report.

ESSEX COUNTY MENTAL HOSPITAL.—A new nurses' home, adjacent to this hospital, which has been built at a cost of £22,000, was opened last week. It accommodates 67 nurses and has a large recreation room.

MANCHESTER ROYAL INFIRMARY.—This hospital reports a large progressive increase in casualties. Last year there were 30,648, a daily average of 84; in 1920 it was only 50. In-patients (11,356) stayed an average of 17.67 days and cost £3 3s. 11d. per week each.—*Old Residents' Club*: The triennial dinner of this club will be held in Manchester on Saturday, Oct. 25th, 1930. Particulars will be circulated to members in due course.

TAVISTOCK-SQUARE CLINIC.—Nearly 300 people attended the annual meeting and luncheon of this clinic on May 5th, and Dr. H. B. Brackenbury, who presided, was able to report a growing interest in its work. A recognition of the psychotherapeutic needs of many insured persons would, he felt, do much to lessen the claims for sickness and disablement benefit now being received under the Insurance Acts. Dr. W. J. Adie said that while there were many excellent old-established hospitals for the treatment of organic nervous disease, facilities were at present inadequate for the treatment of functional disease. Again and again he had been forced to tell hospital patients that he was unable to provide them with the treatment they needed, and that he did not know where they would obtain it. The situation was now a little better because some of them could be sent to the Tavistock Clinic. He was able to recommend the institution with great confidence because he knew that psychotherapeutic treatment was not given indiscriminately, and that great care was exercised in assessing the importance of physical and psychical factors. If more was known about the upbringing of children and how to help young people through adolescence, much mental suffering would be prevented in later life. The Tavistock Clinic was already doing good work in this direction, and with the support it deserved it would do more. Miss Ishbel Macdonald emphasised the need for preventive work and was anxious for the establishment of more homes where patients could be sent during treatment at the clinic, so as to remove them temporarily from their usual environment. (A hostel has recently been opened, but on a very small scale.) Dr. H. Crichton-Miller, the honorary director, spoke of the growth of the clinic—a growth which was unfortunately not associated with growth of the building. The need for extension was very great, for the cases under treatment had increased from 700 two years ago to 914 this year. The number of attendances last year was 7472.

Medical Diary.

SOCIETIES.

- ROYAL SOCIETY OF MEDICINE.** 1, Wimpole-street, W.
TUESDAY, May 13th.—5 P.M. THERAPEUTICS AND PHARMACOLOGY. Annual General Meeting. Election of Officers and Council. Informal Discussion: The Treatment of Disseminated Sclerosis. Opener: Sir James Purves-Stewart. 8.30 P.M., PSYCHIATRY. Annual General Meeting. Election of Officers and Council. Dr. Hubert J. Norman: Psychiatry in Relation to History and Biography.
WEDNESDAY.—5 P.M. SURGERY: SUB-SECTION OF PROCTOLOGY. (Cases and specimens at 4.30 P.M.) Annual General Meeting. Election of Officers and Council. Discussion: Radium in Cancer of the Rectum and Colon. To be opened by Sir Charles Gordon-Watson, who will show a film illustrating the treatment; followed by Dr. Lacassagne, Mr. Stanford Cade, Mr. Lockhart-Mummery, Mr. W. S. Perrin, and others. Mr. Lionel E. C. Norbury: Two Specimens of Rectal Carcinoma after Treatment with Radium. Other cases and specimens will be shown.
THURSDAY.—5 P.M. DERMATOLOGY. (Cases at 4 P.M.) Annual General Meeting. Election of Officers and Council. Cases: Dr. F. A. E. Silcock (introduced by Dr. G. B. Dowling). Papillaris Capillitii. Case for Diagnosis. Dr. R. T. Brain (for Dr. O'Donovan): Psoriasis. Ectodermia of Cavate with Unusual Distribution. Ectodermal Defect, Tylosis and Dystrophy of Nails. Dr. G. B. Dowling: Case of Acne Agminata, Treated with a Gold Compound.
FRIDAY.—8 P.M. OBSTETRICS AND GYNECOLOGY. Annual General Meeting. Election of Officers and Council. Dr. Francis J. Hector: A Case of Endometrioma. Dr. G. W. Theobald: The Toxemias of Pregnancy; a New Conception. Mr. A. J. Wrigley: Puerperal Infection by the Pathogenic Anaerobic Bacteria. 7 P.M., ELECTRO-THERAPEUTICS (at the Langham Hotel, Portland-place, W.). Annual General Meeting and Dinner. Election of Officers and Council.
SOCIETY OF RADIOGRAPHERS. 32, Welbeck-street, W.
WEDNESDAY, May 14th.—7 P.M. Mr. C. H. Holbeach, A.M.I.E.E.: Planning of an X Ray Department.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, May 12th.—8 P.M. Annual General Meeting. 8.45 P.M., Dr. Herbert Spencer will give a short account of 54 autograph Letterson letters presented to the Society.—9 P.M., Sir Arthur Keith: Modern Medicine and Evolution. Annual Oration, which will be followed by a *Conversazione*.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.

THURSDAY, May 15th.—8.30 P.M. Dr. P. J. Kerley: The Pathology of Early Pulmonary Tuberculosis as Revealed by X Rays.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, May 15th.—8.15 P.M., preceded by a Demonstration at 7.45 P.M. Dr. H. M. Sclay: Pellagra in Nyassaland.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, May 16th.—4 P.M. (annual provincial meeting at Harrogate): Discussion on Rheumatism in its Public Health aspect.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, May 12th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Wards.

TUESDAY, May 13th.—10 A.M., Medical Lectures: Medical Words.

2 P.M., Mr. Hamblen Thomas: Throat, Nose, and Ear Dept. 2.30 P.M., Sir Henry Simson: Gynecological Operations.

WEDNESDAY, May 14th.—10 A.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards. Dr. Scott Pinchin: Medical Out-patients.

THURSDAY, May 15th.—11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department. 2 P.M., Mr. MacDonald: Genito-Urinary Department.

FRIDAY, May 16th.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Vinsto: Throat, Nose, and Ear Department. 2 P.M., Mr. Sinclair: Operations.

SATURDAY, May 17th.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Children's Department.

Daily 10 A.M. to 6 P.M. Medical, Surgical, and Special Out-patients, Operations, Ward Visits, Anesthetic Courses.

UNIVERSITY COLLEGE, Gower-street, W.C.

TUESDAY, May 13th.—5.30 P.M., Prof. W. E. Bate: Modern Theories in Histology in the Pre-school Child.

WEDNESDAY, May 14th.—5.30 P.M., Prof. F. J. Cole: The Early History of Generation and Comparative Anatomy. (Third and Fourth of six free lectures.)

LONDON SCHOOL OF MEDICINE FOR WOMEN, Hunter-street, W.C.

MONDAY, May 12th, and following **TUESDAY** and **THURSDAY**.—5.30 P.M., Dr. A. Lacassagne: Treatment of Uterine Cancer by Radiations. (Free lectures.)

ST. MARY HOSPITAL INSTITUTE OF PATHOLOGY, W.

THURSDAY, May 15th.—5 P.M., Dr. Leonard Hill: The Physiology of Diving.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

TUESDAY, May 13th, and following **THURSDAY** and **FRIDAY**.—5.30 P.M., Prof. A. J. Klayver: Activities of Micro-organisms.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 12th, to **SATURDAY**, May 17th.—**MEDICAL SOCIETY OF LONDON**, 11, Chandos-street, Cavendish-square, W. M.R.C.P. Special Course. Lectures every Tues. and Frid. at 8.30 P.M.—Tues., Dr. J. W. McNeve: Recent Views on Diseases of the Liver and Biliary Tract. Frid., Dr. J. W. McNeve: The Structure and Functions of the Spleen in Relation to its Diseases.

HOLBROOK HOSPITAL, Wandsworth Common, S.W. Mond., 10 A.M., Dr. Stanley Ward: Demonstration in O.P. Department. No fee.—**LONDON TEMPERANCE HOSPITAL**, Hampstead-road, N.W. Thurs., 2 P.M., Mr. Herbert Paterson: Demonstrations in Wards and Operations. No fee.—**LONDON THROAT, NOSE, AND EAR HOSPITAL**, Gray's Inn-road, W.C. Intensive course (clinical) in Diseases of the throat, nose, and ear, lasting until May 24th.—**MAUSDELL HOSPITAL**, Denmark Hill, S.E. Course in Psychological Medicine. Clinical practice of Hospital. Special Lectures and Demonstrations.—**ST. JOHN'S HOSPITAL**, Leicester-square, W.C. Afternoon and Evening Course of Instruction in O.P. Department. Lectures on certain afternoon days of the week.—**CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS**, Victoria Park, E. All day course, lasting two weeks. Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales General Hospital, Tottenham, N.

MONDAY, May 12th.—2.30 to 5 P.M.: Medical, Surgical, and Gynecological Clinics. Operations.

TUESDAY, May 13th.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics.

WEDNESDAY, May 14th.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY, May 15th.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.

FRIDAY, May 16th.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C. **TUESDAY**, May 13th.—5 P.M., Mr. W. McKim McCullagh: The Treatment of Post-partum Hemorrhage.

LONDON SCHOOL OF DERMATOLOGY, SUMMER COURSE, St. John's Hospital, Leicester-square, W.C.

MONDAY, May 12th.—5 P.M., Dr. H. MacCormac: Treatment of Syphilis.

TUESDAY, May 13th.—5 P.M., Dr. A. M. H. Gray: The Sarcoids and Lupus Pernio.

THURSDAY, May 15th.—5 P.M., Dr. I. Muende: Pathological Demonstration.

FRIDAY, May 16th.—5 P.M., Dr. Knowsley Sibley: Alopecia.

GREAT NORTHERN HOSPITALS POST-GRADUATE LECTURES.

WEDNESDAY, May 14th.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. Barty King: Demonstration of Cases in the Wards.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, May 13th.—4.15 P.M., Dr. C. H. Melland: Gastric Ulcer.

FRIDAY, May 16th.—4.15 P.M., Dr. D. E. Core: Demonstration of Medical Cases.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION. **WEDNESDAY**, May 14th.—4.15 P.M. (at the Royal Infirmary), Dr. J. C. Middleton: Medical Cases.

Vacancies.

For further information refer to the advertisement columns.

Rath, Royal United Hospital, H.P. £120.

Bedford County Hospital.—H.S. At rate of £175.

Birmingham General Hospital.—H.S. £70.

Birmingham General Hospital.—Res. Anesthetist and Cas. H.S. Each at rate of £70.

Birmingham, St. Chad's Hospital.—Res. M.O. £100.

Birmingham, Selby Oak Hospital.—Cas. O. At rate of £200.

Bolton Infirmary and Dispensary.—Res. Surg. O. £250.

Brighton New Sussex Hospital for Women and Children.—H.S. and H.P. Each £50.

Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.

Bristol Royal Hospital for Sick Children and Women.—Out-patient Phys. Also In-patient Surg. and Out-patient Surg.

Bristol Royal Infirmary.—Hon. Reg. for Ophthalmic Dept.

Bury St. Edmunds, West Suffolk General Hospital.—Jun. Res. M.O. £120.

THE GUARDIANSHIP SOCIETY.

THE Guardianship Society, which arranges for the care and supervision of the mentally and physically defective, held its annual meeting at Brighton on April 12th. A further increase of work in all the departments of the society was recorded in the annual report, "a growth which year by year is a proof of its necessity, and no limit can be placed to its future possibilities." The report stated that unsolicited applications during the 12 months totalled 482, as against 401 in the previous year, the national interest of the society being emphasised by the fact that no fewer than 383 were from districts outside Sussex. A large number of patients were still on the waiting list. During the year the society had 943 persons under care, in addition to which 70 were visited in their own homes, exclusive of after-care patients. The mental after-care department formed to keep in contact with patients discharged from the mental hospitals was becoming increasingly important, 89 new cases being added during the year, bringing the total on the register to 314. The clinic for nervous disorders had completed four years of most valuable work. Since its inception 371 patients had been treated, and this early treatment, the report claimed, had undoubtedly been instrumental in saving many patients from being certified. The society has two cottage farms in Sussex, and the work of training defective lads at these occupational centres, the report said, was proving highly satisfactory. Dr. S. E. Gill, medical inspector to the Board of Control, said his colleagues and he were struck with the excellent work the society was doing; he looked forward to the time when every local authority would have a day training centre comparable to the institutions for the blind and the deaf and dumb, where defectives could go and receive their training while living at home. Other speakers included Dr. J. R. Kaye, formerly senior medical officer for the West Riding of Yorkshire, who gave a short address on the Multiplication of the Unfit.

THE USE OF RATTHANAT.

THE usual methods of rat destruction are not without disadvantages of one sort or another; drowning, ferretting, and shooting require elaborate preparation, and the use of poisons is attended with danger to domestic animals. The Bacteriological Institute of the Chamber of Agriculture of Berlin and Brandenburg has prepared a poison derived, it is stated, from "sea-onions," a popular name for *Scilla maritima* or squill. The poison is made up in cubes of bait attractive to rats, and has been given the proprietary name of Ratthanat. Even small quantities of the preparation when ingested by rats appear to cause death, with hæmorrhage into the intestine and enlargement of the spleen and kidneys. The dying rat seeks water and consequently often dies away from the premises on which the poison was taken. Domestic animals, it is claimed, are unaffected by the poison. Reports on the use of Ratthanat by the Institute for Hygiene, the Health Department of the City of Berlin, and the Prussian Institute of Hygiene are favourable; in each case test rats were used and received the preparation with other food; all the animals under experiment died in one, two, or three days, after a period of distress which usually terminated in coma and occasionally in convulsions. It is claimed that rats will attack the cubes even in the presence of other food and that one cube contains sufficient bait to kill six to eight rats. The poison usually has the effect of sterilising the intestine, thus helping to prevent offensive odours should the rat die in its hole. The bait can be obtained from Rat Exterminators, Ltd., Simpson House, Sheppy-place, Minories, London, E.C. 3.

MENTAL HEALTH.

THE National Council for Mental Hygiene and the Tavistock Clinic held a conference last year which is now reported in a useful book.¹ Lord Brentford, who presided at the inaugural meeting, emphasised the urgency of the problem of mental health by reminding his audience that in 1928 some 50,000 persons in this country came under observation for mental breakdown, and that 4871 committed suicide. Sir Maurice Craig showed the fallacy of the widely accepted idea that mental disturbance is a bolt from the blue; on the contrary, "it is commonly a slow and progressive failure in which the early stages are very frequently overlooked or misunderstood." Perhaps the best definition of mental ill-health was provided by Dr. H. P. Newsholme, who said that "broadly speaking, it implies failure of the individual to use his mental machinery with a degree of efficiency sufficient to maintain easy running for normal demands with a reserve of power for emergencies."

Dr. A. Helen Boyle made a refreshing contribution in her plea that the most healthily minded child is the one with the greatest power of adaptability and judgment, so that a certain amount of irregularity in routine is a positive advantage. Dr. E. A. Hamilton-Pearson backed up this opinion by his counsel that, under right discipline, children should be allowed to buy their own experience, and by his warning that atrophy of mind, no less than of muscle, leads to disablement. The conference was divided into a number of sections, such varying aspects of mental health being discussed as sex education, juvenile courts, the personal equation in industry, mental hygiene in social and public work, the child and the parent, delinquency, and the problem child at home and in school. The general standard of the papers was at an unusually high level, and this unpretentious volume is a useful contribution by experts to a branch of medical study constantly growing in importance.

CURRENT ENGLISH.

THE little Oxford Dictionary of Current English¹ measures 5½ by 3½ by ¾ inch, and contains within this compass all the words which an educated person need know at the present time and far more than he can ever use. It would be difficult for anyone unacquainted with lexicography to estimate the skill and labour which have been put into this book. The final result may be compared with the neat and shining crystals of insulin obtained by evaporation, precipitation, and concentration of a mass of raw material by means of processes which it has taken a century to devise. The task of packing into 600 pages all that would go into them was entrusted to Mr. Ostler, who served for 44 years on the composing and reading staff of the Clarendon Press and whose encyclopedic knowledge has been at the service of two generations of compositors and authors. The dictionary is a guide to pronunciation as well as to choice of words; it warns the unwary that opus has a long o in the singular and a short one in the plural, and that midwifery is discreetly pronounced midfiri. Current medical terms such as hormone, adrenalin, and vitamin are all there (the latter is given a short i); proprietary terms are marked with the letter p. The list of abbreviations will help the reader with most of the useful contractions, but we regret the omission of G.M.C. and C.M.B. Even with compression carried to its limit, it takes two lines to define a liar (being a person who utters an intentionally false statement) and three for a Bunsen burner. One is glad to note that custard must contain eggs and milk, and that bunkum may be spelt either phonetically or in accordance with its derivation. Stunt, dope, dote are given their modern significations. But to prolong this notice would be an injustice to so compendious a book.

Appointments.

BROWNE, JULIA M., M.B., B.Ch. N.U.L., D.P.H., has been appointed Medical Officer of Health, Stepanov.
EASWOOD, W. J., M.B., M.Ch. Liverp., Surgeon-in-charge of the Orthopedic Department, Royal Albert Edward Infirmary, Wigan.
POWELL, A. T., W., M.B., B.S. Lond., D.P.H., Medical Officer of Health, Walthamstow.
RAY, JOHN HOWSON, Ch.M. Manch., F.R.C.S. Eng., Honorary Consulting Surgeon to the Manchester Royal Infirmary.
SOUTHAM, A. H., M.D., M.Ch. Oxf., F.R.C.S. Eng., Honorary Assistant Surgeon, Manchester Royal Infirmary.
SWINDELLS, R. H., M.B., Ch.B. Manch., Medical Superintendent at New End Hospital, Hampstead.
UNGLEY, H. G., M.B., B.S. Durh., House Physician, Royal Victoria Infirmary, Newcastle.
Certifying Surgeons under the Factory and Workshop Acts: BROOKS, G. M., L.R.C.P. Lond., M.R.C.S. (Christchurch); JONES, A. M., L.R.C.P. Lond., M.R.C.S. (Llandudno); NICKSON, H. C., M.B., Ch.B. Birm. (Soham, Cambs); and SPARKS, C. W., L.R.C.P., M.R.C.S. (Atatlock).

¹ Compiled by George Ostler. Oxford, at the Clarendon Press. London: Humphrey Milford, 1930. Pp. 626. 2s.; on india paper, 2s. 6d.

ROYAL NORTHERN HOSPITAL.—The 54,196 out-patients who were treated last year created such serious congestion that the enlargement and reconstruction of this department are a pressing need. There were 5762 in-patients who cost £3 17s. 8½d. each per week. The X ray department treated 9442 cases, and a training school for radiographers has been established. Investigation of the treatment of certain forms of cancer by means of activated fluorescein are stated to have had such satisfactory results that arrangements have been made at the request of the Cancer Committee of the Ministry of Health for the continuance of the treatment and for further research.

An Address

ON THE

INEXORABILITY OF THE LAW OF
EVOLUTION
AS MANIFESTED IN MODERN MEDICINE.*Being the Annual Oration of the Medical Society
of London given on May 12th, 1930,*BY SIR ARTHUR KEITH, M.D. ABERD., D.Sc.,
LL.D., F.R.S.,CONSERVATOR OF THE HUNTERIAN MUSEUM OF THE ROYAL
COLLEGE OF SURGEONS OF ENGLAND.

MEDICAL LONDON FIFTY YEARS AGO.

FIFTY years ago a walk round Harley-street, Queen Anne-street, and Wimpole-street provided a medical visitor from the country with quite an interesting morning. The names on the door-plates were already familiar to him; for the greater part they were those of physicians and surgeons on the staffs of our leading hospitals. The physicians were mostly general consultants, but fame, he knew, had given some of them a reputation for being particularly skilled in certain diseases. The surgeons, too, exercised their art on all parts of the body, but already specialisation had taken hold and some were devoting themselves to particular disorders, such as those of the urino-genital system or even confining themselves to definite organs or systems of the body, such as eye, ear, nose and throat, teeth, skin, and such as required orthopaedic treatment. Our visitor would also have come across the names of men who had made their reputation in the practice of midwifery and diseases of women—a speciality which in 1880 was at least a century old.

SPENCER'S LAW OF PROGRESS.

Our country friend, if he were familiar with Herbert Spencer's law of progress—namely, that it was merely another name for increased specialisation—would have found an opportunity, in the three streets just named, of studying the application of Spencer's law to medicine. Of the 120 men who at that time had segregated themselves from the army of practitioners and taken up an abode in the three streets, some, although on the staffs of hospitals, did engage in family practice; others were not on any hospital staff but sought prestige in practice from their place of residence. The vast majority, however, were consulting physicians, surgeons, or obstetricians, or were specialists in one branch of these three main divisions. Their numbers represented the extent to which medical specialisation had spread in the year 1880.

The Rate at which Specialisation is Growing.

Were our visitor to return now, after an absence of 50 years, he would be astounded at the rate at which the wheel of evolution has moved in our medical world. Familiar names have disappeared from the doors of our three streets and been replaced by others—quite as noteworthy. The brass plates have decreased in size but greatly increased in number; a census shows that the 120 of 1880 have been replaced by 951 in 1930. While the medical population of London (and the same is true of the provinces) has only a little more than doubled its numbers in the last 50 years, the army of specialists, in the three streets already specified, has undergone an almost eightfold increase. Progress signifies that the number of young medical men who turn aside from general

practice for a speciality becomes ever greater. Everyone whose name is affixed to a Harley-street door is not necessarily a specialist, but after making all allowance on this score, there are certainly seven specialists now where there was only one 50 years ago.

How specialisation has sped may also be seen from the fact that the Royal Society of Medicine finds it necessary to divide its proceedings into 24 sections. In our three streets we should certainly have to carry the subdivision farther and recognise about 35 branches of special practice in place of a bare ten of 50 years ago.

*Ancillary Sciences Determine the Rate and Mode of
Medical Progress.*

When we look beneath the surface of things and try to ascertain why the face of medicine has become so changed (and we may be certain it will continue to change) we see that the cause lies, not so much in what medical men themselves are doing, as in what is being accomplished in certain branches of science—particularly in chemistry, physics, physiology, pathology, and biology. The application of modern chemistry to medicine has called into being at least two groups of specialists—perhaps three. Advances in physics have opened three or four new fields of medical practice—for the application of X rays, radium, light, and electricity. Biology—in which we may reckon bacteriology, immunology, and vaccine therapy—has made and is making such progress that a greater number of specially trained men becomes necessary as medical advisers. The technical methods of the physiologist, pharmacologist, and pathologist are being brought more and more into clinical practice, giving those skilled in their use opportunities for fresh departures in special practice.

While the impetus to specialisation comes from advances made in the ancillary sciences our progress is also determined by the trend which events are taking in general medicine and surgery. As region after region of the body has become "safe for surgery" specialisation has been found to be necessary both for the patient's sake as well as for the further increase of knowledge. The same is true of medicine; knowledge regarding the ailments of each system of the body becomes so extensive and the technique needed for their full elucidation has grown so elaborate that it is no longer possible for one man to be master of all. As long as knowledge continues to increase and the methods employed to become more elaborate, division of labour—specialisation—must also increase.

The Direction of Progress.

Thus we see that "progress," which is another name for "evolution," has transformed the face of medicine as practised in the west end of London in the space of time easily covered by living memory. What will be its state in another fifty years? Let us see how far Herbert Spencer in 1880 could have foretold the state which medicine has actually reached in the three streets at the present time. He would have premised that the same spirit—a spirit of humanitarianism—would continue to urge medical men onwards in their attempt to relieve mankind of its load of suffering. He would have been certain, if this were so, that knowledge must increase and with each increase must come an augmentation of specialism. But he could not have foretold the direction in which specialism would spread. Our progress has been determined not by deliberate choice but by the force of circumstances, over which, for the greater part, medical men have had no control. That is what I mean by the "inexorability of the law of evolution as manifested in modern medicine." There is behind the medical army an irresistible pressure which thrusts it forward into the future and it must march, not as it would, but as it needs must.

Evolution as Seen in Medical Schools.

I have carried you to Harley-street to give me an opening for my thesis, but now, for the better understanding of the forces involved in medical progress,

which demands and ever will demand—that the poor must and shall have access, so far as health is concerned, to all the privileges the rich can buy—that, at all costs, suffering must be relieved, then medical progress must go on and follow the path already chosen. Further progress consists, in our modern interpretation, of an ever-increasing degree of specialisation and in an ever-increasing degree of coördination or unification. We cannot escape State control in the long run—however much we may regret the loss of personal liberty which is thereby entailed. What I would especially lay stress on is that medicine is not so free to choose its path into the future as most of us think it is. We may mould circumstances to our wills on some occasions but in most we are carried along in the irresistible current of events. I do not mean we should, like fatalists, cease to strive to steer a course. Nevertheless, in things medical, as in all mundane affairs, the main feature of the law of evolution is its inexorability.

An Address

ENTITLED

WHAT CAN WE EXPECT FROM RADIUM IN THE TREATMENT OF CANCER?

By J. MURDOCH, M.D.,

CHARGÉ DE CLINIQUE À L'UNIVERSITÉ LIBRE DE BRUXELLES;
CHEF DU SERVICE DE RADIOLOGIE DES HÔPITAUX ET AU
CENTRE ANTICANCREUX UNIVERSITAIRE.

ALL therapeutic methods pass through periods of exaggerated enthusiasm alternating with periods of unjustified scepticism, and from time to time it is important to get a clear, unbiased view of things as they actually are and the results that may be expected. Statistics may be made to prove anything, but for radium treatment there are records collected under such very rigid conditions that they might well serve as an example in other fields of medicine, and it is remarkable how similar are the results obtained in the various big radium clinics, although the methods used are entirely different.

We do not know anything definite about the intimate phenomena of the effects of radiation on living cells. It is probable that the biological effects are due to ionisation caused by photoelectrons and Compton electrons produced in the tissues under radiation. Many authors believe that there is an increase of permeability of the cell membrane, and it is certain that the protoplasm undergoes certain modifications. Numerous histological researches have shown the particular effects on the nucleus. At the Brussels Centre, Dustin has made large numbers of biopsies—more than a hundred in certain cases—and determined the variations of the karyokinetic index as a function both of the dose received and the time elapsed since irradiation. He has observed a strict parallelism between the curves of mitoses and the clinical effects obtained. The histological effects of X rays and gamma rays are very similar. Three different stages can be observed. During the first stage the number of mitoses decreases considerably and in favourable cases they disappear completely. This stage begins a few hours after irradiation and lasts from two to seven days according to the nature of the tumour and the dose of radiation applied; it is followed by the appearance of a large amount of pyknotic debris in the tumour. The principal feature of the second stage is the appearance of a wave of atypical mitosis lasting a few days. This wave seems to be an unavoidable sequel to the first

stage, whether radiation is continued or not; nor can the continuity of irradiation shorten its evolution. These atypical mitoses are followed by total or subtotal mitotic arrest. The third stage is characterised by the appearance of cellular monstrosities, very marked in squamous-cell epitheliomas, less so in cylindrical epitheliomas. At this time the tumour diminishes in volume and its disappearance is accompanied by cellular lyses and invasion by poly-

FIG. 1.

Epithelioma of eyelid (A) before, and (B) after treatment.

nuclear neutrophil cells. Either all the cancerous cells are affected and destroyed during the three stages, which means complete cure, or the majority of the cells are killed and the surviving ones embedded in sclerotic tissue where they may remain inactive for a very long period; or the mitotic arrest is sooner or later followed by a recurrence.

One of the most striking features of recurrence is a hyperkinetic stage. The divisional activity of the cells is then invariably higher than it had been in the primary tumour before any treatment. Another feature is a relative diminution of radio-sensitivity of the cancerous cells; mitotic cells are still sensitive to radiation, but it is much more difficult if not impossible, to ensure complete mitotic arrest. Certain cells seem to have become immune to radium and will give rise to new recurrences. It is impossible histologically to foresee the time of recurrence; for as soon as it is exposed to radiation the whole kinetic rhythm of the tumour is upset for a long time. The process varies according to the histological nature of the cancer. Squamous-cell epitheliomas show the three typical stages, the number of mitoses falling either rapidly or by bounds. These phenomena are usually followed by a strong "evolutionary maturation" and the arrest of division involves these cells in a differentiation that kills them. The cancers of the digestive tube form a much less homogeneous group than the squamous-cell epitheliomas. The differences are particularly marked between the various kinds of tumours of the rectum. In adenocarcinomas the rapid maturation is almost totally absent. This is probably one of the principal explanations of the radio-resistance of tumours of the digestive tract. An epiderm cell engaged in keratinic differentiation may give rise to a few atypical mitoses but will never constitute a fertile stock. On the other hand, a mucous cell may, upon finishing secretion, come to a glandular rest and then start again on its karyokinetic activity. In most of the adenocarcinomas it is very difficult to stop the normal mitoses by radiation. Mitotic activity starts again more rapidly and more violently than in the case of the squamous-cell epithelioma, and the waves of atypical mitosis are much less striking.

These histological researches explain why squamous-cell epitheliomas respond more favourably to radiation than adenocarcinomas. But it is not sufficient for a tumour to be radio-sensitive in order that the patient may be cured by radiation. It must also be accessible and the organ involved must be able to stand the treatment. It is easy, therefore, to cure epithelioma of the skin, penis, lips, buccal mucosa, tongue, and uterus, but results are much less favourable in epitheliomas of the pharynx and oesophagus.

* Delivered at the University of Sheffield, in connexion with the Yorkshire branch of the British Empire Cancer Campaign, on May 6th, 1930.

The methods in use at the present time are: 1. Surface applications at various distances from the skin. 2. Interstitial irradiation obtained by needling the tumour. 3. Intracavitary methods in which radium is introduced into the natural cavities. 4. Distance treatment by the "bomb" method (telecurietherapy).

1. CANCER OF THE SKIN AND LIPS.

Although certain authors report excellent results from roentgenotherapy alone, recovery seems more certainly and more regularly obtained by using radium than by using X rays. Cases of spindle-cell epithelioma known to be less radio-sensitive to X rays heal in just as large a proportion as those of basal-cell epithelioma when treated by radium therapy. Why is radium superior? Is its superiority due to the shorter wave-length of gamma rays and are the biological effects of radium different from those of X rays? Or is the better result due to the difference in the time of application, that is to say, to the fact that radium is continuously applied for several days, whereas radiation by X rays lasts a few minutes only? The time of application certainly has considerable influence. According to Regaud, tumour cells are radio-sensitive during cellular division only. A neoplasm composed of short-lived cells dividing at short intervals is more radio-sensitive to a short irradiation than a cancer composed of cells dividing at longer intervals, for the evident reason that a larger number of cells in mitosis are affected by radiation. Mascherpa has shown that the time between two subsequent mitoses is 10 to 12 hours in basal cell epithelioma and 8 to 10 days in spindle-cell epithelioma. The difference in radio-sensitivity of the two varieties of epithelioma would thus disappear as a consequence of continuous radiation. According to recent research work by Jona, Jüngling, Glasser, and Stahel, it seems probable that, in order to produce the same amount of biological

FIG. 2.

Diagram showing arrangement of radium tubes in a mould applied to the face.

reaction, such as an erythema of the skin for instance, it is necessary to apply to the tissues a much larger amount of energy in the form of gamma rays than of X rays. The proportion is about one to four. The energy of the quanta may also have an influence.

The technique we employ is determined by the localisation and clinical form of the tumour. When we have to deal with a small superficial lesion in a part where radiation must be strictly limited on account of the proximity of especially sensitive organs, we sometimes use needling, that is to say, interstitial radiation. A typical case for this treatment is a small epithelioma of the eyelid. By this method of radiation the tumour tissues absorb a very large amount

of energy in the immediate vicinity of the needle, and lesions of the sensitive parts of the eye, viz., the conjunctiva and the cornea, can be avoided (Fig. 1). When the lesion is larger but still superficial, and situated in regions easily accessible to radiation such as the cheeks, the forehead, or the chin, we apply to the surface a certain number of needles embedded in a cast of radioplastin, moulded on to the tumour. In this juxta-cutaneous irradiation the surface-tissues absorb a large amount of energy, whereas the sub-cutaneous tissues are much less affected.

When the tumour is infiltrating it is necessary to put the radium at a greater distance from the skin so as to ensure more homogeneous radiation in the depth of the tissues. Measurements show that whenever radium is placed at a short distance from the skin, the curve of absorbed energy is very unequal and the radium must be applied from a distance of 1 cm., or preferably 2-3 cm., to make the irradiation homogeneous. The distance between radium and skin is ensured by a moulding of Columbia wax or radioplastin, 1 to 3 cm. thick and moulded on to the tumour while warm (Fig. 2). To discover the most favourable arrangement of the tubes on the surface of the moulding may be a complex problem and take considerable time. According to a method perfected by Prof. Stahel, physicist to the Brussels Centre, the doses applied to the skin are calculated in units of energy absorbed per cubic centimetre of tissue. We hope that some day this method may be adopted generally. The unit we have adopted is the erg, the energy unit of the C.G.S. system, and we express the energies absorbed in ergs/c.cm.

A dose of 450,000 ergs/c.cm. produces slight erythema and pigmentation. This reaction is practically the same as the one obtained in deep X ray therapy after application of 600 r. international given in one séance (180 Kv. filtered by 0.5 mm. of copper and 1 mm. of aluminium). For X rays, however, this reaction is produced after administration of 90,000 ergs/c.cm. only. A dose of 550,000 ergs/c.cm. causes a frank erythema not followed by desquamation, but followed by brown pigmentation. A dose of 600,000 ergs/c.cm. causes a deep red erythema appearing at an earlier stage and followed by slight desquamation and deep pigmentation. A dose of 700,000 to 900,000 ergs/c.cm. causes strong radio-epidermitis with formation of blisters and very deep pigmentation. It is the maximum dose that we use in treating skin tumours.

The results, for cases without glandular metastasis, are very encouraging. We cure about 90 per cent. of cutaneous cancers of the face and lips. Of the deeply infiltrating tumours we cure about 50 per cent., but this last class includes a large percentage of hopeless and quite inoperable cases. One may say that cancer of the skin is never too large nor too advanced for treatment by radium therapy.

A patient was treated for a large basal cell epithelioma involving the greater part of the left side of the neck; the sternomastoid muscle was partly destroyed and the carotid arteries were barely covered by a thin layer of tissue. A cast was made in radioplastin and radiation was effected at 2 cm. distance. The amount of energy administered to the middle part of the lesion amounted to from 700,000 to 800,000 ergs/c.cm., and on the border of the tumour from 600,000 to 700,000 ergs/c.cm. The lesion was completely healed eight weeks after treatment.

2. CANCER OF THE TONGUE.

Cancer of the tongue is a form of cancer that has been willingly handed over by the surgeon to the radiologist. Surgical intervention causes an extensive mutilation, which patients desire to escape; the age may contraindicate the operation; the pulmonary complications are frequent, and not always to be avoided even by the use of local anaesthesia; and even if operation is successful, local and glandular recurrences only too often cause terrible deaths. Tongue cancers are not radio-sensitive; they are nearly always spindle-celled, and much more seldom basal-celled epitheliomas, and mixed varieties are common. Tumours taking origin in the lingual glands are very rare. The radio-sensitivity of glandular metastases is even less than that of the primary lesion, a fact which unfavourably influences statistics to an enormous extent, even where it has been possible to cure the primary lesion

After a first treatment, acquired radio-resistance is very marked, and we prefer the diathermy loop to a second radium application when the recurrence is not too large. Nevertheless, in certain favourable cases a second treatment with radium may prove successful. The radio-resistance of cancer of the tongue accounts for the failure of deep X ray therapy. Direct radiation of the tongue with X rays has been tried, but the technique is very difficult and can only be applied in exceptional cases. The technique of transcutaneous X ray radiation of the tongue has been carefully worked out by Jüngling. By means of mouldings of radioplatin he gives a geometrical shape to the region of the neck, thus greatly facilitating the construction of a radiation scheme. It is evident that the whole region must be radiated in a very homogeneous manner while making due allowance for the protection of certain especially sensitive organs such as the salivary glands, the lower maxilla, and the thyroid cartilage. Heavy radiation of the salivary glands may stop their secretion absolutely. This seriously affects the general health of the patient, and it is necessary to preserve at least one of the large salivary glands. Too intense radiation of the lower maxilla causes radio-necrosis, which may develop a few months after radiation as the result of a slight trauma, such as the extraction of a tooth, or even spontaneously. The bone is very sensitive to radiation and doses which only cause atrophy of the skin without ulceration may lead to complete elimination of the maxilla through obliterative endarteritis and subsequent necrosis. Late radio-necrosis of the thyroid cartilage must also be carefully avoided, as it may cause death.

For these technical reasons and owing to the bad results obtained by deep roentgenotherapy, most authors prefer local radium therapy. It is only under special circumstances, when it is impossible to use radium on account of localisation at the base of the tongue or the extent of the lesions, that it is advisable to use radiation by means of strongly filtered X rays, the application being spread over a long period, according to the technique perfected by Coutard. These

permanently. Radio-activity of emanation drops to one-half its strength in $3\frac{1}{2}$ days and is reduced to about one-tenth of its original intensity after 13 days. These seeds measure about 2 mm. in length and a large portion of the beta rays pass through their glass walls, which are only 0.2 mm. thick. The disadvantages of the method are largely due to lack of screening; beta rays produce necrosis and destroy healthy tissue as well as the neoplasm. The selective effect of the gamma rays is thus completely lost; moreover, radiation is not homogeneous and, although the results reported by Janeway and Quick are interesting, the method appears to have no future.

Platinum seeds seem to be more useful. They can be used where it is impossible to introduce needles, such as cancer situated at the very base of the tongue. They may be taken out or left in place.

The technique of needling is very simple. After thorough cleansing of the mouth, extraction of all decayed teeth and also of all healthy teeth in contact with the lesion, and removal of all metal pieces, we secure local anaesthesia with novocain. A thread of thick silk is put through the tip of the tongue so that it can easily be pulled out of the mouth. The needles are introduced into the growth at a distance of 1 cm. from each other and into the healthy tissue around the growth at a distance of 1 cm. from the tumour (Fig. 3). The eye of the needle is provided with a double thread. The thin thread is used for suturing the radium needle to the tongue; the thicker thread is brought out of the mouth and attached to the cheek. Needling is quite easy when the lesion is situated on the margin or on the back of the tongue, but very difficult or even impossible when the tumour is at the base. The needles usually contain 1.33 mg. of radium element, with an active focus of 20 m., and screened by 0.5 mm. of platinum. The application is calculated in such a way that each cubic centimetre of tissue of the tumour receives a dose equivalent

to from 0.85 to 1.0 millicuries destroyed (mc. d.)—i.e., from 100 to 132 milligramme hours (mg.h.). Generally speaking, the period of radiation varies between 4 and 8 days. Three weeks after this treatment the lesion and the adjoining tissues are covered with a white coating; this reaction comes to an end in six to eight weeks. Although the amount of energy absorbed is considerable, cicatrization is not followed either by loss of substance or by considerable fibrosis.

A deeply infiltrating tumour covering approximately a surface of 1.5 cm. was treated by seven needles of 1.33 mg. Three needles were planted into the tumour and four in the surrounding healthy tissue. The needles remained in place

FIG. 4.

Diagram of central horizontal section of tongue showing amounts of energy absorbed from radium needles in and around a tumour.

FIG. 3.

Diagram showing insertion of radium needles in the tongue.

patients may also derive benefit from telecurietherapy by means of the radium bomb, placed at 10 or 12 cm. from the skin.

The methods of radium therapy of cancer of the tongue have been modified considerably. Formerly radium was applied to the surface, but it is now generally introduced into the tumour by platinum needles; the method was invented and perfected by Regaud. Only where the tongue is completely involved and when needling is impossible is surface radiation by an ebonite support useful palliative treatment. Capillary glass tubes filled with emanation have been used; they remain in the tongue

for eight days, and the quantity of energy emitted at the source equalled 13.4 mc. destroyed, or 1785 mg. h. Under these conditions the calculations made by means of the isodoses plans show that at the level of the central horizontal section (Fig. 4) the amount of energy absorbed varies between 3,000,000 and 5,000,000 ergs/cm. in the tumour itself and still amounts to 3,000,000 ergs at a distance of 1 cm. from its border. At the surface of the tongue (Fig. 5) the amount of energy absorbed by the tumour varies between 2,000,000 and 2,500,000 ergs/cm., and is equal to 1,500,000 ergs/cm. at 1 cm. from the limit of the tumour. The tumour thus absorbed quantities of energy amounting to up to ten times the value of an erythema dose in the depth and from 2½ to 4 times the value of this dose at the level of the mucosa. The progress of cicatrisation was normal. The patient died eight months afterwards of brain metastasis without recurrence of the tongue lesion or any radionecrosis.

Diagram showing absorption of energy at surface of the tongue.

without recurrence of the tongue lesion or any radionecrosis.

Regaud is the originator of this method and has published the most reliable statistics. Amongst 287 cases treated from 1920 to 1925, 80 per cent. of which were inoperable, 27 per cent. have completely recovered, and 20 per cent. of the patients recovered locally but died afterwards of glandular recurrences. In about 50 per cent. of all cases, therefore, the local lesion can be cured, and in 25 per cent. of all cases, both operable and inoperable, permanent recovery is ensured. These figures compare favourably with surgical statistics.

Glandular metastases considerably darken the prognosis. We have treated them by many methods without much success. Radiation before or after block dissection does not give reliable results, whether applied by X rays, "collars" of radium, or telecurietherapy with the bomb. We have lately adopted a radio-surgical method based on a block dissection followed by the introduction of needles covered with rubber sheeting into the whole area threatened by recurrence. This method has been employed for so short a time that it is not possible yet to have a definite opinion on its efficiency.

3. CANCER OF THE UTERINE CERVIX.

Cancer of the uterine cervix was one of the deep cancers successfully treated by radium therapy. The good results obtained are due primarily to the anatomical disposition of the organ, which is especially favourable to the application of radium, as well as to the considerable amount of radiation that can be applied to the mucosa of the vagina and the uterus and to the uterine muscle. Deep X ray methods have also reached a high degree of perfection, especially in Germany, and excellent results have been obtained by using deep X rays alone. Far from being opposed to each other, the two methods are probably destined in the future to work together more and more.

Statistics concerning cures of cancer of the cervix should only include cases that have been under observation for at least five years, and the methods

used in the various centres should not change if we are to get a good idea of their value. At the Brussels Tumour Centre we have maintained practically the same technique since October, 1925, although the results published by other clinics sometimes tempted us to modify it. It differs from Regaud's method only in details. It is an "intra-cavitary" method; that is to say, local radiation is effected by introducing radium tubes into the uterus and the vagina. To this radiation by gamma rays we add transcutaneous radiation by deep X rays. It may seem tempting at first sight to destroy an epithelioma of the cervix by introducing needles directly into the tumour. The doses of energy absorbed by the cancerous tissue when treated by needling are certainly very considerable, but various disadvantages have led us to abandoned this method, which is still used in certain centres. Those who tried it first, Regaud and his associates, also Cahen and Delporte, have admitted its disadvantages—viz., the difficulty of disposing the needles correctly, the impossibility of judging the size of the tumour, and the danger of coalescence of the needles which, when the tumour is destroyed, come together in a bundle and produce irregular irradiation and sometimes radionecrosis.

Patients undergo a special examination by the surgeon and the radiologist, and we invariably practise a biopsy at the time of the first examination. Before radium treatment they are watched for 24 hours at least. If there is any fever we put off the treatment and try to bring about general and local disinfection by all means at our disposal. We do not apply radium until the temperature has become normal. If fever continues in spite of our efforts, we apply X rays before local treatment, which sometimes succeeds in cleaning up the local lesion but may cause narrowing of the cervical canal through sclerosis, and so make intra-uterine treatment more difficult. Dilatation of the cervix sometimes causes a rise in the temperature, and we have reduced this manoeuvre to a minimum by inventing a small apparatus which differs slightly from the intra-uterine tubes used in other clinics. It is a simple aluminium tube, the walls of which are grooved to ensure drainage. One end is tapered so that it can be inserted very easily into the uterus with a minimum of dilatation. The filtration of the aluminium is negligible and the

Fig. 6.

Aluminium tubes for insertion into the uterus and cork container for vaginal application.

tube only serves to maintain the necessary distance between the radium and the mucosa of the uterus. There are two models of this intra-uterine tube, viz., one holding a tube of 6-66 mg. filtered by 1 mm. of platinum, and another holding two tubes. We use either the one or the other according to the length of the uterine cavity measured by means of the hysterometer. Vaginal radiation is effected by means of two tubes of 13.33 mg., screened by 2 mm. of platinum; they are contained in cork stoppers (of the Regaud type) which ensure a distance of 1 cm. between the walls of the tubes and the tissues (Fig. 6).

When the condition of the cervix uteri allows us to find the intracervical canal easily, the intra-uterine and vaginal tubes are placed at the same time. When it is impossible to introduce the uterine tube, the two vaginal tubes are put in first in the hope that the cervical canal may become more easily accessible when a portion of the tumour has disappeared.

Recently we have come more and more to use this two-stage application. The intra-uterine tube is left in situ for nine days; the energy emitted at the source equals 21.6 mc.d., or 2877 mg.h. The vaginal tubes are left in place five days, the energy emitted at the source being 24 mc.d., or 3200 mg.h. For local treatment we thus apply 45.6 mc.d., or 6077 mg.h. These doses are somewhat lower than those recommended by Regaud, who applies to the tumour 60 mc. in five days in all (Fig. 7).

The direct measurements of energy actually absorbed by the tissues, determined according to Stahel's method and expressed in ergs/c.cm., show interesting curves. These measurements, taken in a water phantom, show that the uterine mucosa absorbs up to 5,000,000 ergs/c.cm. in the immediate vicinity of the intra-uterine tube—viz., eight

FIG. 7.

These measurements show that it is logical to complete the intra-cavitary application by transcutaneous treatment, either by X rays or by a radium bomb (telecurietherapy). At the Brussels Tumour Centre we apply deep roentgentherapy according to a plan of radiation determined for each patient by Holfelder's method. It is applied to the patient one month after local treatment. The voltage equals 186 Kv. (constant tension); the filtration is 0.5 mm. of copper and 1 mm. of aluminium. By each of the four "portals of entry" 800 r int. are applied. The treatment is spread over eight days. We estimate the quantity thus applied to the whole tumour at 800 r int., to which the amount of energy applied by radium must, of course, be added. Most authors recognise the superiority of such a combined method to both the local and transcutaneous methods employed separately. Forssell, however, relies mainly on local treatment, and Wintz of Erlangen has recently reported extraordinarily favourable results obtained by deep roentgentherapy alone.

Telecurietherapy with the bomb of 4 g. or more radium may appear at first sight to be the ideal method for treating cancer of the uterus, combining both the high degree of homogeneity of the X rays and the lesser wave-length of the gamma rays. All who have tried this method, however, seem to have come back to the local applications. It will probably never be possible to apply to the cervix, by a method

that necessitates the irradiation of the skin, the very high doses that can be applied by the intracavitary method, even with cross-firing. Used like X rays, as a complement to the local irradiation, however, the method has given good results.

Hysterectomy after radium therapy has not given us very good results, and we have, therefore, given it up entirely. A radio-surgical method recommended by Cahen and Delporte consists in the introduction, after laparotomy, of radium needles into the parametria and the uterus, when local application has not been sufficient to cure the patient. In the hands of its authors this method has given very good results, for in inoperable cases they have obtained up to 40 per cent. of cures.

The technique is of primary importance, but the measure of success is influenced by other causes such as the general and local condition, the degree of infection, and the state of the adnexa. Abnormalities in shape and a previous operation, such as hysterectomy, may render the application of radium very difficult and sometimes even impossible. Previous treatments either by X rays or radium also render the prospect of success very slight on account of radio-vaccination of the tissues.

THE RESULTS OF RADIUM THERAPY IN CERVICAL CANCER.

It is now possible to appreciate the exact value of the method, thanks to the work of the League of Nations subcommittee for radiotherapy of cancer.

These statistics, published by Forssell and Regaud, prove that it is possible to cure 40 per cent. of all the operable cases and to save 16 per cent. of all inoperable cases, and it is certain that their results will improve in the future, seeing that the techniques have been perfected since 1923, and that future statistics will reflect these improvements. The statistics which we have provisionally established for the Brussels Centre cannot be compared to the five-year results of Regaud and Forssell. We do not record five-year cures, and it is certain that our percentage of cured cases will decrease in the future.

In 1925 ten cases were treated; four were operable, and of these three have remained well for four years. Three were border-line cases; they are all free from symptoms after four years. Two were frankly desperate cases; they both died during the first year. The total survival after four years is, therefore, 60 per cent. In 1926 we treated 40 cases, of which 11 were operable; six of these cases cannot be included in the statistics for various reasons, and are considered as lost. Of the remainder, 27.2 per cent. are at present free from symptoms. Of the 14 border-line cases, six (42.8 per cent.) are free from symptoms after three years. Twenty-two were frankly inoperable. Thirteen of them received a palliative irradiation with X rays only and died during the first year, and seven had complete treatment; three are well after three years (42.8 per cent.); two were operated upon after their treatment and are well. Of these 22 inoperable cases, 28.5 per cent. are still living. If we eliminate those who were quite hopeless, and only received palliative treatment, 50 per cent. are well after three years. The total three years' survival, including all cases, is 28.5 per cent. In 1927 we treated 47 cases. Of the 12 operable cases, nine are well, giving a two-year cure of 75 per cent. Of the border-line cases, five are well, giving a two-year cure of 45 per cent. Twenty-two were inoperable; three were well, so that the two-year cure is 13.6 per cent., and the total two-year survival-rate 40.4 per cent. In 1928 we treated 61 cases. Sixteen were operable, and of these eight are well: a one-year's cure of 50 per cent. Of 21 border-line cases, ten are well: 47.6 per cent. Of 22 inoperable cases, ten are living: a one-year's cure of 45.4 per cent. The total one year's survival-rate is, therefore, 45.9 per cent.

Judged on the Stockholm figures, radium therapy of the cervix seems to have some advantage over surgery. We must, however, take into account the fact that the results have been obtained by means of a method that continues to be improved, whereas Wertheim's operation has reached a degree of perfection which it will probably not exceed. Patients hardly ever refuse treatment by radium, whereas they are not always willing to undergo operation.

On the other hand, we must not underrate the palliative results obtained in cases where surgery is helpless. In a large number of cases where cure was not permanent, radiotherapy made life bearable for several years by suppressing the alarming symptoms of hæmorrhage and pain. However, it would be premature to decide at present whether quite early epitheliomas of the cervix should be irradiated or operated. Not until several years have elapsed, and we have a sufficiently large number of operable cases treated by radium therapy, will it be possible to choose definitely between the two methods. Border-line and inoperable cases ought, of course, to be treated by radiotherapy.

INFLUENCE OF RADIATION ON OTHER FORMS OF CANCER.

Radium treatment of cancer of the digestive tract has not given results comparable to those I have outlined above. The epitheliomas of the œsophagus, although radio-sensitive, have up to the present given very bad results on account of the situation of the lesions and the thinness of the œsophageal wall. The introduction of radium tubes into the lumen has not, I believe, resulted in definite recovery in a single case. Our best result—viz., two years' survival—has been secured by transcatheter irradiation with X rays. It is possible that telecurietherapy may prove useful for this kind of treatment.

Cancers of the stomach and the intestine do not respond well to radium therapy. We have a few interesting inoperable cases improved by roentgen treatment, but here again the time elapsed is too short to warrant a definite opinion. Cancers of the stomach and the intestines are operated upon in the centre as early as possible.

Cancer of the rectum is also very radio-resistant and the results obtained are very unequal. The radio-sensitiveness of these adenocarcinomas is very low, and their destruction often entails lesions of the normal cells which leads to radionecrosis and failure. The method of choice is still surgical operation, and the ingenious method of Neuman and Coryn—the interstitial needling of the rectum wall from the outside after surgical liberation—is only used by us in inoperable cases. This method sometimes succeeds in making cases operable.

We also operate on carcinoma of the breast. For five years past we have been making two parallel series, one including cases of the breast exclusively treated by operation in the general surgical clinic and the other including cancers of the breast operated in the Tumour Centre and radiated after operation by X rays according to Holfelder's method. The technique of operation is exactly the same in both series. The future will show whether or not X rays applied after operation considerably improve surgical results.

To obtain the best possible results from the radium therapy of cancer, certain conditions of research and treatment are indispensable. The technique of radium therapy is not quite so simple as it looks. Anyone can cure with radium a small epithelioma of the skin or an operable cancer of the cervix, but in order to apply proper treatment by radiation to all cases that present themselves and in order to develop and to improve the method, the coöperation of a large number of workers is necessary. In no other branch of medicine is teamwork more indispensable. Cancer work necessitates the organisation of large centres of treatment and research, relatively small in number but generously supplied, not only with large quantities of radium and powerful installations of X ray apparatus, but also with numerous laboratories well fitted out and especially with a competent staff.

THE CANCER CAMPAIGN IN BELGIUM.

The State has encouraged the creation of centres of treatment and research in the four universities and has endowed each centre with the necessary funds for the equipment of deep therapy and radium departments. An annual subsidy calculated on the number

of patients treated is also allowed. For the Brussels Centre the Public Assistance, which has the direction of our hospitals, pays the upkeep of 60 beds reserved for cancer patients in the university hospital. These beds are grouped together in two wards. Each university hires radium from the Union Minière and 50 per cent. of the sums thus collected go back to the centres in aid of the research laboratories. The social work, such as the following-up of patients, is organised for the whole country by the National Cancer League. The university also directs the medical and research organisations. In Brussels the anti-cancer centre is under the direction of the professor of surgery, the professor of pathology, and the professor of radiology. The senior professor of surgery, who is also in charge of the general surgical clinic, delegates his senior assistant to be responsible for the surgical and radio-surgical work. This specialised surgeon will probably be definitely attached to the centre in the near future. The pathologist directs all the histological diagnosis and research work. The professor of radiology is responsible for the roentgen and radium treatment and directs the physical and radio-biological researches. He is assisted by two physicists and a full-time assistant who has specialised in radium therapy and in radio-biological research work. On the staff are also a physician, an assistant bacteriologist, and an assistant biochemist. The urologists and aurists of the hospital are also on the Tumour Centre staff. Consultations take place thrice a week; the surgeon, pathologist, and radiologist all see the patients together and decide in common upon the method of treatment.

This organisation has given good results during the four and a half years it has been in operation. The surgeon and the radiologist have ceased to be sworn enemies and have even conceived a certain respect for each other; mutual and unceasing criticism has prevented us from becoming unilateral, and the two methods—surgical and radiological—instead of being opposed, work very smoothly together. It even happens that the surgeon becomes enthusiastic about radium; and I know that I rely more and more upon my colleague's skill. The physician is one of the most useful members of the team; he is responsible for general medical attendance, a most important part of cancer treatment and one that is too often neglected. He also carries out biochemical treatments for patients who cannot be improved by surgical or radiological means.

Although treatment by radiation is being perfected daily, it is reasonably certain that radium will never cure more than a certain percentage of cancer cases. Research work must therefore continue to seek chemical therapeutics which electively influence the cancer cells, or biological means that increase the resistance of the organism. We shall not be justified in speaking of cure of cancer until we have discovered a substance acting upon metastases as well as upon primary lesions. Unfortunately, we are still far from having reached this ideal. Neither copper, selenium, or magnesium have given really stable and scientifically controlled results, and their application to patients who might still be saved by recognised methods is not justified.

In order to enable the organisation of a centre to do really efficient work, it is imperative that the patients be sent at the first stage of their illness instead of when treatment can only be palliative. All those who have organised cancer centres have had to go through the disappointing period when practically hopeless cases only were committed to their care. Happily, confidence has been slowly growing, and we receive ever-increasing numbers of cancer patients who still have a good chance of being cured. It is, therefore, necessary that the general practitioner should work in close coöperation with the staff of the centres. He has the most delicate task of all, upon which depends the final result—viz., early diagnosis. He must educate his patients and encourage them to be thoroughly examined at the first suspicious symptom; he has to explain the urgency of a biopsy, his rôle is capital and sometimes very difficult. Although a multiplication of centres

of treatment is not always an advantage and has to be limited, on the other hand there will never be too many cancer diagnosis clinics, or, as we call them, "centres de dépistage," where several doctors coöperate and do their utmost to diagnose cancer at an early stage. These dispensaries are in a position to give valuable advice, and can avoid the fatal loss of time that elapses only too often between the first symptom of cancer and its effectual treatment.

THE RESPONSE OBTAINED IN HEALTHY PIGEONS BY THE ADMINISTRATION OF SUBSTANCES EFFECTIVE IN PERNICIOUS ANÆMIA.*

By JANET M. VAUGHAN, M.B. OXF.,
GULLI LINDH MULLER, M.D. COLUMBIA,
AND
GEORGE R. MINOT, M.D. HARVARD.

(From the Thorndike Memorial Laboratory, Boston City Hospital, Boston, Massachusetts.)

RECENT work on the treatment of anæmia has facilitated the differentiation of a group of human anæmias which must be regarded as due to the deficiency of some substance essential for the normal production of adult red blood cells. Such anæmias, including pernicious anæmia, are characterised by a megaloblastic hyperplasia of the bone-marrow.¹ The bone-marrow of the healthy grain-fed pigeon is also of this type.² It appeared, therefore, possible that the administration to pigeons of substances capable of alleviating a deficiency in man associated with megaloblastic hyperplasia of the marrow might provoke a response in the bird similar to that resulting in clinical cases. If such were the case it might provide a biological test for the potency of these substances.

Intravenous administration of a series of relatively pure liver preparations† known to be effective when given intravenously in pernicious anæmia gave a consistent response in 14 healthy birds. Two pigeons only failed to react to a potent fraction. These two negative results were obtained probably because, owing to scarcity of material, it was only possible to give an extremely small dose. The response was characterised by a rapid increase in the circulating reticulocytes, from an average control level of 9.2 per cent. to one of about 18 per cent. This was accompanied by a pronounced gain in the birds' weight when less pure preparations were used. Similar effects were obtained when liver extract No. 343 (N.N.R.) was given by mouth, except when sepsis was present, which is in agreement with clinical observations.

An analysis of the character of this response is given in the Table. It is clear that though the average pigeons for the height or the reticulocyte rise may agree relatively well that there is considerable variation between maximum and minimum figures independent of the dosage. The same variability is found in the date of the initial rise and in the duration of the response.

Hitherto birds from the market have been used whose age and previous conditions of life are unknown. It is clear that in future more completely standardised pigeons must be used if consistent results are to be obtained. Burn³ has recently pointed out that all methods of biological assay are liable to such variation unless certain mathematical considerations

are taken into account and a large series of animals examined.

No such definite responses were obtained when extracts ineffective in pernicious anæmia were employed. Negative results were also obtained with intravenous injections of sodium chloride and histamine, preparations of both fractions of vitamin B (vitamin B₁ (G), B₂ (F), and liver extract No. 343 (N.N.R.)), in which the active principle has been destroyed.⁴

Table showing Character of Reticulocyte Response in Healthy Pigeons Receiving Liver Extracts Effective in Pernicious Anæmia.

No. of pigeons.	Extract.	Dosage.	Reticulocyte response.				
			Max.	Min.	Aver.	Day initial rise.	Duration.
7	132 E	200-25 mg.	20.9	14	18.2	2	6
1	132 EB	25 mg.	16.4	—	16.4	3	5
1	132 ECDB	25 mg.	18.7	—	—	7	11
1	132 ECDB	10 mg.	17.9	—	—	7	Killed 11th day
2	134 ZHB	10 mg.	22.1	21.0	21.2	5-6	Killed 6th day
10	343 N.N.R.	1-½ g.	21.1	15.8	17.28	3-8	4-27

Castle^{5,6} has shown that beef muscle previously digested by healthy gastric juice is as effective as liver in pernicious anæmia. Human gastric juice fed to pigeons caused no reticulocyte response but beef muscle promptly did, so. Probably the pigeon's gastric juice,⁷ like normal human gastric juice, can elaborate from beef muscle material that promotes blood regeneration.

The positive action of those substances effective in pernicious anæmia upon the bone-marrow of the healthy corn-fed pigeon would appear to be of biological significance. The results recorded in this preliminary report are not consistent enough to allow final conclusions to be drawn as to the possible value of such experiments as a test for the potency of liver extracts.

FURTHER OBSERVATIONS ON THE ÆTIOLOGICAL RELATIONSHIP OF ACHYLIA GASTRICA TO PERNICIOUS ANÆMIA.*

By WILLIAM B. CASTLE, M.D. HARVARD,
WILMOT C. TOWNSEND, M.D. HARVARD,
AND
CLARKE W. HEATH, M.D.

(From the Thorndike Memorial Laboratory, Boston City Hospital.)

OBSERVATIONS have already been reported¹⁻³ demonstrating that by an interaction of normal human fasting gastric contents and beef muscle, both of which are separately ineffective, a substance is produced which will cause a prompt hæmatopoietic effect and clinical improvement in Addisonian pernicious anæmia

* Read at the meeting of the American Society for Clinical Investigation at Atlantic City on May 5th.

† We are greatly indebted to Dr. Edwin J. Cohn and Dr. Thomas L. McMeekin, of the Department of Physical Chemistry of the Harvard Medical School, who made the liver preparations and supplied them for our experiments. The clinical tests were made on patients under the care of Dr. George R. Minot, who provided necessary information as regards the potency of the different preparations.

* Read at the meeting of the American Society for Clinical Investigation at Atlantic City on May 5th.

comparable to that obtained with liver feeding. The nature of this reaction has now been studied by means of observations upon 15 additional cases of pernicious anemia in respect to the nature of (1) the extrinsic factor of the reaction contained in beef muscle, and (2) the intrinsic factor present in normal human gastric contents.

These observations demonstrate that the proteins precipitated at pH 6 from beef muscle may act as the extrinsic factor. Normal human saliva, and duodenal contents collected by a special technique so as to be free from gastric juice, are entirely ineffective when incubated with beef muscle. Hence, by elimination, the intrinsic factor appears to be secreted by the normal gastric mucosa, as was originally supposed from a consideration of the essential pathological physiology of the pernicious anemia patient. Further observations have demonstrated that the essential reaction between gastric juice and beef muscle may take place in neutral solution, that heating the gastric juice to 40° C. for three days or to from 70° to 80° C. for one half hour will abolish its effectiveness. If normal gastric juice is treated with casein solution⁴ and then with magnesium carbonate,⁵ the pepsin and rennin may be completely removed, leaving behind an unknown factor which, however, can react in neutral solution with beef muscle to produce the hematopoietic substance. The gastric juice of two patients with blood pictures entirely consistent with the diagnosis of pernicious anemia (sprue and multiple intestinal anastomosis), both of which subsequently showed a typical response to effective liver extracts, has been found in each case to contain normal amounts of hydrochloric acid, pepsin, and rennin but to be entirely incapable of reacting with beef muscle. The irrelevance of any of the existing tests of gastric function for the detection of the essential factor of the normal gastric juice is thus made clear. Although the nature of the extrinsic factor of the essential reaction is demonstrated to be in all probability protein or a closely related substance, the nature of the intrinsic factor contained in the normal gastric juice remains unknown. However, it is certainly not hydrochloric acid, pepsin, or rennin. It may act in neutral solution and is destroyed by heating as above described.

In contrast to our original negative experiments with pig stomach mucosa after autolysis in acid,⁶ it has now been found possible to reproduce the activity of 300 g. of fresh pig stomach mucosa by incubating 25 or 100 g. of this material with 200 g. of beef muscle. These experiments suggest that the effectiveness of pig stomach feeding demonstrated by Sturgis and his associates after our original negative results with autolysed mucosa⁷ is the result of post-mortem changes within the tissue similar to physiological reactions occurring between normal human gastric juice and beef muscle. The activity of the pig stomach is furthermore apparently not identical with that of liver since heating the former to 100° C. for five minutes is sufficient to markedly diminish its potency in contrast to the lack of effect on liver extract under similar circumstances.

ROYAL WEST SUSSEX HOSPITAL.—The feature of the annual meeting on April 8th of the governors of this large hospital at Chichester was the record of the success of the contributory fund which was founded in 1926. The year 1925 closed with a debt on the 12 months' working of the hospital of £2758. Since then in successive years the deficit has fallen to £2639, £1076, £040 and £225, respectively. The contributory fund in its first year produced £178, but last year £2523; and it is estimated that it will provide at least £3000 in the current year.

VITAMIN A AND STREPTOCOCCAL ANTITOXIC IMMUNITY.

By A. H. G. BURTON, M.D. LOND., D.P.H.,

MEDICAL OFFICER OF HEALTH, ILFORD;

AND

A. R. BALMAIN, M.D. LOND., D.P.H.,

DEPUTY MEDICAL OFFICER OF HEALTH, ILFORD.

INVESTIGATIONS into the immunity produced in patients after attacks of scarlet fever and diphtheria have shown that a number do not become immune. Such lack of immunity has been investigated by us in connexion with relapses in convalescents.¹ The reason for the failure to develop immunity is obscure. We have suggested elsewhere² that it is possibly due, in some instances, to hereditary lack of antibody-producing capacity. Other possible explanations are that there has been an insufficient stimulus to the antibody-producing mechanism or that substances which are necessary for the production of antibodies have been deficient. Vitamin A has been considered an important anti-infective substance, the lack of which predisposes to infections. Whether such deficiency causes lack of sufficient stimulus or whether vitamin A is essential for the production of antibodies and the deficiency of it deprives the cells of a substance which is essential to antitoxin production is not known. The term "anti-infective" was applied to vitamin A in a report based on experimental work in animals by Green and E. Mellanby³ (1928) who repeated the experiments of previous workers, with the result that their animals fed on a diet deficient in vitamin A died, and post-mortem examination showed the presence of various infective lesions. It has been suggested that infection is associated with a metaplasia of epithelial cells due to vitamin A deficiency. In a further investigation E. Mellanby and Green⁴ (1929) undertook a preliminary exploration of the specific action of vitamin A in human infection. They studied the prophylactic and curative effect of vitamin A on pregnant women and in cases of puerperal septicemia. It is obvious that many pregnant women take a diet inadequate in vitamins, and it would therefore be conceivable that if vitamin A is anti-infective in action these women would be more susceptible to sepsis during the puerperium. Mellanby now reports⁵ the complete recovery of eight out of nine cases of puerperal streptococcal septicemia treated with preparations containing vitamin A. Mellanby and Green had previously suggested⁶ that if it is proved to have anti-infective qualities of a curative nature, it must also be of inestimable value in prophylaxis. This form of prophylaxis is too costly, however, to undertake unless some definite results are to be achieved. Mellanby states that the effect of the vitamin was apparently rather to increase gradually the general resistance than to act suddenly, as might be expected in the case of a substance having a specific bactericidal or antitoxic effect, although he also says that he believes that vitamin A plays a part as an anti-infective agent to bacterial infection and has the property of raising the resistance of the body to such infection.

It is difficult, a priori, to see on what grounds it can be held that the ingestion of a vitamin or any food factor can effect a prophylactic action without the stimulus provided by a specific toxin. The conclusion of G. Ramon⁷ (1929) was that no production of antitoxin occurs independently of the presence of antigen, specific antitoxin depending upon a chemical nucleus derived from the antigen.

We decided to investigate the prophylactic effect of vitamin A on the antitoxic immunity as demonstrated by the Dick tests in (a) a group of pregnant women attending the antenatal clinic, who presumably had no stimulus provided by a specific antigen; (b) in patients suffering from scarlet fever who had,

of course, such a stimulus. The preparation of vitamin A which we employed was Radiostoleum, M vi. in capsules. In group (a) 221 pregnant women attending the Ilford antenatal clinic were Dick tested. Those who were Dick-positive were ordered radiostoleum in capsules by the mouth three times a day. They were re-tested at monthly intervals until labour occurred, or until the Dick reaction became negative. Mellanby appears to believe that a fortnight's administration of the vitamin would produce an effect in a case of puerperal septicaemia; consequently it would appear that the length of administration in our cases should have been ample to have produced a result. Table I. shows the results of this procedure.

TABLE I.—*Ilford Maternity Home (Antenatal Clinic). Period August 24th to Dec. 2nd, 1929.*

Radiostoleum and Dick Tests.

Result.	Individual cases treated.
Negative	153
Positive (test not repeated)	16
" (repeated tests)	36
" turned negative	16
Total cases tested	221
Total positive at first test	68 cases.
Percentage positive at first test	30.7
Repeated monthly tests in 52 cases—	
Percentage of cases turned from positive to negative	30.7
13 of the 16 cases which turned negative, remained negative on repeated tests	25 per cent. of the total positives.
36 cases who were positive at initial test were re-tested at monthly intervals and remained positive.	
Re-tested twice	12 cases.
" three times	14 "
" four times	10 "
Total	36 "
All these cases were taking radiostoleum by the mouth M vi. in capsules t.d.s.	
In six of the cases the radiostoleum was not taken quite consecutively.	
10 cases who were positive at the initial test became negative on re-testing; of these 13 remained negative—	
Re-tested as follows—	
Once	6 cases.
Twice	6 "
Three times	1 case.
Total	13 cases.
Three cases were positive at the initial test, became negative at the re-test and returned to positive on further re-testing (two of these cases were re-tested one week after giving a negative test) and remained positive two months later.	

It will be noted that the percentage (30.7) of initial positive results compares with those of Burt-White (27)' and Weiss (39)⁸; Kunz and Nobel⁹ only found 11.8 per cent. positive (in predominantly city patients). The turnover from positive to negative may be due possibly either (1) to the development of antitoxin in response to an antigen which was latent (a few of the 16 cases developed such conditions as tonsillitis, rhinitis, or influenza; the majority, however, were quite well), this may possibly have been accelerated by the administration of toxin in the Dick test; (2) to changes in the body mechanism due to such causes as change of tonus of the vegetative nervous system and shifting of the hydrogen-ion concentration, as suggested by von Groer¹⁰; (3) to some specific action of the vitamin A, either with or without a latent antigen stimulus; (4) to a natural variation in streptococcal immunity, people not being persistently immune or susceptible; or (5) to the Dick test not being an accurate estimate of antitoxin immunity.

Table II. shows that the size of Dick reaction varied with the tendency to change over to negative.

No cases with a very large Dick-positive result became negative, and the majority of the cases which became negative were the minimal Dick-positive results. This suggests the possibility that the cases which became Dick-negative were already undergoing

a process of latent immunisation. The fact that the administration of vitamin A in 30 cases had not the slightest effect is sufficient demonstration that this vitamin, as with other non-specific substances, cannot cause an appearance de novo of antitoxin.

TABLE II.—*Relationship between Size of the Dick Reaction and Tendency to Turn Negative.*

Cases.	Size of reaction.			
	10-20 mm.	21-30 mm.	31-40 mm.	Over 40 mm.
Repeated positive (36 cases)—				
Largest reaction	1	7	17	11
Cases which turned negative (16)	10	5	1	0

The work of Weiss,⁸ who tested patients in pregnancy and during the puerperium, showed that of 100 cases tested, 11 became Dick-negative, while nine which had been Dick-negative in pregnancy became positive during the puerperium. Weiss suggested that there was a variability of the reactions caused by the process of childbirth, but not of any definite direction of the changes. This would appear to give added support to No. 4 of the possibilities enumerated above, and it is quite possible that if we had Dick tested the whole of our cases monthly, we should have found that some of the Dick-negative cases became Dick-positive. In our own series three cases which became Dick-negative subsequently returned to their original Dick-positive condition. We have observed this in convalescent scarlet fever patients both in those treated and those not treated with vitamin.

Burt-White,¹¹ Colebrook and others performed the Dick test in 26 cases before and after labour, and in one case there was a change from positive to negative result, the puerperium being afebrile. As, however, only one test appears to have been applied to each patient before labour, too much stress cannot be laid on these results.

In order to test the effect of administration of vitamin A in persons who had a streptococcal antigen stimulus, we administered the vitamin to cases of scarlet fever in the Ilford Isolation Hospital. The radiostoleum was given three times a day in capsules of M vi. to 64 cases of scarlet fever, out of a consecutive series of 117 cases admitted during the period August to November, 1929. Dick tests were performed on all cases at weekly intervals; 47 patients received radiostoleum from the day after admission, and 17 began it during convalescence (Table III.).

TABLE III.—*Result of Dick Test in 64 Cases of Scarlet Fever to whom Radiostoleum was Given.*

Repeated Dick tests in convalescence.	On discharge.	No. of cases.
Negative	Negative	20
Positive	Positive	22 (a)
Variable	"	14 (b)
		8 (c)

(a) In ten cases radiostoleum was started in convalescence.
(b) In four cases radiostoleum was given only one week before final test.

(c) In three cases radiostoleum was started in convalescence.

Percentage of these cases which were negative

on discharge 65.6

Percentage of these cases which were positive

on discharge 34.4

Results of Dick tests in 53 cases of scarlet fever to whom no radiostoleum was given:—

Dick-negative during convalescence 40

becoming positive 13

Of the whole consecutive series of 117 cases

70 per cent. of cases were negative on discharge from hospital.

30 per cent. of cases were positive on discharge from hospital.

It is obvious that the figures just given are not of value unless compared with a consecutive control series of cases; this is given in Table IV.

TABLE IV.—(Control). Results of Weekly Dick Tests in 107 cases of Scarlet Fever, admitted to the Ilford Isolation Hospital, December, 1927–May, 1928.

Weekly Dick tests in convalescence.	On discharge.	No. of cases.
Negative	Negative	36
Positive	Negative	29
Variable	Positive	11
	"	31

60.7 per cent. of cases were negative on discharge.
39.3 " " " positive " "

Whereas 34.4 per cent. of the cases to whom vitamin A was given were Dick-positive on discharge from hospital, 39.3 per cent. of cases in the control series were positive. The difference of 5 per cent. cannot be held to show that any material effect is produced by the administration of vitamin A. We believe that the small difference was due to such factors as the infecting type of streptococcus and the individual power of developing immunity. We conclude that there was no difference in the production of antitoxin in the cases which received vitamin A and those to whom it was not administered.

We further investigated the case of a child who was still Dick-positive after an attack of scarlet fever, a relapse of scarlet fever and two successive immunisations against scarlet fever with toxin. She was treated for a month with radiostoleum III vi three times a day, and at the end of that period was Dick tested, and was then found to be still Dick-positive, the reaction being $39 \times 27 \text{ mm.}$, the control being negative.

Puerperal Cases.

Joe¹² found that of 22 cases of puerperal sepsis due to hemolytic streptococci, 15 were Dick-negative and seven were Dick-positive. He argues from this that invasion by the hemolytic streptococcus is apparently not restricted to the Dick-positive cases, and that an antitoxic immunity is no barrier to a general infection of the blood stream, since three cases of septicæmia and one of pyæmia were all Dick-negative. These results, however, may not altogether bear this implication as it is not stated at what date in the infection the Dick test was performed. A number of cases of scarlet fever are Dick-negative when the attack has started, but this is no evidence that they would not have been Dick-positive if they had been tested a little time before the actual date of the attack, and as the date of the Dick test before death is not given, the conclusion of Joe, that an antitoxic immunity is no barrier to a general infection of the blood stream, does not seem to be clearly substantiated, as the general infection of the blood stream possibly occurred before the Dick test became negative. The work of Burt-White suggests strongly that there is a correlation between Dick-sensitiveness and streptococcal infection.

We were able to follow up 92 cases of our series at the maternity home. Puerperal pyrexia occurred in six, three of whom were Dick-negative and three Dick-positive. The only case, however, which was at all probably of streptococcal origin and was a case of an acute pyosalpinx, was Dick-positive at the first test and remained Dick-positive in spite of treatment with radiostoleum.

We have also seen one case in which the administration of the vitamin appeared to have a definite effect. The following is an account of this case:—

A primipara, aged 23 years, delivered at home without instruments, had a normal labour; abdominal pain commenced on the second day, offensive lochia appeared on the third day, and rigors and vomiting began on the fifth day. She was admitted to the cubicle pavilion of the Ilford Isolation Hospital on the sixth day after labour with a

temperature of 101.0°F. , a pulse-rate of 84, and a respiration-rate of 18. She was flushed and anxious, and her abdomen was distended, tender, and quite resonant; some resistance was present below the umbilicus. The cervix and vagina were not lacerated, the uterus was not abnormally large, and there was no tenderness at the fornices. The lochia were slight and hemorrhagic. She had an ulcer on a finger of the left hand, due to a whitlow which had been opened on the third day after labour; *Staphylococcus aureus* was found on culture from the cervix and the finger, but the blood culture was sterile. The urine contained no organisms or pus cells. She was given 60 c.cm. of antiscarlatalin serum and intra-uterine glycerin injections. Tenderness became most marked over the right side of the abdomen which was resistant to palpation. On the tenth day after labour the temperature was 102.8°F. , the pulse-rate 108, and the respiration-rate 30; free fluid was diagnosed in the abdomen and laparotomy was performed by Dr. Everard Williams. Foul-smelling pus was found in the right paracolic gutter and Morrison's pouch; culture of this pus showed streptococci and *B. coli*. Two drainage-tubes were inserted. The patient ran an intermittent temperature until the fifteenth day after the operation when the temperature was 102.4°F. On the sixteenth day radiostoleum (liquid a drachm twice daily) was commenced. On the twentieth day the temperature was normal and she was doing well. On the thirtieth day the tube from the central incision was left out. The patient vomited on the next day, her temperature rose, and the abdominal condition suggested retained pus; the tube was replaced and the temperature became normal within 12 hours. The patient was discharged from hospital five weeks later with a small central sinus, and sent away for convalescence.

Obviously it cannot be claimed that the administration for four days of radiostoleum two weeks after the operation could be the cause of the recovery of this case.

We are inclined to think that in our own case, and possibly in some of those described by Mellanby, the improvement effected by the administration of the vitamin was a coincidence. The difficulty of deciding on the effect of any particular treatment in puerperal septicæmia is well shown in the recent work by Burt-White¹³ on the treatment of puerperal septicæmia by concentrated scarlatinal antitoxin, where he reported 27 cases treated with eight deaths; after that he treated three cases with the same serum, all of which proved fatal.

We have come to the conclusion that there is no evidence at present that the administration of vitamin A in pregnancy has any effect in increasing the resistance of the body to streptococcal infection. Whether or not it has any effect in raising the general resistance is unknown and impossible to determine. The term "general resistance" is a loose one and we have no evidence that, if a person is not actually immune to a specific infection, any "general resistance" will prevent him from contracting that infection.

Results and Conclusions.

Vitamin A, in the form of radiostoleum, was administered to 52 women during pregnancy; in 16 women the Dick reaction turned from positive to negative; in three of these, however, it again reverted to positive. Sixty-four cases of scarlet fever were given radiostoleum, but the Dick reaction in convalescence was not considered to show any marked alteration from that in a control series of 107 cases. A child who had had scarlet fever and a relapse and two courses of inoculations with toxin against scarlet fever and was still Dick-positive, remained Dick-positive after a course of radiostoleum for one month.

The results which we have obtained suggest that there is no prophylactic value in administering vitamin A in pregnancy to prevent the development of puerperal fever; also that it is doubtful whether the effects which have been described as following its administration for the purpose of treatment are not a coincidence. The conclusions based on experimental evidence of other workers have recorded that a deficiency of vitamin A in the diet predisposes to changes in the epithelial linings of mucous tracts in animals and, therefore, allows infection to occur.¹⁴ This does not, in our opinion, justify a belief that the adequate supply of such vitamin would, in the presence

of a sufficient infective dose and the absence of immunity, prevent the occurrence of infection.

THE DICK TEST IN RELATION TO INCIDENCE OF PUERPERAL INFECTIONS.

REPORT ON FIVE HUNDRED CASES AT ST. MARY'S HOSPITAL, MANCHESTER.

By LOIS STENT, M.B. MANCH.,

SHERIDAN DELÉPINE FELLOW IN THE DEPARTMENT OF BACTERIOLOGY AND PREVENTIVE MEDICINE, UNIVERSITY OF MANCHESTER.

THE success of the Dick test in distinguishing those who are immune or susceptible to scarlet fever, and the prevalence of infection with the *Streptococcus hæmolyticus* in the puerperium has led recently to several investigations on the relation of the Dick test to the incidence of puerperal sepsis (Burt-White, 1928,¹ amplified by Burt-White, Colebrook, Morgan, Jervis, and Harre, 1930²; Salmond and Turner, 1929.³

Burt-White showed that 30 per cent. of 27 Dick-positive cases became febrile in the puerperium compared with 2 per cent. of 73 Dick-negative cases. In Salmond and Turner's results 20 per cent. of 168 Dick-positive and 15 per cent. of 373 Dick-negative cases developed fever, and Burt-White, Colebrook, Morgan, Jervis, and Harre found 6.9 per cent. of 230 Dick-positive and 4.9 per cent. of 770 Dick-negative cases to become febrile.

The present investigation comprises a study of 500 women with the object of determining the relation between the results of the Dick test and the character of the puerperium. Of these, 248 were tested in the last week of pregnancy, 152 during labour, and 100 within 24 hours of delivery. In considering the results no distinction has been made between these groups; the percentage of Dick-positive and Dick-negative cases in each group was approximately the same; of the cases tested before or during labour, 28.5 per cent. were Dick-positive; of those tested within 24 hours of delivery, 26 per cent. were Dick-positive.

Method.

The toxin used for the Dick test was prepared from cultures of the Dochez strain of scarlatinal origin grown in Hartley broth for 44 hours. The reaction was adjusted to pH 7.6 before filtration. One batch of toxin has been used throughout the investigation. It was stored in a 1 in 10 dilution at $\pm 5^{\circ}\text{C}$; further dilutions were made every four days. This toxin produced good reactions in a dilution of 1 in 10,000. A dilution of 1 in 1000 produced slightly bigger reactions than the toxin issued by Messrs. Burroughs Wellcome and Co. for the Dick test; 0.2 c.cm. of a 1 in 1000 dilution was the amount of toxin used in the test. A control injection of Hartley broth 1 in 1000 was always made. All readings were taken between 20-24 hours after the injection and a reaction was considered positive if an area of erythema 1 cm. or more in diameter developed.

The standard of morbidity adopted was that formed by the B.M.A.: "all fatal cases and all cases in which the temperature reaches 100°F . on any two of the bi-daily readings from the end of the first day to the end of the eighth day after delivery." For the purpose of this investigation an attempt was made to subdivide the morbid cases into three grades according to severity. The first grade included all the cases which just came within the minimal requirements of the standard. The second grade included all cases with a temperature of 100°F . or over sustained for 48 hours with perhaps an occasional rise during the remainder of the puerperium; in these cases the pulse was increased in proportion to the rise of temperature, involution was retarded, and invariably the lochia was foul-smelling; headache was constantly present. These were cases which might be termed moderate sepsis. The third grade contained all cases of "septicæmia" and cases with persistent or intermittent fever lasting more than 48 hours; constitutional symptoms were severe and the lochia scanty.

Relation of Dick Test to Incidence and Degree of Morbidity.

The information under this heading is shown in Table I.

TABLE I.

	Cases tested.	Cases morbid.	Per-centage morbid.	Degrees of morbidity in cases in grades—		
				I.	II.	III.
Dick-positive.	140	14	10	8	2	4 (1 death)
Dick-negative.	360	46	12.8	21	20	5 (2 deaths)
Total ..	500	60	12	29	22	9

In this series, 28 per cent. (140 cases) were Dick-positive; 72 per cent. (360 cases) were Dick-negative. This corresponds to the figures obtained by others (Burt-White 27 per cent. positive; Salmond and Turner 29.6 per cent. positive; and Burt-White, Colebrook, Morgan, Jervis, and Harre 29.2 per cent. positive). The incidence of morbidity was 12 per cent. This is greater than in the series reported by Burt-White, Colebrook, Morgan, Jervis, and Harre, whose morbidity-rate was only 5.4 per cent., but it is approximately the same as the results shown by the other investigators. This difference may be accounted for by the adoption of the B.M.A. standard for this series, which would include cases omitted in the series quoted above.

In the Dick-positive group the incidence of morbidity was 10 per cent. as compared with 12.8 per cent. in the Dick-negative group. This difference (2.8 per cent.) is not significant as it is less than the standard error (6.1). Comparing the Dick-positive and Dick-negative groups as to the incidence of morbidity of each grade, it has been found that the observed differences are not significant when the standard error of sampling is taken into account. The observed difference in grade I. was 11.5 per cent. (standard error 15.1). In grade II. the difference was 29.1 per cent. (standard error 11.8). In grade III. the difference was 17.8 per cent. (standard error 12.7). There is thus no indication that immunity to toxin as judged by the Dick test decreased the liability to puerperal infection. The total number of severe infections was small, and the percentage incidence does not fall outside the limit of the standard error and must be attributed to chance sampling. That most of the severe infections in the Dick-negative group were associated with hæmolytic streptococci will be shown in discussing the bacteriological findings.

Incidence of Morbidity in Relation to Interference.

Interference and the unavoidable trauma which accompanies it must always be considered an important factor in the subsequent infection in the

puerperium. Young⁴ (1928), in an address on maternal mortality from puerperal sepsis, discusses the factors which lead to infection during labour and the puerperium and gives evidence that trauma is the most important cause of the death-rate from sepsis.

In this series a comparison has been made between cases which were delivered spontaneously and those which had some form of major interference. By interference is meant any form of instrumentation, manual removal of the placenta, or induction other than medicinal. It is, of course, probable that factors other than the actual manipulation—e.g., prolonged labour, hæmorrhage, &c.—which are usually associated with the type of case requiring interference, were partly responsible for the morbidity recorded. The results are shown in Table II.

TABLE II.—Relation of Interference to the Incidence of Morbidity.

	Interference.			No Interference.		
	Cases.	Morbid.	Standard error.	Cases.	Morbid.	Standard error.
		%	%		%	%
Dick-positive ..	41	7 (17)	±5.86	99	7 (7.0)	±2.6
Dick-negative ..	118	28 (23.7)	±3.9	242	18 (7.4)	±1.7
Totals ..	159	35 (22.0)	±3.3	341	25 (7.3)	±1.4

The total morbidity is 22 per cent. with interference as compared with 7.3 per cent. without interference. This difference (14.7 per cent.) is about four times the standard error (3.57) and is, therefore, significant. In the non-interference group there is no significant difference in the incidence of morbid cases among those who were Dick-positive or Dick-negative, the observed difference (0.4 per cent.) being less than the standard error (3.07). In the interference group the observed difference in morbidity between the Dick-positive and Dick-negative cases is 6.7 per cent., the standard error being 7.05. Thus there is no evidence that the observed differences between Dick-positive and Dick-negative cases occurred otherwise than as chance variation. Under the circumstances in which the liability to infection was greatest (interference) it will be seen that immunity to toxin did not tend to reduce the incidence of morbidity. Seven of nine cases which had the most severe grade of infection (Table I.) had been subjected to interference.

Bacteriological Examination.

Whenever possible severe cases of infection were examined bacteriologically. Material was taken from the uterus by means of a guarded swab introduced into the cervix uteri under aseptic precautions. Blood cultures were made and the urine examined in selected cases.

Method.—Anaerobic and aerobic cultures were always made. The hæmolytic streptococcus was identified after 24 hours incubation on horse-blood agar plates by a zone of hæmolysis of 1–2 mm. surrounding the colony. A summary of the bacteriological findings in eight cases (six of which were Dick-negative) is given in Table III. In all, the infection was concluded to be of genital origin except in case 190, where the severity of the illness was due to *B. coli* infection of the urinary tract, and case 349, which developed pulmonary tuberculosis. Six out of eight cases showed mixed cultures; from six Dick-negative cases the hæmolytic streptococcus was isolated from the uterus in four and present in the blood of the fifth, but in only one instance was it in pure culture. *B. welchii* was present in two mixed cultures.

Examination of the Lochia.—The lochia of 15 cases of moderate sepsis (grade II.) was examined, 14 of which were from Dick-negative cases. In four the hæmolytic streptococcus was the predominating

organism; hæmolytic *Staphylococcus aureus* predominated in six; diphtheroids in two; *B. coli* in one; and non-hæmolytic *Staphylococcus albus* in two. Hæmolytic streptococci were not isolated from the Dick-positive case.

TABLE III.—Summary of Bacteriological Findings.

In each case, what appeared to be the predominating organisms is stated first.

DICK-POSITIVE CASES.				
Case.	Degree of morbidity	Uterine culture.	Blood culture.	Result

 † This organism closely resembles the one described by Harris and Brown⁵ (1927).
 ‡ Tuberculosis diagnosed three months later.
 § *B. coli* cystitis.
 Hm. = hæmolytic; Staph. = *Staphylococcus aureus*; Strept. = streptococcus; R = recovery; D = death.

Discussion and Summary.

The results of this investigation show that immunity to streptococcal toxin measured by the Dick test did not decrease the liability to a morbid puerperium. In a series of 500 cases the standard error of sampling is necessarily high and before making a final conclusion a much larger series would have to be investigated, but if the results of other workers on this subject are considered with the present ones it is justifiable to state that the Dick test is not a reliable method of indicating a susceptibility or otherwise to puerperal infections.

There were in all only nine severe infections in this series. Of these, five which were Dick-negative were examined bacteriologically; four were infected with *Streptococcus hæmolyticus*, and two died. It is evident that immunity to toxin as judged by the Dick test did not prevent streptococcal infection. Moderate cases of sepsis may occur as frequently in those who are immune to streptococcal toxin (Dick-negative) as those who are susceptible (Dick-positive). This fact may depend on the infrequency of hæmolytic streptococcal infections in this type of case. Colebrook (1929) and Colebrook and Harre (1930) found 7 and 7.6 per cent. of their milder cases to be due to this organism. Armstrong and Burt-White (1929) found a higher incidence (23 per cent.).⁶ Infection was significantly greater (four times the standard error) in cases which had been subjected to interference. In the majority of cases of sepsis there was a mixed infection locally, but in those which gave a positive blood culture the hæmolytic streptococcus was isolated in each instance. Local infections may be aggravated by the presence of anaerobes; in two out of eight cases *B. welchii* was isolated from uterine cultures.

The failure of antitoxic immunity as indicated by the skin test to prevent streptococcal infections may result from several possible factors. Trauma and mixed infections may aid the invasion of streptococci. It is possible that some strains have a high invasive power which antitoxic immunity does not hold in check. The question of the identity of toxins from strains of different sources may still

be open to doubt, and even if they are identical the toxin which produces a skin reaction may not necessarily be the only toxin responsible for pathogenic effects.

I wish to express my thanks to the medical board of St. Mary's Hospital for permission to utilise their cases and to the resident medical and nursing staff for their help in this work. I am much indebted to Prof. H. B. Maitland for his useful criticism and advice and to Dr. E. H. Scholefield for his valuable help in interpreting the tables.

Clinical and Laboratory Notes.

A NOTE ON

MARGINAL OSTEOMYELITIS OF THE JAW.

BY J. DUNLOP KIDD, M.C., M.B. GLASG.,
D.M.R.E. CAMB.

OSTEOMYELITIS of the upper or lower jaw has, of course, been recognised for a long time, but it has usually been of a diffuse type involving large areas of bone. There is another type, however, which is not so well known, nor have I been able to find any exact description of it in the most recent books dealing with dental pathology. It is not a condition that spreads far from the alveolar margin, and I should like to call it "marginal osteomyelitis." I do not think an accurate diagnosis is possible without an X ray examination. I have only seen about half a dozen cases in a scrutiny of the dental radiograms of some 2000 patients.

Marginal osteomyelitis is a definite sequela of pyorrhœa, and the infection starts from the sockets of septic teeth. Usually, after the extraction of even the most septic teeth, the socket drains freely and regeneration takes place at a fairly early date, the socket being filled in with new alveolar bone. This process can be checked by a series of radiograms. If there is not free drainage, or if some septic focus is left behind and shut off, then marginal osteomyelitis may follow; but this may not supervene till weeks or months after the extractions have taken place.

Intra-oral dental radiograms¹ of the affected area show in the early stage that the sockets of the extracted teeth are patent, that there is no sign of regeneration, and that the inter-radicular processes remain distinct. Later films show more definite bone changes, all, or only some of which, may be seen on the same film. The first is the increased translucency of the alveolar bone; next, the margin becomes feathery, worm-eaten and irregular, small detached sequestra being seen. Then small areas of absorption, rather like small cysts, appear either close to the margin or at varying distances from it. Here and there a little bone sclerosis may be evident, and in one case definite new periosteal bone was seen, practically the same as is seen in a periosteal sarcoma.

The area infected does not tend to spread much laterally, but is confined to the areas from which pyorrhœally infected teeth have been extracted. Bacteriological investigation yields a streptococcal growth, usually in pure culture. Judging from the cases I have been able to trace, the systemic effects

of marginal osteomyelitis are the same as from pyorrhœa or peri-apical tooth abscesses, but more virulent, as might be expected. When the medical attendant of a patient suspects dental infection as the cause of some morbid condition, he naturally asks that an X ray examination may be made of the teeth. This may show no dental sepsis; but how often are the edentulous areas also examined? Probably very seldom, unless the dentist suspects a broken stump, the supposition being that if there are no teeth there can be no dental sepsis. In my opinion, a complete radiographic examination of the mouth should include the edentulous areas as well as the standing teeth.

Notes on Four Cases.

(1) Male, aged 53. Severe pyorrhœa—all teeth extracted eight years ago—septicæmia with infection of right knee-joint, which is now stiff. X ray of upper and lower alveolar margins showed marked osteomyelitis in canine and central areas. Pure streptococcus growth from these areas—extensive local curetting; right antrum also infected; vaccine treatment gave marked improvement.

(2) Male, aged 60. Anæmic and toxic—"an ill man"—upper left premolar to right canine areas were edentulous and showed marginal osteomyelitis on X ray examination; pure streptococcus obtained; vaccine and local treatment given with great improvement in condition.

(3) Male, aged 60. Pale, anæmic, and toxic—gastric symptoms; upper left and lower right molar and premolar areas. X rays showed marginal osteomyelitis and periosteal new bone; pure streptococcus obtained; vaccine treatment given: great improvement.

(4) Female, aged 42. Severe pyorrhœa—teeth extracted some years ago; anæmia and general malaise, practically an invalid; upper and lower right premolar and canine areas showed marginal osteomyelitis; recurrent exacerbation of general symptoms every four or five months; patient in bed; prolonged vaccine treatment with recovery.

TREATMENT OF

GENERAL PARALYSIS OF THE INSANE

BY INJECTION OF SULPHUR.

BY NOEL G. HARRIS, M.B. LOND.,

ASSISTANT MEDICAL OFFICER, SPRINGFIELD MENTAL HOSPITAL.

Schroeder,¹ in a paper published in November, 1929, records the therapeutic effect of injections of sulfosin. Much of what he claims I should like to confirm in this brief report, which I intend as a prelude to a fuller account. There are two important points which make the method worthy of full investigation. (1) It is generally agreed that the earlier malarial or other forms of "pyrexial" therapy are begun in cases of general paralysis of the insane the greater is the chance of recovery. Up to the present time, however, hardly any cases are treated outside hospitals or nursing homes, so far as I know, because of the difficulties involved. Hence many cases have been left to degenerate until they were certifiable, when the chance of successful treatment was much less. (2) It is also common experience that some cases entirely fail to react to malarial inoculation, while cases that have been successfully inoculated and yet do not improve cannot, as a rule, be successfully reinoculated within six to nine months.

If, therefore, it can be shown that the treatment of general paralysis by injections of sulphur in olive oil is as effective as malarial therapy, it places a valuable new method of treatment in the hands of the practitioner situated even in the most remote district, for the technique is simple and the substance is easy to handle. Moreover, it forms a second mode of attack should malarial therapy fail.

At present there are two preparations on the market—collosol sulphur and sulfosin Leo.² The latter is the preparation used by Schroeder in his work.

¹ Schroeder, Knud: THE LANCET, 1929, ii., 1081.

² The radiograms illustrating this note have been omitted owing to the loss of detail on reproduction.

² Collosol sulphur is obtainable from British Colloids, Ltd., 22, Chenies-street, London W.C.1, and sulfosin Leo from C. L. Benard, Ltd., 113A, Wardour-street, W.1.

and is put up in boxes containing phials of 1 c.cm., 5 c.cm., and 10 c.cm., also in boxes containing ten phials of 10 c.cm. Colloidal sulphur is put up in phials of 1 c.cm. and 5 c.cm., or in sterile bottles containing 1 oz. I have been using both these preparations in order to contrast the efficacy.

The technique I have followed is precisely that of Schroeder. 1 c.cm. of the preparation is injected intramuscularly into the outer side of the thigh. Unlike Schroeder, we find it better to make the injection at about 7 P.M. in order to simplify the nursing, for then the most important half-hourly temperatures are taken in the morning rather than during the night. After the injections the temperature is taken every two hours until pyrexia commences, when the temperature is charted every half hour until it is normal again, then the two-hourly charting is resumed. The temperature in my cases has usually fallen to normal in about 10 to 14 hours, although there is frequently a secondary smaller rise which, however, soon subsides. After the temperature has been down to normal for some hours the next injection can be given and the dose increased by 1 c.cm., unless the previous temperature has been much over 104° F. This is continued until ten injections have been given.

I do not altogether agree with Schroeder that the degree of pyrexia can be regulated by the dosage. The data so far at my disposal tend to suggest that a high degree of fever can be maintained without increasing the dose in some patients, while in others an increase of several c.cm. may not produce a relatively larger increase in fever. I think that each individual has probably to be studied in this connexion.

The injections have caused more discomfort in my cases than Schroeder suggests, and one patient had marked inflammation and oedema down the leg, but the pain seems to disappear rapidly, without ill-effects. It is too early to compare the clinical results of the two preparations used, but they both produce excellent pyrexia.

The material on which I base this report is as follows: The treatment was begun on Dec. 11th, 1929, and a total of 14 cases have been treated with a series of ten injections, while one other is under treatment. In all but one temperatures ranging from 101° to 105° F. were produced by each injection. The case which showed only a slight pyrexia after each injection had been twice previously inoculated with malaria, once by mosquitoes and once by blood, but on each occasion without any successful reaction. He was in extremis when the injections of sulphur were started and died subsequently. At autopsy it is interesting to note that besides the changes common to general paralysis a stone of over 4 oz. was found in the remains of the left kidney, which had been reduced to a fibrous sac, while the right kidney was also partially destroyed by another stone. Another of the patients had malarial treatment with good pyrexia in November, 1928, but had shown no mental improvement. This patient had an excellent pyrexia following each injection of sulphur. A third patient whose first ten injections have been completed was a case of about three years' standing. He had been inoculated several times with malaria, always unsuccessfully. He was in a very advanced stage when the sulphur injections were commenced, and, owing to his lack of cooperation, it was impossible to record the temperature. He has, nevertheless, made a most remarkable improvement. He is now up and about, having put on much weight, and he is much better mentally. This case suggests that with reasonable care it is not essential to work by the temperature alone. Of the other cases, all have given or are giving excellent reactions, and five show considerable improvement already. It is, of course, too early to say much about clinical improvement.

Conclusion.

There seems no doubt that injections of sulphur in olive oil produce a high degree of fever, even in patients who have had malarial treatment previously or who have failed to react to malarial inoculation. The injections are simple and safe to give, and are

well worthy of a trial by any practitioner. The earlier the diagnosis is made and the treatment commenced, the better is the end-result likely to be.

My thanks are due to my medical superintendent, Dr. F. J. H. Courts, for his permission to publish these cases.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

At a meeting of this Society on May 8th, with Dr. F. J. H. Courts, the President, in the chair, a discussion on

STRICTURES OF THE URETHRA

was opened by Mr. JOCELYN SWAN. Nowadays, he said, the urological surgeon did not see the severe type of stricture which was formerly met with fairly commonly in hospital work. He did not doubt that this was largely because of better and more thorough treatment of venereal disease. Students now saw stricture cases at an earlier stage, and a patient was seldom allowed to go on to a serious condition before seeking expert advice. Strictures could be divided into congenital, traumatic, and inflammatory. The first two could be quickly dismissed. Congenital strictures were found in early childhood about the meatus or the posterior part of the fossa navicularis, and were due to errors of development. Valvular strictures, seen occasionally in the posterior urethra, were responsible for the very dilated ureters and hydronephrosis seen in infant life. Congenital strictures were often formed of mucous membrane with the concavity backwards, so that it was easy to pass a small catheter or bougie and conclude that no narrowing was present. But as soon as pressure of oncoming urine was exerted this membrane bulged forward and blocked the urethra. It was not so much a stricture as a congenital malformation of the urethra. Traumatic stricture was a more serious problem because of the length and often the tortuous form of the urethra after an injury. The urethral wall might be torn, and there might be discontinuity between the two ends. In the process of healing much fibrous tissue formed.

Inflammatory Strictures.

It was safe to say that fully 90 per cent. of inflammatory strictures followed gonorrhoeal infection. Staphylococcal urethritis seldom produced stricture; its sequel was rather a superficial inflammation. Why should gonorrhoea occasionally result in stricture? It would be generally agreed that the cause was not so much the actual disease as the treatment which was applied to the gonorrhoeal infection. And it was not usually the severe case which was followed by stricture, but the slight case, which often had been neglected, was tedious in treatment, and had persisted for a long time. He was sure he had seen patients whose urethral stricture was a result of long-continued over-treatment. Fortunately, however, this severe treatment by applying strong solutions to so-called mucous patches had largely gone by the board. In his early days he had seen many cases in which the urethra had been directly painted with silver nitrate, grs. 30 to 60 to the ounce, through an endoscopic tube. This was followed by septic infiltration of the urethral wall and definite stricture.

The reason why stricture was mostly in a particular position had given rise to much speculation; three-quarters of them were in the bulbous urethra. His view was that this was the site because it was the first part of the curve upon which the urine impinged in ordinary micturition. Stricture of the urethra also followed syphilis; he had seen many cases of mental stricture following mental chancre, and from the same

cause stricture in the terminal inch of the urethra; and likewise gummatous stricture. After gonorrhoeal infection there was a deep infiltration extending through the mucous coat of the canal, followed by the formation of fibrous tissue. Strictures in the urethra were often multiple; indeed, some authorities said that 40 per cent. of them were multiple, but Mr. Swan did not put the proportion so high. When, therefore, the endoscope revealed a fairly wide stricture in the urethra it was necessary to make sure there was not also a deeper placed and narrower one. The tighter the stricture the more proximal it was. The lumen of the stricture was not necessarily in the centre of the infiltration; often it was placed eccentrically, and on passing a fine bougie the stricture was found to be a long one. The term "bridle stricture" he regarded as a misnomer; the band which was supposed to cross from one side of the urethra to the other was almost always formed by the passage of instruments, in other words, by a false passage. There had been a burrowing outside the urethral wall.

Effects of Stricture.

When the urethral canal was narrowed the thing that made most difference to the patient was dilatation of the proximal urethra, for with such dilatation came a liability to infection. The prostate, also, might be infected as a result, and in a secondary way the epididymis and bladder, and later the ureters and kidney. Infection was the bugbear of every surgeon who had to deal with strictures. As regards symptoms, when a patient complained of a persistent slight discharge the surgeon should in every case make a proper examination of the urethra, preferably with the endoscope. No significance attached to the so-called twisted stream described in text-books; a stream of fluid propelled through a vertical orifice was almost sure to emerge in a twisted form. What was significant was a statement that the stream had not the force it once had. Another complaint of a patient with stricture was his inability to finish off the act properly and cleanly; when he supposed it to be finished, a few drops subsequently dribbled into his clothing. That was an important sign, and the dribbling gave the surgeon an idea of how tight the stricture had become, and the degree of dilatation behind the urethra. Usually the man with stricture had not any appreciable increase in frequency; and if a patient with stricture complained of increased frequency, and especially of having to rise in the night to pass water, this was almost certainly due to infection having spread behind that stricture—in other words, the patient probably had cystitis. On the stricture becoming tighter there might be a history of retention, and this might occur even with wide calibre strictures. The patient perhaps caught a chill when motoring, or over-indulged in alcohol, and got an attack of retention in consequence. Occasionally there was the incontinence associated with an over-distended bladder. Mr. Swan looked upon the patient with an over-distended bladder, whether due to stricture or to an enlarged prostate, as in a very precarious position. The best and safest means of treating an over-distended bladder was to decompress the bladder very very slowly; one should never attempt to draw off all the urine at once.

Examination of Cases.

A general idea seemed to prevail that the first thing to do for a patient with stricture was to pass a bougie or sound; actually this was about the last thing to be done. In any case suspected or known to have stricture it was best to wash out the anterior urethra and inspect it with the endoscope, preferably with one capable of distension with air. This method should be used from the start. One could not only see the stricture, but could glean a good idea as to the size of bougie it would be possible to pass in the initial stage of dilatation. It should never be forgotten that strictures might be multiple, and that the one first seen might not be the only one or even the narrowest. With good distention and efficient lighting a stricture further down would be visible if it existed. If the

surgeon decided to start examining with a bougie or a sound, he should use a flexible one at this stage, commencing with a 22 or 24 French (or No. 12 English). Passage should be carried out with the utmost gentleness, and with full aseptic precautions, and any obstruction met with must be noted. If there was obstruction a bougie should be found of a size which would just fit. When this had been passed enough had been done until the next sitting, five days later. Next time the surgeon began with this size and worked upwards. Mr. Swan never used a steel bougie smaller than a No. 15 French for much harm might be done by using smaller sizes in steel. He used sizes up to No. 19 French, and followed them up with steel sounds. The bougies should have a gradual taper, and English makers did not equal the French in this regard.

The urologist confronted with a patient complaining of difficulty of micturition or slowing of the stream should never omit to test the knee-jerks. Many patients were sent up as cases of stricture or prostatic trouble who were found to have early tabes or some other nervous trouble.

Complications.

The complications of stricture could be summed up in the words "retention and the outcome of sepsis," the latter including peri-urethral abscess, prostatitis, epididymitis, cystitis, pyelonephritis, and extravasation; this last was nothing more or less than a more acute form of peri-urethral inflammation, and could no longer be considered a true extravasation of urine, since it was due to anaerobic organisms getting loose and spreading into the cellular tissue. Fistula must also be included. It was not unusual to find that the dilated portion of the urethra behind the stricture contained a stone. In most cases, he thought, the stones had descended into the urethra and had enlarged there.

Treatment.

The treatment adopted in a particular case would depend not only on the size of the stricture, but on the accompanying conditions—i.e., whether the patient had a peri-urethral abscess or fistula or some other complication. Taking the stricture itself, the first aim must be to dilate it. Nowadays very few strictures were utterly impassable, but in dilating them it was very important to go slowly. It was possible to go up to a much larger size than was formerly taught, and he did not hesitate to go up to a No. 11 or No. 12 English, at least. After that one could pass on to the use of sounds. Continuous dilatation, by leaving the instrument in, was apt to set up urethritis, and this might lead to septic complications. If a patient had a very tight stricture—even if this caused retention—and if a fine or filiform bougie could be got in it should be left in and the patient should be allowed to dribble alongside it drop by drop until the bladder was in this way slowly decompressed.

As to the curability of a stricture, he would say that when it had reached a stage requiring dilatation it could not be more than relieved in this way. In a general way the axiom "once a stricture always a stricture" was true, but there were exceptions. A stricture could be dilated to No. 16 English, then the patient could be required to attend once a week or fortnight, and at the end of three months he should be re-examined with the endoscope; perhaps by then there would be little remaining of the stricture, and a longer time could elapse between sittings. This treatment should be followed by the regular passage of a sound. The neglected stricture would contract again.

Dilatation would not always succeed; there were cases in which the stricture was very hard and fibrous, so that it was very difficult to even dilate one side at a time. If after four or five days no impression could be made on the stricture, the speaker would cease these efforts and advise operation. Strictures which were resilient could be dilated, but the effect did not last; these also he preferred to operate upon. If attempts at dilatation of a stricture were accompanied by

bleeding, no further effort should be made for the day, and if there was a repetition of bleeding at a future sitting he would advise operation. Where a stricture was accompanied by epididymitis or a perineal abscess it should not be dilated, but should be operated upon. What should the operation be? In the absence of fistula or abscess he did not doubt that the best results ensued from internal urethrotomy. But this operation required experience; it was not as simple as the reader of text-books might believe. He did the Maisonneuve operation, cutting from the distal to the proximal side. A very fine guide was passed through the stricture; screwing it on to a steel guide, a siliform bougie was passed into the bladder, and the knife was passed down the steel director so as to divide the stricture. American surgeons deprecated tying in a catheter after doing internal urethrotomy, but the speaker did not know why they should. He left a catheter in for 48 hours, washing out the bladder morning and evening. At the end of 48 hours he filled the bladder, took the catheter out, and told the patient to pass urine. The old Syme operation, done on a director staff, he considered unnecessary, because if so large an instrument as a Syme director could be passed, the stricture was dilatate, and there was no need for the patient to be in bed three weeks. The only form of external urethrotomy was the Wheelhouse, in which the urethra was opened in front of the stricture, then the lumen was searched for with a guide and the stricture was divided. Another form was excision or resection of the stricture and joining up the two ends of the urethra. In resecting strictures he preferred to unite the upper wall of the urethra, leaving the inferior part open, and have a large catheter passed right through. If these procedures resulted in the patient having a rigor, he should be given hot drinks and hot bottles should be put round him.

A complication for which the surgeon should be prepared was high fever followed by anuria. This was sometimes so urgent that it called for decapsulation of the kidney. In one such case which ended fatally there was no lesion of the kidney to point to the reason for the anuria. In spite of all that could be done, anuria was almost always fatal. A peri-urethral abscess must be opened. If it were in the penile urethra it was better to open it through an endoscope tube than from the outside, which might cause a fistula. If the abscess developed in the perineum, it should be opened by a free incision, the stricture being treated at the same time.

With a stricture of fairly wide calibre retention might be abolished by putting the patient in a bath and giving morphia, afterwards wrapping him in blankets. A catheter should not be passed if this could be avoided. When a patient was declared to have renal inefficiency it meant that his kidneys were feeling the stress of back pressure or infection. Such a patient was losing his tone, and was beginning to lose weight; his appetite was not good, he had a dry tongue, thirst, and perhaps headache. His renal functions must be properly tested before manipulation of the urethra, and the tests should include estimation of the blood-urea. If the blood-urea was above 50 the kidneys were beginning to fail, and this meant an increased operation risk.

Mr. Swan concluded with a warning not to follow the tendency of the present day to rely on laboratory findings to the comparative neglect of purely clinical methods. Accessory tests should remain accessory tests.

Discussion.

Major F. C. DOBLE agreed that a large proportion of strictures were due to vigorous treatment of gonorrhoea. He thought the bulbous urethra was most often affected because the strong solutions used remained there.

Dr. T. J. WRIGHT (Norwich) asked about the prevention of embolism after passing the urethroscope, and spoke of the efficiency of Coleman's dilator.

Dr. H. C. SEMON spoke of a case in which stricture was complicated by condyloma acuminata, and asked

whether caustic applications to the fossa navicularis were contra-indicated.

Mr. SWAN said that he had a great liking for Coleman's dilator in appropriate cases, and that for the condylomata mentioned by Dr. Semon he would use diathermy, as it left a soft and supple scar. Or radium might be used in such a case. The only filiform bougies he used were soft; he did not even go to the length of using whalebone ones.

INSTITUTE OF RADIOLOGY.

DOSAGE OF RADIUM THERAPY: DR. MURDOCH'S REVIEW.

At the Institute of Radiology on May 8th the chair was taken by Dr. N. S. FINZI, and a lecture was given by Dr. JOHN MURDOCH of Brussels. When the permanent results of large radium institutes were compared, he said, a striking similarity appeared, despite the fact that very different methods were applied. It must be admitted that present methods were mainly empirical, lacking the indispensable basis of all scientific therapeutics—viz., an unquestionable unit of dosage. We knew everything about the dose emitted but nothing whatever about the dose absorbed by the tissues, and until quite recently it had been impossible to give correct instructions, based on physical data, for making surface masks. The method of ionisation, which had given excellent results in measuring X rays, had not been used to the same extent for measuring gamma rays, on account of technical difficulties due to the size of the ionisation chambers. Various investigators had tried to overcome the difficulty by using biological or photometrical methods. The biological tests tried had included the skin-erythema dose, the growth of germinating peas, the reaction of the epithelium of the uterus, the temporary castration dose, the intensity of necrosis in a rabbit's muscles, the decoloration of butter, and the percentage mortality in the eggs of ascaris. These methods could never be as accurate as physical tests. The size of the ionisation chamber prevented the measurement of radiation in the immediate vicinity of the source, just where the effects were most considerable. The smallest ionisation chambers were those of Ferroud (1.8 c.m.), Shliss and Kessler (1.5 c.m.), Mallet (1 c.m.), Huth (0.5 c.m.), and Glasser, Portmann, and Seitz (25 c.m.), but in none of these could measurements be made at a distance of less than 1 cm. from the axis of the radio-active preparation. Prof. Stahel, of Brussels, had succeeded in 1923 in constructing a chamber of which the volume was only 2 c.m., using a liquid instead of a gas medium to avoid diminution of sensitivity. Hexane, an ether of petroleum, had been selected. In this chamber the "wall effect" was only felt in a field a few tenths of a millimetre thick and the secondary electron rays covered a very short distance; the absorption of photo-electrons and Compton electrons was almost complete. The phenomenon described by Jaffé as "column ionisation," however, made it impossible to comply entirely with the conditions laid down in the definition of the international "r."

In 1918 and 1919 Regaud and Ferroud had adopted the unit of "destroyed millicuries," and the majority of Anglo-Saxon, German, and Scandinavian radiologists used the milligramme hour. Both these systems defined the quantity of radium used and the time of treatment, but ignored filtration and distance. The "D" unit of Mallet and Proust bore no relation to other physical units. Deauville had proposed the erg as a curie-therapeutic unit in 1923, and in 1928 Stahel had adopted this and measured the quantities of energy absorbed by units of volume of irradiated tissue, the results being expressed in calories-cubic centimetres or ergs-cubic centimetres. Stahel's method of making these measurements was ingenious and delicate, involving the estimation of ten-thousandths of a degree centigrade per minute, and the elimination of heat due to alpha and beta rays.

Clinical Application of the Erg-Cubic centimetre Unit.

The combination of ionometric and energy measurements had enabled the physicist to draw up a series of isodoses corresponding to the various needles and tubes in use. The curves had been established for a standard tube containing one milligramme of radium element, and the figures shown in the various curves were those of the quantities of ergs absorbed per hour by a cubic centimetre of tissue at the spot under consideration. Curves had been plotted in planes parallel with the main axis of the preparation at graduated distances from 0.5 to 5 cm., and also at perpendicular planes. By means of these planes of isodoses an irradiation scheme could be prepared to ensure homogeneity of dosage throughout a tumour of any form and surface, with a determined surface- and depth-measurement of absorbed energy.

Dr. Murdoch then showed slides illustrating the preparation of schemes for tumours with flat and curved surfaces respectively, with and without a support of Columbia wax. The arrangement was principally based on tubes containing 13.33 mg., but where the dose was too small it could be increased by adding tubes of 6.66 mg. or needles of 1.33 mg., dividing the values by half or ten respectively and adding 6 per cent. for needles to make up the difference in filtration. When a curved surface was to be irradiated the correction resulting from the convergence of the γ rays had to be established. Once the arrangement and power of each source of radium had been chosen in such a way as to ensure that each spot of the radiated surface received almost the same quantity of energy in erg-cubic centimetre milligramme-hour units, the time of application was determined automatically from a table.

Appliances and Cases.

A row of five standard 1 mg. tubes produced very unequal radiation at a depth of 0.5 cm., the difference between the two extremes being 25 per cent. Inequalities disappeared, however, at a distance of 1 cm., and still more at 2 cm. At a depth of 1 cm. a single tube gave a maximum of 1400 ergs-cubic centimetre milligramme hours, but five tubes increased the intensity to 2200 ergs/c.cm. mg. hr. Five parallel tubes also gave a very homogeneous absorption at 0.5 cm. but an almost homogeneous radiation at 1 cm., the maximum intensity being 1.43 times that of a single tube. Twenty-five tubes arranged in five rows at equal intervals of 20 mm. gave a central field of about 6 cm. diameter at a depth of 1 cm. with a practically homogeneous radiation of 4520 ergs/c.cm. mg. hrs. Four tubes arranged in a cross in a circle of radius 2 cm. meant a deficient irradiation of about 15 per cent. in the centre. If they were brought 5 mm. nearer the centre the energy received there would increase from 1600 to 2600 ergs/c.cm. mg. hrs., and if they were moved 5 mm. away it would decrease to 1000 ergs/c.cm. mg. hrs.

Dr. Murdoch then showed slides of a number of typical cases treated by these methods, illustrating their application to neoplasms of the face, palate, nose, and neck. One of the great advantages, he said, was the possibility of making masks to cover large surfaces with a relatively small quantity of radium. It was quite easy to limit exactly the border-line of the irradiation and to avoid all overlapping and all under-dosing of intermediate areas.

The skin was very radio-sensitive, and a slight erythema was caused by a dose of 450,000 ergs/c.cm., as by a dose of 600 r. given in one séance. A dose of 550,000 ergs/c.cm. caused frank erythema and brown pigmentation and 600,000 ergs/c.cm. caused a deep red erythema followed by desquamation. Radio-epidermitis with blisters and strong pigmentation was produced by 700,000–900,000 ergs/c.cm., and higher doses might cause serious burns. A dose of 400,000 ergs/c.cm. would cause conjunctivitis lasting less than six weeks. Mucous surfaces could absorb much larger doses; the mouth could stand more than 900,000 ergs/c.cm. with a reaction lasting four or five weeks and

consisting of a white diphtheroid membrane. Similar doses could be applied to the vagina. The tongue could absorb large amounts without loss of substance or marked fibrosis; in one case over 5,000,000 ergs/c.cm. had been absorbed in the tumour and over 3,000,000 units at a centimetre beyond its borders. The tumour depths thus received quantities of energy amounting to ten times the erythema dose; the cicatrisation had been normal. Similarly in the vagina the absorption of eight times the erythema dose did not cause any exaggerated reaction and cicatrisation was complete after six weeks. The distribution of isodoses round the uterus showed how rapidly the intensity fell off. At a distance of 4.5 cm. from the cervix the intensity at the level of the parametria was only equal to a single erythema dose—i.e., 600,000 ergs/c.cm.

In conclusion, Dr. Murdoch said that the adoption of a unit indicating the amount of energy absorbed per unit of volume of tissue made dosimetrics independent of technical conditions. The dose received and not the dose emitted was measured and the only essential elements were the amount of energy absorbed at the surface, the percentage of the depth dose, and the time of application. Different treatments and types of treatment could thus be compared. Moreover, the handling of radium was reduced to a minimum. The plan was worked out on paper and scratched on the wax and the tubes were put in place in a few minutes.

At first sight it seemed impossible to administer these amounts of energy by any method that necessitated the irradiation of the skin, such as the radium bomb.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

At a meeting of this Section, held on May 14th, the chair was taken by Dr. PHILIP HAMILL, the President, and a discussion on the

TREATMENT OF DISSEMINATED SCLEROSIS

was opened by Sir JAMES PURVES-STEWART. He said that the irregularity of the course of the disease and the frequency of remissions and relapses enhanced the difficulties of discussing the subject. Alleged "cures"—very few of which were on record—were either cases of wrong diagnosis or of prolonged remission. Treatment might be by drugs—of which arsenic was the most useful, especially the silver salvarsan type—or by specific causal methods. Exogenous vaccines had proved very useful in many hands and might act by producing a pyrexial reaction or by protein shock. The causal method had become attainable since the discovery of a specific organism.¹ Miss Chevassut had cultured an organism from about 93 per cent. of 200 cases, with a large control series. Cases which had given negative results had been found to be under arsenical medication. The organism, *Spherula insularis*, was not unlike that of bovine pleuro-pneumonia and had two forms—a sphere and a granule. A large sphere was about the size of a staphylococcus and a large granule about one-tenth of that size. Culture had to be made in Hartley's broth to which human serum had been added; the organism was very sensitive, and its culture demanded considerable care and experience. Injection of the culture into monkeys had at first proved disheartening, but eventually two out of six had developed degenerations. One showed them in the direct cerebellar tract and at the junction of the postero-internal and postero-external tracts, with spots of degeneration also in the lateral tracts. In the second monkey the degeneration was in the antero-median region. An inhibitory substance sometimes appeared in the blood of rabbits and of patients after successful vaccine treatment, but an

¹ THE LANCET, 1930, i., 552.

anti-serum had not yet been produced. In consequence of this discovery vaccines had been made from actively growing cultures, either in serum or in normal saline, and both gave satisfactory results. The virus must be killed by phenol, not by heat. Over 200 patients had been treated but only 73 had yet been under observation long enough for study—i.e., for at least two years. In these 73, encouraging serological and clinical results had been obtained. The globulin reaction diminished and disappeared and the gold curve and cultures became completely negative, while the blood became inhibitory to the growth of the organism.

Signs and symptoms came to a standstill and in some cases improved, although, of course, having a residue corresponding with the degenerations. Among eleven early cases negative cultures had been obtained in five, and nine had shown improvement in their gold and globulin reactions. Of 29 moderate cases, six had become negative while 23 had improved. In 33 advanced cases there had been no negative cultures, though in 20 the gold and globulin reactions had diminished. Two or three series of twelve doses of vaccines of increasing strength were usually needed before any objective improvement was obtained, although clinical improvement began early. That this improvement was not merely remission was shown by the fact that in remissions the serological findings were still positive and the organism could be cultured from the cerebro-spinal fluid.

Discussion.

Dr. DOUGLAS MCALPINE referred to work by Adams, of Glasgow, and others on the improvement of the cerebro-spinal findings after arsenical treatment. This had been in favour of the effect of arsenic. He asked if there could be a control series of serological tests in cases treated by arsenic, and another to show whether arsenical treatment caused any inhibitory effect of the blood-serum on the spherula.

Dr. WILFRED HARRIS congratulated the authors on what he hoped would be a far-reaching advance in therapeutics, whether or not the spherula proved to be the causative organism of disseminated sclerosis.

Dr. KINGSTON BARTON said he had known cases which had had very little treatment go on for a very long time. Disseminated sclerosis was mixed up with psychosis, and light might be thrown on it from that side. In private practice one of the greatest difficulties was the liability to bacilluria, and hexamine might hold the balance between health and illness. Insomnia might be controlled by giving very minute doses of hypnotics—e.g., half a grain of veronal, and in this way drug addiction could be avoided.

Dr. HILDRED CARLILL asked what should be done in clinical cases of disseminated sclerosis in which the organism could not be found. He had had remarkable success with the vaccine.

Miss KATHLEEN CHEVASSUT said that it was quite impossible to get a culture if the fluid had been contaminated, and completely sterile lumbar punctures were difficult to secure. Only a small percentage had proved negative, and it was worth while to do repeated lumbar punctures. There seemed to be some unknown factor that influenced cultures. A trace of arsenic in the cerebro-spinal fluid inhibited culture, but this did not necessarily mean that it destroyed the organism in the body; it might have a mechanical effect. The colloidal gold curve had been fully investigated in Sir James Purves-Stewart's cases, both disseminated sclerosis and controls, and its relation with arsenical treatment had been studied. The Glasgow cases had had intensive arsenic treatment, and possibly the effects of the arsenic excreted into the cerebro-spinal fluid had chemically interfered with the very delicate gold reaction. The infective agent was probably not the sphere but the granule, and

a very wide field of research was still open in this connexion.

The PRESIDENT asked whether the vaccine used was always autogenous and whether it degraded on keeping and must be freshly prepared.

Dr. Z. KUBIE asked whether there were any indications of a living process, such as consumption of oxygen and evolution of carbon-dioxide, in these cultures, and also whether the interval between the induction of treatment and the appearance of remission showed any constancy. Recent work in New York hinted that there was a lipolytic agent in the blood-serum of patients of disseminated sclerosis; some suggestive results had been secured with quinine.

Miss CHEVASSUT said the vaccine was merely a culture killed with phenol. The number of granules was counted under the microscope and the number per c.c.m. calculated. The difficulty lay in the recognition of the positive culture and not in the preparation of the vaccine. It must be given intravenously to be effective and must be autogenous. It did not seem to keep more than three months. It was given at weekly intervals.

Dr. BROUGHTON ALCOCK asked at what stage a patient was declared unable to respond, and if any injury followed the use of the vaccine in the late stage. Was there any simple laboratory method of diagnosis?

Sir JAMES PURVES-STEWART, in reply, said that the diagnosis was both clinical and serological. In some very slight cases the serological observations were very valuable, but the disease should never be excluded on a laboratory specimen. Sometimes a patient would be a little sleepy or have a few minutes' collapse after a large dose; no other bad effects had ever been seen. The extent of the disease and not the time that had elapsed was the important point in classifying a case as "early" or "late." Clinical improvement often appeared in a month or two, and serological improvement was noted after the first course of vaccine. Psychological factors played a part, as in any disease, but did not change serological reactions. The Glasgow work was in accordance with Miss Chevassut's observations. So far, the risks of making a stock vaccine had prevented the attempt, but that was, of course, the object of research. At present patients with profound permanent degenerations were not treated.

MIDDLE-CLASS PAYING WARDS.—The experiments begun two years ago by the Norfolk and Norwich Hospital of opening a house for the treatment of paying patients of the middle class has been so successful that the accommodation is to be enlarged. The house, which is adjacent to the hospital, and is run as an integral part of it, originally contained 12 single rooms with a theatre, but two rooms were subsequently added, and now a new ward of 20 beds is to be built. All patients are under the care of a member of the honorary staff, and admission is obtained either by paying £4 4s. per week plus a sum for medical attendance, which must not exceed 15 guineas, or by joining a contributory scheme with premiums amounting to 30s. a year. The cost of the new building will be defrayed in about eight years by the balance left from contributors' premiums, after deducting 12s. a day for each in-patient, and a levy from the fees of the honorary medical staff.

OPHTHALMIC HOSPITALS.—Last year the Royal Westminster Ophthalmic Hospital treated 1110 in-patients and 12,482 out-patients. The 14 rooms provided for patients who, while ineligible for admission to the public wards, are unable to pay nursing-home charges, have been used during the year by 130 patients. An electrotherapeutic department and a department for the treatment of squint have been opened.—The Royal London Ophthalmic (Moorfields) Hospital treated 2534 in-patients who were residents, on the average, 16.02 days and cost £3 7s. 2.05d. per week. There were 51,021 out-patients who cost 6s. 4.01d. each; there were 3380 operations in the out-patient theatre. In the refraction department 11,987 (5008 new) London County Council school-children received attention.

New Inventions.

A NEW PNEUMOTHORAX NEEDLE.

THE needle as shown in the sketch is made so that information of the position of the point as it goes through the chest wall is given by the manometer before the stilette is withdrawn. The needle is of the orthodox "Clive Riviere" pattern and has a terminal and lateral opening. The stilette, when in use, closes the terminal opening, but does not obstruct the lateral opening. It is kept in position by a small pin which fits into the opposite end of the instrument. This prevents the stilette turning round when in use. The needle is sharp-pointed, slightly bevelled, and when passed into a patient's chest with the stilette in use gives a reading on the manometer of the pneumothorax apparatus immediately the lateral orifice enters the pleural cavity. It has been found in practice that the lateral orifice does not get blocked in passing through the chest wall. The instrument is particularly useful in induction of the treatment.

Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E.1, are the makers.

FREDERICK R. G. HEAF, M.D., M.B.Camb.

RETRACTOR FOR BONE-PLATING.

THE illustration shows a pair of retractors which have been in use for the last two years and I have found them a great convenience, particularly in plating the shaft of the femur through the anterior incision described by Fleury. Owing to their slightly clawed edges which meet behind the linea aspera and to their

weighted outer ends, they are self-retaining. When they are in place with the towels tucked round outside them, they leave nothing exposed except the necessary length of bone including the fracture. The risk of infection or laceration of soft structures is minimised and the fixation of the plate is easier because the exposure is so complete. There is no difficulty in applying them; they stay put until removed; and their weighted outer extremities tend to lift forward the bone and restore its natural anterior bow.

The retractors are made by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W.

MAURICE G. PEARSON, B.Sc., M.B.Lond., F.R.C.S.

NEW FALMOUTH HOSPITAL.—Two Cornishmen resident in South Africa, Mr. William Mountstephens, a native of Falmouth, and Mr. Albert Charles Collins, a native of Stithians, have jointly presented Falmouth with a new hospital which has cost £18,000 without counting site and equipment, and was opened recently by Mrs. German, of Truro, a sister of Mr. Mountstephens. There are men's and women's wards of 12 beds each, and a children's ward with eight cots.

Reviews and Notices of Books.

HUMAN SPEECH.

Some Observations, Experiments, and Conclusions as to the Nature, Origin, Purpose, and Possible Improvement of Human Speech. By Sir RICHARD PAGET, Fellow of the Physical Society of London, and of the Institute of Physics. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1930. Pp. 360. 25s.

THE scope of this work is well described in the subtitle, and covers observations, experiments, and conclusions on the nature, origin, purpose, and possible improvement of human speech. Sir Richard Paget has made very extensive experiments into the mechanism of the production of vowel sounds and of consonants, and has confirmed his theories by making models which imitate with a high degree of accuracy the various sounds produced by the human organs of articulation. He finds that the sounds produced in articulation are musical tones of definite pitch, the result of characteristic combinations of resonances set up in the human vocal cavity when tongue and lips are set in different and appropriate postures. In vowel sounds the main result is to produce, at each posture, a different pair of principal resonances, each pair being in association with a particular vowel. The pitch of these resonances is more easily recognised when speech is whispered; the effect of phonation is to cause, by vibration of the vocal cords, the passage of rhythmically pulsating air which colours the musical note by emphasising such overtones as lie within the pitch of the resonators. The production of the consonants is more complicated, for more than two resonators are in action; they are marked out, not only by pitch, but also by their change, and rate of change, in pitch, and they are all made by complete or partial closures of the front or back orifice of the anterior oral resonator. The essential difference between the so-called unvoiced and voiced consonants is not that of phonation, for they can be clearly distinguished in whispered speech; the difference is one of resonance, and the voiced series are produced, when whispering, either by the acoustic effects of direct access to the trachea, or by the resonance of a cavity formed between the true and false vocal cords. Dr. G. Oscar Russell, of Ohio University, has employed a form of pharyngoscope by which the movements of the throat can be studied during speech; this action of the ventricular bands, to form a resonating cavity, has been established by these means, which also show that the epiglottis coöperates, by a backward movement, in forming a constriction to produce a posterior resonator. Thus it is claimed that these parts of the larynx both act as essential organs of articulation.

The remainder of the book has less special interest to the laryngologist. In it the author develops the theory that language originated in gestures made with the lips and tongue in substitution for gestures made with the hands, which were becoming increasingly occupied with other functions. This "gesture theory" is copiously supported by an examination of the position of the lips, tongue, and mouth in the simple words of primitive languages. Finally, the author gives his views on the imperfections of language, and his suggestions for its improvement, for he believes that any imperfections of an existing language which cause difficulty in the process of coding thought into speech, or decoding speech into thought, are a stumbling block to the intellectual and material progress of the people who speak the language in question. We are all aware that modern languages and modern spelling, which have been evolved spontaneously, are full of serious defects—for instance, we have but five symbols for our thirteen or fourteen fundamental vowel sounds—but some of us are doubtful whether drastic conscious attempts at improvement are either possible or likely to be successful. Sir Richard Paget does not

advocate simplified spelling, or any other particular system, at the present time; he pleads for a period of liberty from rigorous orthography, coupled with the teaching of the phonetic alphabet to all English-speaking children, and the foundation of an "English-speaking Union," directed towards the improvement of the language and the ultimate standardisation of its pronunciation. Two points of medical interest are to be found in this part of the book. One is the suggestion, on the oral teaching of deaf mutes, that whispered speech should be taught in the first instance, as being homogeneous and simpler. The second is that, after excision of the tongue, the natural resonance of the vocal cavity is altered and lowered by increasing its volume and that this destroys the accurate reproduction of speech sounds; it is suggested that the original resonance might be restored in such cases by effectively lowering the roof of the mouth by means of a plate.

The book is written in a most lucid and interesting manner; Sir Richard Paget deserves congratulation on the results of an immense amount of patient labour in a field which has hitherto not received much attention.

DISEASES OF WOMEN.

Seventh edition. By HARRY STURGEON CROSSEN, M.D., F.A.C.S., Professor of Clinical Gynecology, Washington, University School of Medicine, &c.; and ROBERT JAMES CROSSEN, M.D., Instructor in Clinical Gynecology and Obstetrics at the same school. London: Henry Kimpton. 1930. Pp. 1009. 50s.

This book, which has established itself as one of the leading text-books on gynecology in any language, has been well known in this country for many years. It is so well written and illustrated that the authors' argument can be followed without difficulty. During the four years since the last edition was published a considerable amount of experimental work on the physiology of reproduction and its relation to diet and internal secretions has been published. This work has been incorporated and serves to clear up our ideas on these subjects, although much is still obscure.

The author's attitude adopted towards radium treatment of cancer of the cervix is worthy of note. In America generally the radical operation is regarded as obsolete and radium as the only proper form of treatment. Prof. Crossen takes the view that the operation is not obsolete and should be employed in early cases with preliminary radium. This is an illustration of the balanced outlook maintained throughout the work.

CLINICAL PEDIATRICS.

Diseases of the Skin in Infancy and Childhood. By HOWARD FOX, A.B., M.D., Professor of Dermatology and Syphilology, New York University; Former President American Dermatological Association. Supervising Editor: R. S. HAYNES, Ph.B., M.D., Clinical Professor of Diseases of Children, Columbia University, New York. London: D. Appleton and Co. 1930. Pp. 372. In three volumes. Vol. XVI. 48s.

THIS is a straightforward and thoroughly scientific treatise on the cutaneous affections commonly met with in infancy and childhood. The author is one of the most prominent of American dermatologists, and is frequently an honoured guest at meetings held in other countries. In his classification and the general arrangement of his book he adopts a compromise between aetiological factors and clinical appearances, noting that there can be no really satisfactory solution of the difficulties until it is possible to base nomenclature on the known causation. Designed for the use of the practitioner, the book has hardly any histological descriptions or plates, but the deficiency is more than balanced by a wealth of clinical photographs, all most carefully selected

to illustrate typical cases. There are 20 chapters, a brief and very simple formulary which contains all that the most scrupulous practitioner needs to memorise. The chapters on eczema and the tuberculides are particularly well done; it is interesting to note that lichen nitidus finds a nosological place among the latter, and that lupus erythematosus and granuloma annulare are also classed as tuberculous in origin, although in Europe their aetiology is still sub judice. Certain opinions are expressed about the treatment of tuberculosis verrucosa cutis, scrofuloderma and erythema induratum, with which few dermatologists in this country would agree. The two former diseases would not here be submitted to X ray therapy, but to surgical and actinotherapeutic measures, while it is our experience that Bazin's disease (erythema induratum) mostly yields to a few doses of novarsenabillon.

The book, which is very well got up, will be useful to all without special dermatological training, particularly to those working with children.

RECENT ADVANCES IN CARDIOLOGY.

By C. F. TERENCE EAST, M.A., M.D.Oxf., F.R.C.P.Lond., Junior Physician, King's College Hospital; and C. W. CURTIS BAIN, M.C., M.B.Oxf., M.R.C.P.Lond., Assistant Physician, Harrogate Infirmary. London: J. and A. Churchill. 1929. Pp. 342. 12s. 6d.

THIS book reviews advances in cardiology made during the past ten years or so, more especially for the benefit of practitioners who qualified before that time. As the authors point out, the advances to which they refer really go back farther, and date from the work of Mackenzie. In recent years the tendency has been to devote less attention than previously to morbid anatomy and more to the disturbances of cardiac function, the study of which has been greatly facilitated by the introduction of the polygraph and electrocardiograph. It is principally with functional disorders and their diagnosis and treatment that the book is concerned. The opening chapter on coronary thrombosis is the best in the book; it gives an admirable account of the condition. This is followed in the natural sequence by a summary of the current views on the aetiology of angina, and a consideration of a miscellaneous group of factors helpful in the diagnosis of myocardial disease. Some of these hardly seem to merit a place amongst "recent advances." Gallop rhythm, for example, has long been recognised as a sign of sinister significance, and nothing of importance has been added to our knowledge of this disturbance in recent years, nor can we fairly claim to have made much advance in the treatment of the cardiac complications of pneumonia. Sections such as these might be better described as current conceptions rather than recent advances in cardiology. But they are none the less likely to be of value to practitioners provided they remember that the work is not intended to be a text-book and deals only with one aspect of the subject. The chapter dealing with the X ray examination of the heart is concise and well illustrated, and the chapter on the electrocardiograph gives a clear account of the fundamental principles on which this method is based.

PRACTICAL MASSAGE AND CORRECTIVE EXERCISES.

Fifth edition. By HAAVIG NISSEN, late President of Posse Normal School of Gymnastics, and Lecturer and Instructor of Massage and Swedish Gymnastics at Harvard University Summer School. Philadelphia, Pa.: F. A. Davis Company. 1929. Pp. 271. \$2.50.

THIS book is not calculated to find any great demand in this country. The student in training will find it inadequate to meet his or her paramount need, that of satisfying the examiners of the Chartered Society of Massage and Medical Gymnastics, while

medical men will require something far more authoritative and up to date. The traditional teaching of bygone ages is reproduced, regardless of the advance in medical knowledge. Forcible stretching is still included under the head of "Passive Movements," and we read of the value of kneading, which is "used to crush newly formed vessels." We are told that another form of massage may cause "impure matters" to be "more firmly embedded in the walls of the blood-vessels," and other relics of the past are included in the text. Even the anatomy is not up to date, as an elaborate argument is based upon the supposition that inversion and eversion of the foot takes place at the ankle-joint, while the description of the action of various muscles is misleading. On the pathological side we are told that "great force must be applied when the shoulder or elbow-joints are stiff from dislocations, fractures" without any word of warning as to its dangers, and the perilous advice is given elsewhere that "muscles and nerves" should be put on the full stretch, "especially in paralysis." These are merely a few examples drawn from a large number. Those who wish for guidance in the matter of physical treatment should seek it elsewhere.

LE DIAGNOSTIC DES ANGINES AIGÜES.

By A. B. MARFAN, Professeur Honoraire à la Faculté de Médecine de Paris. Membre de l'Académie de Médecine. Paris: Masson et Cie. 1929. Pp. 87. Fr.10.

In writing this little book on acute inflammations of the throat Prof. Marfan had two objects in view. He wished to show that on purely clinical examination it is possible, in the majority of cases, to make a diagnosis of diphtheria, thereby enabling anti-diphtheritic serum to be given without delay; also he wished to plead for a revision of the clinical descriptions of the acute inflammations of the throat, in particular the so-called herpetic type. The early administration of serum in diphtheria is clearly so important, from the point of view both of treatment and prophylaxis, that for this section this book is of value; it is obviously written by one with wide experience of throat affections and should prove helpful to those who are called upon to make difficult decisions. The concise account of the many acute conditions met with in the throat, with special stress on the differential diagnosis from diphtheria, is admirable.

MEDICAL INSURANCE EXAMINATION.

Modern Methods and Rating of Lives. Second edition, enlarged. By J. PATERSON MACLAREN, B.Sc., M.B., C.M., late Examiner for University of Cape of Good Hope and Chief Insurance Medical Officer. London: Baillière, Tindall and Cox. 1929. Pp. 646. 30s.

In his introductory remarks the author emphasises the extreme importance of medical examination for life insurance. He maintains that ability to assess length of life can only be attained after years of experience of diverse forms of practice. Recent developments in aids to diagnosis have in his view, led to greater accuracy in this assessment. The book is divided into three parts. The first describes and explains the general examination and confidential report; the second deals with the examination of the various systems in detail, and the third with diseases as insurance impairments. A brief outline of the methods adopted in rating is given; diseases of the various systems are clearly discussed and tables are included showing the ratings adopted by various companies for degrees of disease or deviation from normal. In this edition the problems of diagnosis and prognosis in relation to abnormalities of blood pressure, early pulmonary tuberculosis, heart murmurs, new growths, glycosuria and albuminuria have been dealt with more fully. Throughout an effort is made to show how the various

findings should be correlated by an examiner in assessing a risk; for example, in reporting on hypertension the examiner is advised to put to himself such questions as: Has the proposer a strong will? Does he indulge in any excesses? Will he be likely to amend his diet habits or mode of life? On the answers will depend his recommendation to accept, with or without loading, to postpone, or to reject. The ratings quoted are exceptionally full; the book is amplified by 12 illustrations, and in the index heavy type is used to direct attention to the more important references. The book clearly expresses the special attitude which the insurance examiner should adopt to medicine, and might be read with advantage by the general physician who is largely concerned with prognosis as well as by those who do many examinations for insurance.

DIETETICS.

The Science of Nutrition Simplified. By D. D. ROSEWARNE, M.R.C.S. Eng., L.R.C.P. Lond., late Honorary Actino-Therapeutist and Assistant Physician, City of London and East London Dispensary. London: Henry Kimpton. 1929. Pp. 314. 6s. 6d.

Food Values in Practice. By ETHEL M. DOBBS, M.A. Lond., Lecturer in the Department of Hygiene and Public Health, Battersea Polytechnic. London University Press, Ltd. 1929. Pp. 240. 4s.

Dr. Rosewarne's small book aims at presenting the most important principles of nutrition in language that can be understood by the ordinary reader. Its last chapter is devoted to an account of some of the larger text-books dealing with particular aspects of the subject for the benefit of readers who wish to study the science of nutrition more thoroughly. The exposition of the subject is clear and, on the whole, free from prejudice. The section dealing with infant feeding is disappointing in view of the promising results that are being obtained all over the world by the application of modern knowledge to the problem of the prevention of disease in early childhood. Cow's milk, with the possible addition of lactose, is apparently considered a complete diet for the infant from birth till the age of nine or twelve months. Those with experience of the feeding of infants in large cities will not agree that such a diet can ensure the prevention of rickets, the formation of good teeth, and the prevention of nutritional anaemia.

Miss Dobbs aims in her little book to provide a working knowledge of the essential functions in the human body, and at the same time to give practical instruction in the marketing and storage of food, the construction of dietaries, and the methods of cookery. The fact that she is acquainted with some of the modern discoveries in the field of nutrition will not necessarily ensure that the housewife supplies her family with the food best calculated to keep them in good physical condition. Those with limited incomes are bound to find difficulties in purchasing a sufficiency of the protective foods that are needed at all ages, and even such foods may not exert their full beneficial effect if they are purchased without due regard to individual qualities, or are injudiciously cooked and served. The instruction here given will help the organiser of the household budget to choose wisely. The last hundred pages are devoted to selected recipes suitable for healthy individuals and for those suffering from simple ailments such as constipation and obesity. A practical book such as this should prove of great value to the housewife, whether she be rich or poor.

Buchanan's Dissection Guide, edited by E. Barclay-Smith, R. H. Robbins, and J. E. Frazer, has just been published by Messrs. Baillière, Tindall and Cox at the price of 10s. 6d. (not 12s. 6d., as erroneously stated in an advertisement).

THE LANCET.

LONDON: SATURDAY, MAY 17, 1930.

THE TEACHING OF PREVENTIVE MEDICINE.

THE progress of education is marked by the efforts of the teachers who have gained a footing in the curricula to obtain greater recognition for their subject, and the struggles of reformers to find room for new fields of study. Science is still contending with the classics against heavy odds in the scholastic world, and in elementary education the three r's are faced with the encroachments of art, domestic science, hygiene, and handwork. Indeed, since continuity of policy and freedom from turmoil are necessary to the pursuit of learning, it would be disastrous if chopping and changing of curricula to meet the desires of educational radicals were unresisted by their more conservative, because less dissatisfied, professional colleagues. In medicine this struggle for recognition is more frequently recurrent and more acute than in other provinces of education, because the march of knowledge is more rapid and along so irregular a front. New developments lead to new specialisms and new lectureships, and time has to be found for each of these subjects in the curriculum.

This constant state of flux in medical education has, of course, resulted in a good deal of unevenness in the allocation of time to different studies in the various medical schools, in spite of the coördinating influence of the General Medical Council. The presence in a particular school of a brilliant exponent of some branch of technique, or the accident that a chair or lectureship has been endowed, may be determining factors, and experiments of this kind help us to assess the value of special courses of study before they are generally accepted. A time arrives, however, when it is desirable to pool experience and to arrive at a national policy. The Society of Medical Officers of Health, being impressed with the unsatisfactory provision made for the teaching of preventive medicine in several schools, appointed last year a committee, under the chairmanship of Prof. W. W. JAMESON, to inquire into this subject and also into the requirements of the various examining bodies. Their report, which appears in the May issue of *Public Health*, sets out in detail the status of the teachers of this subject, the number of lectures and demonstrations given, the syllabus in certain schools, and the examination requirements. A useful summary is also given of the position in foreign countries. Briefly, the information collected indicates that there is great inequality in the teaching of preventive medicine in the different medical schools of this country, lecture courses varying in length from 10 to 60 lectures and practical demonstrations from nil to 12. On the whole, European and American countries appear to devote more time and attention to the subject. The committee has made recommendations which, in view of the importance of preventive medicine, cannot be regarded as unreasonable even by those who are alarmed at the prospect of an overloaded curriculum and further extension of the period of undergraduate study. The

number of lectures, it is suggested, should be not less than 24, the course being held not earlier than the penultimate year of study, and no student should be allowed to qualify without having passed a separate examination in public health and preventive medicine.

Most important of all, however, is the prominence given throughout the report to the need for permeating the whole curriculum with the preventive idea. It is now seven years since the General Medical Council resolved that "throughout the whole period of study the attention of the student should be directed by his teachers to the importance of the preventive aspects of medicine" and Sir GEORGE NEWMAN, in his "Recent Advances in Medical Education in England," showed how it could be done. Yet the committee of the Society of Medical Officers of Health has been unable to ascertain any instance of a school where a concerted endeavour can be said to have been made to introduce into the teaching a real emphasis on the importance of prevention. The schools are lagging behind public opinion. It is notable that the state of affairs is worst in London, where teaching is based on hospital units, and where the atmosphere, necessarily clinical, is uninfluenced by the great public health movement of which the health authorities are the centres. In the provinces, and especially in the ancient universities of Scotland, where there is more community of interest between town and gown, the place of prevention is less liable to be forgotten by those responsible for teaching medical students. The Society of Medical Officers of Health are forwarding their committee's report to the General Medical Council by whom it will no doubt receive the consideration which it deserves.

THE COST OF LITIGATION.

THE London Chamber of Commerce, through a subcommittee of its Parliamentary and Commercial Law Committee, has been examining the causes of the present high cost of litigation and the possibility of mitigating them. One suggestion in the subcommittee's report is that in all cases involving technical matters an assessor should sit with the judge as adviser, in the same way as the Elder Brethren of the Trinity House in Admiralty cases, to assess damages. No expert evidence, says the report, should be given; but in cases involving more than, say, £2000, the parties should be allowed each to put forward one expert on each side to act as a demonstrator of the technical points at issue, though not as a witness; in cases over £10,000 the parties to be allowed to call one expert witness on each side if they wish. The possible use of members of the medical profession as assessors is a point which has often been urged in the past. Workmen's Compensation Act procedure has managed to take advantage of medical knowledge in this way and machinery exists by which a High Court judge could avail himself of medical assessors' services though he is naturally reluctant to relinquish his judicial responsibilities. The Chamber of Commerce plan, however, seems more suitable for cases concerning commercial contracts than for the kind of litigation in which doctors are themselves mainly concerned. Rule-of-thumb scales for valuing litigation will hardly suit actions against physicians or surgeons for alleged negligence. Would *Harnett v. Bond*, for instance, have been classified beforehand as a £2000 case or a £10,000 case? Other recommendations in the subcommittee's report appear similarly to have special application to the classes of proceedings dealt with in the Commercial Court rather than

to the ordinary actions which come before a jury. There is a suggestion that pleadings be further cut down and that viva voce evidence and cross-examination be eliminated and replaced by agreed documents and brief signed statements. A case like *Crotch v. Miles* could hardly have been dealt with thus. To deny the right to call expert witnesses may amount to a denial of justice. Endeavours have been made, notably in the Chancery Division where there are no juries, to limit the numbers of expert witnesses; but these efforts are not universal. Undoubtedly the modern trial is unduly prolonged. A fashionable leader nowadays takes several days over a cross-examination where the giants of the past were content with a couple of hours. Yet brevity sometimes defeats itself, nor have all judges the same standard of brevity. Lately, in a claim for damages arising out of a motoring accident, counsel for the defendant took the point (at the close of the plaintiff's case) that there was no evidence of negligence to go to the jury. The judge agreed and stopped the case without calling on the defendant. For this success the counsel was scolded by the Court of Appeal. He was told he had fired too soon. In remitting the case for a fresh trial the Court of Appeal punished the defendant by giving the plaintiff the costs of the appeal and directing that the defendant, even if successful at the re-trial, should not have the costs of the first trial. The Chamber of Commerce report says that dates should always be fixed for trials—a great convenience if only the length of a case can be accurately foreseen. It comments, too, upon the illogical rule by which a junior counsel must receive a brief fee equal to two-thirds of his leader's fee though he would probably be prepared to fight the case single-handed for much less. Professional fees are matters which may in time be adjusted by the laws of supply and demand. It is significant that for many months business in the Temple has been reported to be very slack. The Chamber of Commerce remedies may not all be equally acceptable, but the fact that the inquiry should have been instituted is evidence of grave dissatisfaction with the present conditions of litigation.

MEDICAL SERVICE UNDER NATIONAL HEALTH INSURANCE.

THE report made by Sir ALFRED WATSON, the Government Actuary to the Ministry of Health, after a scrutiny of the sickness and disablement experience in a group of approved societies, is an extremely valuable document, as the comments made upon it at the time of its issue and its subsequent discussion in the House of Commons show very clearly. It forms a review from certain aspects of the administration of the National Health Insurance Act, revealing the facts that, while certain of the benefits promised under the Act could not be said to have materialised, the pecuniary cost of the machinery, already a heavy burden, bade fair to advance to a point at which it would be insupportable. Many questions involved in a discussion of the working of the Act were debated in the House during the past few days, and as one result it became known that the Ministry of Health propose to follow up various lines of investigation, indicated by the facts in the report, and intend to take the public into their confidence at definite intervals. This means alike that the Ministry recognise the imperfections of the Act as definitely requiring amendment or removal, and admit that only with the coöperation

of the public can the necessary changes be effected. There is not, either among the public or in the ranks of the medical profession, any serious consensus of opinion that the Act does not represent a large attempt to secure the improvement and maintenance of the national health on some broad contributory scheme—there being no other practicable course; but from all sides the working of the Act has given rise to legitimate criticism since it became the law of the land. The insured population find that the benefits are not administered in a symmetrical way, the contributions exacted being everywhere the same while the benefits accruing vary greatly according to the success and economy of the particular approved society. The doctors admit that the scheme, as far as it goes, has in many directions advanced their material interests, but it has brought under their charge a vast mass of patients for whose treatment they have become responsible when they are often unable to provide the appropriate care, and where always their professional work has to be conducted in accordance with regulations that in individual instances may be vexatious even though they are necessary as part of the extensive scheme. The approved societies are regarding their pecuniary commitments with a steadily increasing apprehension, and would assuredly welcome changes promising to lighten their burdens as stewards; and such changes would be all to the good if resulting economies were not made at the expense either of the insured population or the doctors.

We reported at length last week, under the heading of Parliamentary Intelligence, the debate on the administration of the Act in its early phases; the sequel to the debate will be found in our columns to-day, where the feeling of dissatisfaction, in many regards with the Act, as it is, is reflected in the speeches of all the participants in the discussion. Indeed, no one can read those speeches, delivered from their different angles, without seeing how widespread now is the opinion that the National Health Insurance Act will have to be reformed, though it is not so easy either to anticipate in which direction reform will first be attempted nor to forecast how far any particular additions or modifications will have immediate beneficial influence on its working. The gist of Sir ALFRED WATSON'S report was that the burden of the sick, receiving benefits under the Act, was increasing in a threatening manner, and where the fact was admitted without reserve one of two conclusions was reached in most places where public expression of opinion found vent—namely, that a significant proportion of the national sick list was to be regarded either as the outcome of malingering or as the result of lax certification on the part of the doctors; in a sense this is but one opinion looked at from two points of view, for the pretender to pathological conditions can only make good his claims at the expense of the critical acumen of the doctor. In the House of Commons Dr. H. MORGAN repudiated vigorously the suggestion that the doctors could be accused of manufacturing malingers in this way, while his words were those of wisdom as far as he viewed the increases of the money spent upon administration being not essentially due to lax certification but rather to a generally imperfect method of looking at the benefits to be expected from the Act. Colonel FREMANTLE followed and quoted a statement made by the chairman of the National Conference of Friendly Societies last November which had similar force, for he affirmed that no scheme, however good, would succeed if it removed the incentive to provide for the future and encouraged all and sundry to look to the State to make provision for that future.

The debate in the House of Commons should prove of real use in helping the legislature to appreciate that the reform of medical service under the National Health Insurance Act is called for on all sides, and that, while there should be no insuperable difficulty in reconciling conflicting interests when the radical faults are faced, there must be a willingness to proceed thoroughly. It is not sufficient to attribute the present situation of the service either to a want of conscientiousness on the part of doctors or to an exhibition of laziness and duplicity on the part of panel patients. Nor is it unreasonable on the part of approved societies to ask for protection through legislation against the risks of disabling expenditure. Many of the cases which are open to criticism as being examples either, on the one hand, of malingering, or, on the other hand, of lax certification may well be exactly those cases where early treatment has been required or where an extension of treatment, when a certain measure of convalescence has been reached, is necessary to firm recovery. The reluctance of the doctor to give a certificate in early stages while a certain capacity for work remains should not require to be excused on the ground that there must be no laxity in certifying, while the greatest factor in the preservation of public health is the early identification and treatment of disease. Nor should patients be too promptly sent back to work in response either to pressure from approved societies or their individual desire to carry on—and medical men do not agree that the insured population show any general desire to remain out of work when capacity to work has been reached. In the long run the funds of the approved societies would benefit from the earlier treatment of a growing proportion of their charges, as well as from increasing relief to their expenditure on recurrent conditions of sickness. These are things which will have to be remembered in that general improvement of medical service of the insured, which must soon be forthcoming, implied in the extension of benefits and of institutional care and the regularised assistance of a specialist consultant service. The position, as far as it is critical, demonstrates that the beneficiaries under the Act are relying upon it with a growing confidence; we have not here a disgruntled people demanding the removal of things that irk, but an intelligent people who see that something good would become something better if the lessons of experience were followed.

TREATMENT OF URETHRAL STRICTURE.

THE subject selected by Mr. JOCELYN SWAN for his paper before the Medical Society for the Study of Venereal Diseases is of considerable interest to all engaged in general practice. Especially important is the cause of urethral strictures, and, as will be seen from the report on p. 1069, Mr. SWAN himself, and some of those who spoke after him, were of opinion that many are produced by over-drastring treatment. The urethral mucous membrane is a delicate structure and it is not surprising that some of the methods formerly in vogue—especially during, and for a few years after, the late war—resulted in its damage and subsequent fibrosis. At that time the great increase in the incidence of gonorrhoea led to desperate efforts to find more efficient methods of treatment. The fact that the gonococcus soon penetrates the lining of the urethra and gets beyond the range of local antiseptics induced experimenters to seek methods of reaching it by means of electrolysis, cauterisation, and penetrating lotions. The immediate result was undoubtedly an increase in

traumatic urethritis and a higher incidence of stricture. Fortunately, the pendulum has swung back again and most of these heroic methods have been abandoned. The fact that our chief hope of dealing with the gonococcus lies in preserving the vitality of the tissues has been recognised, and probably we shall see fewer strictures during the next decade. Moreover, the wider use of the urethroscope will undoubtedly lead to an earlier recognition of stricture formation and consequently to prompter treatment. It is the old and neglected stricture that is difficult to dilate. The more adult the fibrous deposit and the greater the submucous fibrosis, the less response follows to the passage of bougies or the use of the Kollman's dilator. If a stricture is recognised before it has materially altered the calibre of the urethra a complete cure may be possible. If it has been left until the passage has become so narrow as to produce an obvious change in the character of the stream no treatment except excision can restore the normal lumen of the tube. The moral to be drawn from Mr. SWAN's paper is, therefore, first that we must make every effort to avoid by over-drastring treatment the formation of strictures, and, second, that by the use of the urethroscope we must learn to detect them at a stage when they are amenable to treatment.

In discussing the treatment of the long-standing stricture Mr. SWAN laid emphasis on the excellent results of internal urethrotomy. The fact that in our hospitals this operation has largely displaced the older measure of external urethrotomy is in itself an indication of an improvement in the general level of treatment. There are few cases, even amongst the neglected, in which the expert fails to pass a filiform bougie, and therefore there are few instances in which a Wheelhouse operation is forced upon the surgeon. Nevertheless, by looking through the operative statistics of general hospitals, institutions are still to be found in which internal urethrotomy is seldom performed, and for this reason Mr. SWAN's insistence on the excellence of the results obtained from the Maisonneuve method is to be welcomed.

Since it is in the hands of the general practitioner that the early recognition of stricture rests, the part he plays in the improvement of its treatment is all-important. The fact that the old and desperate cases that formerly thronged the out-patient departments of our hospitals are nowadays seldom seen is proof that he is beginning to recognise his responsibility.

THE RATING OF HOSPITALS.—The town council of Blyth (Northumberland) has voted to the Knight Memorial Hospital in that town a sum equal to the difference between the old rates and those imposed by the recent reassessment. The Northumberland county council has convened a conference of representatives of the five assessment committees of the county and officials of the local hospitals together with the rating officers, to consider the whole question of hospital rating.

MANCHESTER RADIIUM INSTITUTE.—At the annual meeting of the Manchester and District Radium Institute on April 30th it was stated that the waiting-list was "appalling." If all those who were waiting took their turn, it would be three or four months before they could be admitted to the institute. Selection had therefore to be resorted to, and in many cases patients were dead before they could be admitted. There was need for more radium, more staff, and more money. The report for 1929 by the honorary radiologist, Dr. G. E. Birkett, states that the number of patients registered was 1267. Of these, 724 were found to be suitable for treatment, 618 were treated and 76 were still awaiting treatment. During the year the number of in-patients was 321. The limit of hospital patients was now ten; for private patients four. There are four additional beds at the Christie Hospital. Modern technique demands a longer stay in hospital, and the average period is probably four times as long as in 1921.

Annotations.

"No quid nimis."

PUBLIC ASSISTANCE COMMITTEES AND THE PRESS.

A DEPUTATION from the Newspaper Society, asking the Minister of Health's aid in asserting the right of the press to be present at meetings of Public Assistance Committees, has met with scant success. The Minister held out no hope of official efforts towards new legislation in the near future, and added that in any case he would have to consult the views of local authorities first. The present situation is perfectly clear. After certain local incidents had given prominence to the need of legislation, the Local Authorities (Admission of the Press to Meetings) Act of 1908 was passed "for the admission of the press to the meetings of certain local authorities." The specified authorities comprised county and county borough councils, borough councils (including those in metropolitan boroughs), urban and rural district and parish councils, boards of guardians, and any other local body having the power to make a rate. Boards of guardians, as is well known, have been abolished by the Local Government Act of last year. References in Statutes to guardians are (by virtue of the table of equivalents in the tenth schedule to the Act) to be construed as references to county and county borough councils. Both the latter bodies were already within the Act of 1908, so that representatives of the press have the right of entry to their meetings. But the new Guardians Committees, or Public Assistance Committees, are not within the 1908 Act either by virtue of specific mention therein or by virtue of succession or by virtue of being entitled to raise a rate. Thus to extend the 1908 Act to a Public Assistance Committee will require fresh legislation, and no student of the political horizon or of the congested programme of the Government will be surprised to hear that the Minister of Health deprecates further commitments at the moment. There seems little prospect of a private member being able to introduce the necessary Bill in default of official action. There remains, therefore, only the appeal by the local press to the individual committee as a matter of favour. The functions delegated to the committees are wide in scope; further delegation may make them even wider. If the local government electors are to have adequate information of what their representatives are doing, the press should have reasonable access to meetings. The committee could always—as the bodies within the 1908 Act are entitled to do—exclude the reporters by special resolution whenever such a course is deemed desirable.

FURTHER ADVANCES IN THE PATHOLOGY OF PERNICIOUS ANÆMIA.

Two communications from the Thorndike Memorial Laboratory at the Boston City Hospital, which appear on another page, show that many of the problems arising out of the liver treatment of pernicious anæmia, which was initiated in this laboratory, are being tackled with promising results. Dr. W. B. Castle and his collaborators had previously demonstrated that by an interaction of normal human fasting gastric contents and beef muscle, both of which are separately ineffective, a substance is produced which will cause an improvement in pernicious anæmia comparable to that obtained with liver feeding. They have now studied this reaction on 15 additional cases of pernicious anæmia in order to ascertain the nature of (1) the extrinsic factor of the reaction contained in beef muscle, and (2) the intrinsic factor present in normal human gastric contents.

They find that the proteins precipitated at pH 6 from beef muscle may act as the extrinsic factor. The nature of the intrinsic factor contained in the normal gastric juice remains unknown. None of the existing tests of gastric function serve to detect it; we know only that it may act in neutral solution and is destroyed by heating, and that it is not hydrochloric acid, pepsin, or rennin. It seems probable that the ingenuity of these workers will shortly devise some means of identifying this elusive factor. Meanwhile Dr. Janet M. Vaughan, and Dr. Gulli Lindh Muller, working with Dr. George R. Minot, the director of the laboratory, have made interesting use of the circumstance that the bone-marrow of the healthy grain-fed pigeon is of the same type as the bone-marrow in humans, pathologically characteristic of pernicious anæmia. The idea occurred to them that the administration to pigeons of substances capable of alleviating a deficiency in man associated with this megaloblastic hyperplasia of the marrow might provoke a response in the bird similar to that resulting in clinical cases. This response, which consists mainly of a rapid increase in the circulating reticulocytes, might then form the basis of a biological test for the potency of these substances. Intravenous injections of liver preparations known to be effective in pernicious anæmia gave a consistent response in 14 healthy birds. Two pigeons failed to react to a potent fraction, possibly because only extremely small doses were given. Negative results were obtained with extracts ineffective in pernicious anæmia and with liver extract in which the active principle has been destroyed. These results are likely to have considerable biological significance, though as yet they are not consistent enough to justify the assumption that a sure test for the potency of liver extracts has been discovered.

THE TAVISTOCK CLINIC.

A YEAR ago the clinic for functional nervous disorders at 51, Tavistock-square, London, believed that it was doing absolutely all the work that was possible in the limited space at its disposal, yet it has continued to expand, chiefly by means of working on Saturday afternoons and up to 10 o'clock at night. It received 625 new cases during the year, and had a total of 918 under treatment. There are now 14 members of the medical staff in regular attendance, and some of them contrive to engage in research as well as treatment. The periodical staff meetings to discuss the work have done much to foster a corporate spirit. In addition to the doctors, there are now two lay workers, a psychologist for mental tests and a specialist in speech defects. At present the speech therapy department, which was only opened last October, is confined to children, but it is shortly to be extended to adults. There has been a considerable increase in the number of probation cases referred to the clinic by the courts, and also of ex-Service cases sent by the various organisations that deal with old soldiers. One of the urgent needs is a better social service, for the funds will at present only allow one paid half-time social worker and, valuable as voluntary help is, it cannot but be irregular; and the time of the physicians is taken up—especially in the children's department—with many investigations which could profitably be relegated to a visitor. This department has increased its work by one-third during the year, and the children are brought earlier than they used to be; nevertheless the belief that a child will grow out of its difficulties is still the cause of much waste of valuable time. The experience of the physicians here is that the child far more often grows into them or into worse ones. A Margaret Morris class was started in April, and has proved a useful part of treatment, while other interesting therapeutic measures include fencing and groups for painting and artistic expression. The long-desired hostel was opened in September, and has room for 14 patients. It is run on communal

lines, every inmate helping in the work of the house. A weekly fee of £2 12s. includes residence and treatment at the clinic, as well as the benefit of occupational classes twice weekly. The clinic has worked during the past year in co-operation with the National Council for Mental Hygiene, as well as with other kindred organisations, and combined efforts have done much to help the financial situation. Nevertheless, there is a deficit of nearly £500 on the year's accounts, and an additional £1000 in annual subscriptions is needed to place the work on a satisfactory basis. That it is a work appreciated and needed is shown by the fact that the waiting-list has had to be closed owing to the number of applicants, and that there is at the present time an unofficial list of some 250 people waiting to be put on the waiting-list as soon as it is reopened.

FLUCTUATIONS IN VENEREAL DISEASE.

In this self-satisfied age we may think that such phrases as "genius epidemicus" are an anachronism, but it seems doubtful whether the factors governing the rise and fall of the venereal diseases can even now be given any more accurate description than "mysterious." The encouraging reports quoted in our issue of April 26th (p. 927) are somewhat discounted by the story of the behaviour of these diseases in Helsingfors and in all Finland, which Dr. N. E. Wilén contributes to the February number of *Finska Läkaresällskapets Handlingar*. The curves for syphilis, gonorrhoea, and ulcus molle during the last two decades have been on the whole parallel, he says, and thus far it is evident that they have followed some common law. But while measures directly devised for combating these diseases seem to have influenced them but little, social upheavals of various kinds apparently played a comparatively important part. The years 1900, 1912, and 1923 showed the lowest dips in the incidence of the venereal diseases grouped as a whole; they amounted to 7.2 per thousand inhabitants in the first year, to 12.2 in 1912, and to 14.6 in 1923. The highest peaks were observed in 1905, 1917, and 1927, the corresponding figures being 25.3, 27.8 and 26.7 respectively. The Russianising of the Finnish police force in the period 1900-05, and the great strike of 1905 corresponded with high rates. The regulation of prostitution was abolished on May 10th, 1907, but the marked decline in the incidence of all the venereal diseases about this time was demonstrable from 1905 to 1910—i.e., it occurred before as well as after this event. With regard to the possibility of salvarsan and allied drugs influencing the syphilis rate, it should be noted that it was not till after the late war that these drugs were extensively used in Helsingfors. In 1910, the year when salvarsan was introduced, there were 12 new cases of syphilis per 10,000 inhabitants in the capital. This figure rose considerably during the following years, attaining a peak of 64 in 1919. From this year till 1923 there was a remarkable decline, the number of new cases being reduced in the last-named year to 10. Since then, however, there has been an almost unbroken rise, the corresponding figure for 1929 being 29. Hence Dr. Wilén's conclusion that "it would therefore seem that salvarsan treatment is unable to counteract the periodic increase in the incidence of this disease to the extent hoped for." His study of the incidence of syphilis in Stockholm before and after the Swedish law (Jan. 1st, 1919) against venereal disease shows that while there were only 32 new cases of syphilis for every 10,000 inhabitants in 1918, this figure rose to 40 for 1919. It is true that the following years showed a marked decline, and in 1925 there were only five new cases in Stockholm per 10,000 inhabitants. In 1927, however, this figure jumped to 12. What is still more remarkable is that, during these post-war years, the syphilis curves of Helsingfors and Stockholm ran parallel to a striking degree, although the venereal disease legislation of Sweden was not paralleled in Finland. Dr. Wilén concludes that

his Scandinavian studies give a certain degree of support to the thesis of Buschke, Gumpert, and Langer, who in 1927 in the *Münchener medizinische Wochenschrift* expressed doubts about the modern treatment of syphilis being the chief factor in its periodic decline. These writers consider that the incidence of the venereal diseases is mainly determined by economic and social factors, and that the explanation for the fluctuations in their frequency is to be found (or hidden) in the term "genius epidemicus."

THE PSYCHOLOGY OF THE BLIND.

BEFORE the nineteenth century the blind in all countries necessarily led isolated lives, and only those specially favoured by circumstances could manage by prodigious efforts to develop their faculties. Most people still find it hard to realise that a person blind from infancy, if only he is given the opportunity to develop those other senses which are relatively unimportant to the sighted, can acquire a consciousness of the world in which he lives very little inferior to that of the sighted person. This result, however, can only be attained by appropriate training, which can be bestowed on blind pupils collected in a school, but hardly on the isolated blind child. The movement for the amelioration of the condition of the blind really started in 1784, with the establishment in Paris of the first school ever known for blind children by Valentin Haüy. The movement has continued to gain momentum up to our own day, when the State—more especially in England—has taken the blind under its special protection. Of this movement the Blind Persons Act of 1920, a measure aiming at the organisation of voluntary effort throughout the country and its supplement by monetary aid from the State, probably marks the climax. Two books recently published¹ give a clear account of the problems involved in the care and education of the blind and of the psychological aspects of their development. Mr. Ritchie, who gives his principal attention to the history of the movement for the betterment of the blind, is also concerned with their mental processes. His last three chapters provide an excellent summary of the consequences involved by the absence of the sense of sight on the mental content, behaviour, and character. Prof. Villey, who provides a psychological study of great value, complains that the blind are still victims of the ignorance of the public concerning their real position in the community. An excuse for this ignorance is that in some cases blindness is only part of a diseased condition of the body that involves mental defect, but mostly this is not so. The deprivation of a single sense, even the most important one, need not, by itself, render the blind man either intellectually or morally inferior to his sighted neighbours. In reading the history of the educational facilities offered to the blind the paramount importance of the invention of the Braille alphabet becomes obvious. Mr. Ritchie describes its struggle and final victory over competing systems, practically the only other survivor of these being the Moon system, which, being easier to learn, is more adapted to the use of those who become blind late in life. The Braille alphabet, unlike its predecessors, abandoned any pretence of making the embossed letters adapted to the sense of touch resemble the letters adapted to the sense of sight. Full advantage is taken of the extreme sensitiveness of the finger-tips, and its success is largely due to this fact. The National Library is now a varied collection, showing not only wise discrimination but a wide catholicity of choice. In the year ended in March, 1929, the number of

¹The World of the Blind. A psychological study by Pierre Villey, Professor of Literature, Caen University. Translated by Alys Hallard. London: G. Duckworth and Co., Ltd. 1930. Pp. 403. 7s. 6d.—Concerning the Blind. Being a historical sketch of organised effort on behalf of the blind of Great Britain, and some thoughts concerning the mental life of a person born blind. By J. M. Ritchie, M.A., Ph.D. London: Oliver and Boyd. 1930. Pp. 235. 7s. 6d.

Cross Organisation. On Thursday afternoon there will be a meeting of County Directors with Sir Arthur Stanley in the chair. On Friday the final plenary meeting will receive reports and adopt resolutions; to be followed by luncheon at the Mansion House and a reception at the College of Nursing. On Saturday afternoon Princess Mary will inspect detachments at Hatfield House. During the week will be thrown open to delegates such places of interest as the British Red Cross Clinic at Peto-place, the Star and Garter Home at Richmond, Surrey, the camp at Osborne, I.O.W. for women V.A.D. members, the Red Cross Hostel for International Students at 15, Manchester-square, and the Joint Red Cross Hospital Library at 48, Queen's-gardens, Lancaster Gate.

KATSUSABURO YAMAGIWA.

THE death of Prof. Yamagiwa, of Tokyo, removes a pioneer from the world of cancer research. Born in 1863, he studied medicine at Tokyo Imperial University, graduating in 1888. In 1891 he was appointed assistant professor of the University, but was given a Government grant for a period of study leave in Germany, where he stayed until 1894.

On his return he was promoted to a full professorship and assigned to the department of pathology and pathological anatomy. He held this post until his retirement in 1923, when the University made him Emeritus Professor. He was elected to the Imperial Academy in 1919, when he received the Academy prize. Yamagiwa made many important contributions to pathology, but the work which brought him world-wide fame was his demonstration in 1915 that in experimental animals

cancer could be produced by the application of coal-tar to the skin over prolonged periods. This was no chance observation, but the outcome of long years of work devoted to surmounting the difficulties of proving that chronic irritation may cause cancer. Holding that continued traumas of various kinds capable of stimulating epithelial growth would lead eventually to the development of cancer, he realised the importance of Fibiger's demonstration, published in 1913, that cancer could be produced at will in the stomach of rats by feeding the animals with a certain worm (*Gongylonema*). "Encouraged," Yamagiwa writes in the introduction, "by the glorious achievement of Fibiger"—and rarely has a scientific worker paid a more generous tribute to another—he began with Ichikawa a series of experiments in which they applied different traumas to the ear of rabbits. They succeeded eventually in producing cancer by long-continued painting with tar, and in this way inaugurated a new era in experimental cancer research. Prof. Yamagiwa founded in 1906 a journal devoted exclusively to cancer research, under the title of *Gann*. This periodical has since become the official organ of the Japanese Society of Cancer Research, whose president, Dr. Mataro Nagayo, contributes to the current issue a fine appreciation of the founder.

A COURSE IN ALLERGY.

A post-graduate course in allergic disorders will be held at the Pharmaco-therapeutic Institute at Leiden, from June 10th to 12th, when lectures and demonstrations will be given by Prof. W. Storm van Leeuwen, Prof. G. A. Rost of Freiburg i/Br., Dr. Dekker of Spa Wald, Rheinland, and J. van Niekerk, Conservator of the Institute. Lectures and demonstrations will be given in German, and will include the general conception of allergy, the significance of skin reactions, the preparation of extracts, the inspection of allergen-free installations in private houses, the relation of asthma to climate, the treatment of hay-fever and asthma in general practice, and the social significance of allergens in relation to the prevention of tuberculosis and asthma. The fee for the course is 30 marks, remitted to young assistants. Advice and information as to lodgings may be obtained from Frl. van der Waals, Pharmaco-therapeutic Institute, Leiden, Holland.

FRIDTJOF NANSEN.

In an age of memorable exploits, the expeditions of Fridtjof Nansen in the Arctic have remained outstanding. But the life just ended was twice remarkable;—for the far-sighted organiser of exploration was able to turn his gifts to the great advantage of European goodwill. His career was an unusual mixture of the scientific and the political. In 1887, just before his expedition across Greenland, he wrote a treatise on the Structure and Combination of the Histological Elements of the Central Nervous System. In 1906, after taking an active part in the separation of Norway from Sweden, he left the chair of Zoology at Christiania to serve as the first Norwegian Minister in London; and in 1919 he once again transferred his main attention from the problems of science to those of mankind. At this time the Council of Four were wondering how to deal with Soviet Russia, and Nansen proposed a scheme of famine relief which was accepted in principle but unfortunately abandoned. The League of Nations, however, entrusted him with the task of repatriating prisoners of war, and the success of this work led to his becoming High Commissioner for Refugees. As an internationalist he demanded more altruism from governments than they were capable of, but in the suspicious atmosphere of post-war Europe his labours for the settlement of refugees have had an important influence. This was appropriately recognised by the award of the Nobel Peace Prize in 1921, while his reputation in this country was reflected in his election, four years later, as Lord Rector of St. Andrew's University.

Mr. Thomas Peel Dunhill, assistant surgeon to St. Bartholomew's Hospital, has been appointed an honorary surgeon to the King in succession to the late Sir Alfred Fripp. Mr. Albert James Walton, surgeon to the London Hospital, has been appointed to take Mr. Dunhill's place as surgeon to His Majesty's household.

MATERNITY HOSPITALS.—In his report for 1929, Dr. W. H. F. Oxley, hon. visiting medical officer of the East End Maternity Hospital, Commercial-road, refers to the "serious diminution" in the number of out-patients, and explains it by the growing demand from women to have their babies in hospital. During the year 1929 patients were received into the institution or attended in their own homes.—Last year the Clapham Maternity Hospital, which is entirely under medical women, had what is stated to be the lowest mortality in England—one in 1275. There were 897 in-patients and 443 out-patients.—The annual report of the Jewish Maternity Home, in Underwood-street, Whitechapel, records the creation of a pathological laboratory for research into the causes and prevention of maternal mortality. There were 720 in-patients, and there was a considerable increase in the number of cases attended by the maternity nurses.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXXII.—THE SIGNIFICANCE OF BLOOD CHOLESTEROL.

CHOLESTEROL exists in the body in two forms, as the so-called free form and also in combination with higher fatty acids as esters. These two forms are not equally distributed; in the brain and in the red blood corpuscles there is free cholesterol only, in bile the cholesterol is largely in the free form but in all other organs, including the blood plasma, the cholesterol is present in both forms, the ester generally in somewhat greater quantity than the free form. In blood the cholesterol content of the red blood corpuscles appears to be practically constant in both health and disease. For this reason it is essential that all estimations of blood cholesterol should be done on plasma (or serum) so that changes in the cholesterol level of the plasma should not be masked by the constant mass of corpuscular cholesterol, and also so that the interpretation of blood cholesterol values should not be complicated by the presence of anaemia.

Method of Estimation.

Cholesterol and its esters are insoluble in water and are carried in the plasma in close association with the proteins, particularly with the globulin. Even when hypercholesterolemia is present the plasma is not necessarily opalescent. The method of estimation of cholesterol is of great importance. Methods which only determine the value of the total cholesterol of either plasma or whole blood are of very limited value. There are a variety of colorimetric methods of estimation in which both forms of cholesterol are determined, the main advantages of which are the ease and rapidity of performance and the small quantity of blood required. The alternative method of estimation is a gravimetric one, using digitonin. This method has a high degree of accuracy but is technically more difficult and requires 15–20 c.cm. of whole blood for each determination. Its reliability is accepted, whereas the colorimetric methods are apt to be vitiated by a variety of inaccuracies. Nevertheless, results of comparative value can be obtained, provided rigidly comparable conditions are adopted. In this article only those results will be discussed which have been verified by the digitonin method of analysis and which can be compared with the normal range of values determined by this method.

It is important to realise at the outset that in health the range of plasma cholesterol values is considerable. The following figures are the result of examination of about fifty normal individuals of both sexes. The figures represent grammes of cholesterol per 100 grammes of plasma.

Grammes of Cholesterol per 100 grammes of Plasma.

	Total cholesterol.		Free cholesterol.		Ester cholesterol.	
	Average.	Limits of variation.	Average.	Limits of variation.	Average.	Limits of variation.
M.	0.170	0.11–0.22	0.05	0.005–0.082	0.12	0.08–0.14
F.	0.153	0.08–0.23	0.054	0.02–0.091	0.10	0.054–0.14

M. = male; F. = female.

It will be seen at once how wide is the range of normal values, but in general the actual level of plasma cholesterol in a single individual is more

constant. The ratio of ester cholesterol to total cholesterol in the plasma is in the majority of cases between 60 and 70 per cent. In normal individuals unexplained variations may occur in this ratio, but though very low values of free cholesterol may be observed, such low values have not been noted as regards the ester form.

Effect of Diet.

During health the level of the plasma cholesterol may be altered by feeding. As a result of a single meal, certain changes ensue which are not of the nature of an alimentary hypercholesterolemia, as ordinarily understood, but which may consist sometimes in an increase, and sometimes a decrease, compared with fasting values and sometimes in a considerable alteration of the ester to total ratio, in either direction, apparently independent of the type of the meal. There is consequently no obvious relation between the amount of cholesterol ingested and the cholesterol level of the plasma during digestion, and the changes which occur in the plasma are considered as evidence of an active endogenous metabolism in which cholesterol takes a part. It follows that in studying the variations of plasma cholesterol in health it is necessary to take the blood with the patient in the fasting condition, as for example before breakfast. The level of the cholesterol content of the plasma, taken while fasting, can be raised or lowered by sufficiently prolonged feeding with diets of high or low cholesterol content. Such changes are most marked as regards the cholesterol in ester form; the free cholesterol remains practically constant.

Pregnancy.

Apart from the changes just mentioned, the only physiological condition in which the plasma cholesterol level is altered is in pregnancy. In this condition, from about the twentieth week, the free cholesterol increases to a maximum which it reaches about the thirtieth week and concurrently the ester cholesterol falls to a minimum. From this time the amount of free cholesterol decreases and the ester increases till an almost normal ratio of free and ester cholesterol is attained before or near parturition. The plasma cholesterol values generally become quite normal in the first or second week of the puerperium. A few cases only show such an increase of total cholesterol as may be considered hypercholesterolemia, but the free cholesterol alone sometimes reaches a maximum of about 0.25 per cent. These changes form a very characteristic picture but so far they have not been explained.

Cholesterol Level in Certain Pathological Conditions.

At various times hyper- or hypocholesterolemia has been stated to occur in a large variety of disease states, but in many cases the changes noted have been within the limits of normal variations. Hypocholesterolemia does occur, at the height of the fever only, in a variety of febrile and infective conditions, but the clinical significance of this is not understood. In this connexion it might be noted here that the degree of hypocholesterolemia found in cases of enlarged prostate with infection of the urinary tract has been suggested as a test of the operative risk of such cases, but the value of this has not been confirmed. True hypercholesterolemia occurs in certain types of nephritis, hypothyroidism, biliary stasis, and diabetes.

Nephritis.—Hypercholesterolemia is a frequent occurrence in nephritis and is present in all those cases which possess the "nephrotic" syndrome, marked by diffuse parenchymatous degeneration, heavy albuminuria, changes in the plasma proteins, and where oedema is the chief symptom. Consequently, increases of plasma cholesterol are found in those cases of acute nephritis of prolonged duration, where albuminuria is persistent and haematuria absent, and in all that group of chronic nephritis which includes, at one end of the scale, the so-called

pure "nephrosis" and, at the other end, cases of parenchymatous nephritis in which the initial "nephrosis" is more or less rapidly followed by sclerosis and contraction of the kidney. The hypercholesterolemia may reach as much as 1.0 per cent. of total cholesterol in the plasma, and the ester to total ratio may assume abnormal values in either direction. The cholesterol increase is present throughout the course of these cases of nephritis so long as there is any tendency to oedema and it persists in cases of subacute parenchymatous nephritis for long periods even though, as frequently occurs, oedema is temporarily absent. In these cases recovery is rare and after a period of months or years, if infective conditions have not led to a fatal result, the tendency to oedema is replaced by the tendency to vascular changes, increase of blood pressure, and signs of nitrogen retention, and at about the same time the hypercholesterolemia diminishes. To use, for simplicity, an old terminology, when a large white kidney contracts to a small white kidney the plasma cholesterol becomes normal, but in these cases there may be some overlapping of the characteristics of the two stages and hypercholesterolemia may still be present when the vascular changes and threatening uræmia herald the termination of the disease. Estimation of plasma cholesterol aids diagnosis in those cases of contracted kidney where no history can be obtained of the previously occurring stages, for if hypercholesterolemia is found the renal lesion must be a sclerosis secondary to a diffuse nephritis, which was not recognised because the sum of the factors which usually produces the oedema in these cases had not reached a sufficient value. Hypercholesterolemia is not found in cases of interstitial nephritis or in arterio-sclerotic kidney, or in arterio-sclerosis. The presence of hypercholesterolemia generally signifies a grave prognosis. The cause of the hypercholesterolemia is not known, but is possibly related to the disturbance of the plasma proteins which results from the proteinuria. The kidney does excrete traces of cholesterol in the urine, but even in "nephrosis," where the excretion is much increased, the amount does not exceed 40 to 50 mg. per day.

Myxœdema.—The total cholesterol of the plasma in this condition may be increased by nearly 50 per cent. over normal values, and after administration of thyroid gland the values generally become normal. Epstein and Lande thought that blood cholesterol was inversely proportional to the basal metabolic rate and they found an analogy between myxœdema and pure "nephrosis," where the basal metabolic rate is also below normal; this argument was then used to explain the occasional beneficial results of thyroid medication in "nephrosis." However, this relationship of basal metabolic rate and blood cholesterol does not exist in states of hyperthyroidism where, as in exophthalmic goitre, the blood cholesterol is within normal limits.

Biliary Stasis.—Hypercholesterolemia has been stated to occur in cholelithiasis and in affections of the liver, but there can be little doubt that in all the earlier investigations the hypercholesterolemia noted was due to the biliary stasis and not to the pathological condition which preceded this. Hypercholesterolemia is not a feature of uncomplicated cholelithiasis. When, however, biliary stasis occurs, as for examples from impaction of a stone in the common bile-duct or from catarrhal jaundice, the blood picture shows interesting changes. In the early stages the cholesterol ester rapidly diminishes and may almost disappear from the blood plasma, while the free cholesterol may remain normal or show slight increase. This characteristic change in the plasma cholesterol can also be observed in those cases of cholecystostomy where none of the bile is reaching the intestine. This change consequently must be due to the disturbance of fat and cholesterol absorption from the intestine which results from the absence of the bile. If complete biliary obstruction persists for many weeks then the plasma cholesterol

steadily increases as regards both forms till marked hypercholesterolemia occurs, but the ester to total ratio remains low, averaging 30 to 40 per cent. If the biliary obstruction is not quite complete or is intermittent the hypercholesterolemia does not appear. It is usually considered that the increase of plasma cholesterol is due to the retention of biliary cholesterol, but this explanation is by no means satisfactory. To explain this hypercholesterolemia no hypothesis would be acceptable which ignored the very close chemical relationship of the bile acids and cholesterol.

Diabetes.—True hypercholesterolemia occasionally occurs in severe cases of diabetes. It is stated that plasma cholesterol determinations are of value in diabetes as an index of prognosis, and that if the hypercholesterolemia persists despite insulin treatment the prognosis tends to be more serious in the sense that treatment is more difficult. The increase of plasma cholesterol in diabetes mellitus is possibly due to the disturbance of fat metabolism and transport. Hypercholesterolemia in diabetes (and also in biliary obstruction) may lead to deposition of cholesterol in the skin as xanthoma.

NATIONAL HEALTH INSURANCE IN SCOTLAND.

THE serious effect of the present industrial depression in health insurance finance is the subject of comment in the first annual report just issued (Cmd. 3529) of the Scottish Department of Health. In 1929 the numbers insured under the Unemployment Insurance Acts had only increased by 0.16 per cent. over those in 1927, contrasting with an increase of 4.76 per cent. in the Midlands and North of England. Reduction in the iron and steel, and coal-mining industries was mainly due to migration, but lack of new entrants was an increasing factor. Juvenile unemployment was rife. Of the 1,837,000 members of approved societies in Scotland, 43 per cent. were insured in industrial assurance companies, 48 per cent. in friendly societies, and only 7.4 per cent. in trade-union societies. The total membership of the new insurance section among deposit contributors was only 341.

The work of departmental inspectors continues to increase. Establishments visited numbered 25,644, and arrears collected amounted to £11,951 for health insurance and £12,836 for unemployment insurance. A feature of contribution irregularity in recent years has been the prevalence of illegal use of stamps. Prosecutions for this class of offence resulted in 25 convictions, with fines amounting in all to £158, and one term of six months' imprisonment. The judicial decision of questions of employment under the Act has often proved difficult. Of 70 cases submitted during the year, no fewer than 37 were pension cases in relation to past employment. Many cases turned on the question of an existing contract of service. Sixty-four disputes between societies and their members were referred to the Department: 22 were decided in favour of the member, 21 in favour of the society, and ten were withdrawn.

About 2000 practitioners and 1400 chemists are under contract with insurance committees. During the year there were 21 complaints against practitioners but no question arose of the removal of a doctor or chemist from the panel lists. The Department had to deal with seven appeals only against decisions of insurance committees in complaints against doctors and chemists. The complaints against chemists arose out of the operation of the drug-testing schemes.

During 1929, 598 samples were tested, 49 were reported to committees, and a censure or fine was imposed in 16 cases. Surcharges amounting to £209 were made against practitioners for excessive prescribing.

The cost of insurance committees' was £50,008; medical benefit cost £792,000; the mileage fund was £42,500, and special grants to necessitous areas and for post-graduate work amounted to £3110. A great effort is being made in Scotland to bring the regional medical officers of the Department into closer relationship with the practitioners. Both for purposes of second opinion and help in diagnosis, and for advice on questions of certification, these consultations are being encouraged. The state of the Drug Fund, which is estimated as amounting to 23-8d. per insured person, has shown the need for constant supervision of prescribing. Insulin was supplied to 1115 persons, and its cost amounts to about 4 per cent. of the Drug Fund.

The new Local Government Act is expected to increase the hospital provision for insured persons. The figures given for expenditure in benefits show that the combined cost of sickness and disablement benefits has risen in all classes. The increase in expenditure in 1929, with that in 1928, amounting to £200,000, is entirely due to an increase in sickness benefit. The influenza epidemic in the early months of 1929 accounts for some of this, but a considerable proportion of the increase remains unexplained. The questions of medical certification and claims supervision have been considered, and various suggestions are made for stricter supervision and control. During the year 44,941 persons were referred to the regional medical staff, an increase of 6021 cases over 1928. A scheme has been set up in certain areas whereby the advice of the regional staff may be sought by practitioners in the cases of certification difficulties. In the cases referred the practitioner's opinion was upheld in 37 and reversed in 18 per cent.

Additional benefits have been provided by certain societies, but the value and extent of these benefits have been curtailed by lack of funds. For hospital treatment the Department decided that the societies could make a contribution towards the cost incurred by the member, and regulations have been issued fixing the maximum contribution for 1930 at 2d. per member. The third valuation of the funds of approved societies operating in Scotland showed results generally satisfactory but not uniformly so. The financial position of certain societies had deteriorated seriously during the valuation period. The continued rise in expenditure makes the future outlook both uncertain and anxious.

On the whole the report reveals the same tendencies as are shown in the Government Actuary's report in England, but industrial depression appears to have been a larger factor in Scotland. Elimination of undue claims is regarded as vitally important in the interests of the general body of insured persons.

SCHOOL MEDICAL SERVICE.

	No. on roll.	Average attendance.	Routine inspection.	Special re-inspection.	Per cent. of defects.
County of Brecon..	9076	8128.5	3037	1400	14.8
Colchester..	5757	88.5	1778	3115	20.9
Eccles ..	—	—	2127	3725	24.59

County of Brecon.

Dr. Herbert Davies agrees with Sir George Newman that the purpose of preventive medicine "is indeed to strengthen and protect the weak, but also to make the strong stronger." To this end parent and teacher must join in co-operation with doctor and nurse. Dr. Davies reviews the hygienic conditions of schools in the county, important for their direct influence on the health of the

children and the efficiency of instruction, still more as a means of training young minds to appreciate the value of sunlight, fresh air, and cleanliness. He classifies the schools as: (a) single roomed; (b) grouped rooms intercommunicating; (c) central hall with rooms grouped around; (d) corridor type. Lighting is a vital matter; the importance, he says, of securing sunlight in classrooms cannot be overestimated. In this respect a number of schools are deficient, especially in type C which results in school-rooms being placed with wrong aspects. The problem of heating is closely associated with that of ventilation; unless the heating surface is of ample capacity a sufficiently frequent change of air, he remarks, cannot be undertaken. Arrangements are being made for the drying of children's clothes, a real need in scattered rural areas. Ventilation is often unsatisfactory. In the A type much of the air comes through the cloak-rooms which serve as lobbies, passing over masses of damp clothing. In types B and C the vitiated air tends to move from room to room instead of being cleared right away. The practice of flushing rooms with fresh air during recreation is fortunately becoming more universal in the county. Dr. Davies remarks on the difficulty of keeping rooms clean is increased by their being filled with heavy furniture; great improvement has followed the replacement of heavy desks by folding chairs and tables, and he recommends the provision of store rooms so that all furniture not in use at the moment can be removed. Dirt and mud from the playgrounds soon clog the mats so as to be useless; at least a pathway in the playgrounds should be paved and foot scrapers provided at the entrance. Dr. Winifred Probert assists him in the general work and treats visual defects.

Colchester.

Dr. W. F. Corfield mentions Circular No. 1054 of the Ministry of Health, unusual in bearing also the signature of the Board of Education, which dealt with the pre-school child, indicating the gap between the activities of the infant welfare schemes and those of the school medical service. The orthopaedic clinic in the borough has brought to light a number of cases of slight rickets in these children, and the health nurse is being encouraged to follow up children of from 2 to 4 years of age. With a second nurse whose appointment is in prospect, it should be possible for every child to be regularly visited at least every three months until 5 years of age, or until it attends school. But much further help would be given by the establishment of nursery schools or crèches; distance from home and danger of infection are objections which do not apply to such poor and densely populated districts. The liability to infection is no greater than in the streets and if an epidemic appears the centre can be closed for a while; the advantages are that the children can be taught order and cleanliness, their lives are made brighter, and defects are far more easily detected. Special arrangements are now made for orthopaedic treatment of these children; there were as many pre-school children as scholars at this clinic. Similar arrangements are made for their dental care. Co-ordination is so close that the health visitors, who are also school nurses, in one house may have an infant and a school child to deal with, in another a child of 4 who attends school, and in a third a child of the same age who is still attending the infant welfare centre of the health authority. When pre-school children are taken under the official wing will it be as school-children or as infants? Dr. Corfield's view is that the time is ripe for a full reconsideration of the care of children from birth (or before) to 15 years of age, and he thinks that one responsible authority would make for unity and simplicity. In dental work, a step forward is the appointment of a full-time dentist, who devotes one session a week to infant welfare work; he is to be assisted by an extra nurse. Co-operation of the parents is good, their attendances reaching 80 per cent.; Dr. Corfield thinks they appreciate what is done and would not subscribe to the loose statement sometimes made that "anyone can do school medical

pure "nephrosis" and, at the other end, cases of parenchymatous nephritis in which the initial "nephrosis" is more or less rapidly followed by sclerosis and contraction of the kidney. The hypercholesterolemia may reach as much as 1.0 per cent. of total cholesterol in the plasma, and the ester to total ratio may assume abnormal values in either direction. The cholesterol increase is present throughout the course of these cases of nephritis so long as there is any tendency to oedema and it persists in cases of subacute parenchymatous nephritis for long periods even though, as frequently occurs, oedema is temporarily absent. In these cases recovery is rare and after a period of months or years, if infective conditions have not led to a fatal result, the tendency to oedema is replaced by the tendency to vascular changes, increase of blood pressure, and signs of nitrogen retention, and at about the same time the hypercholesterolemia diminishes. To use, for simplicity, an old terminology, when a large white kidney contracts to a small white kidney the plasma cholesterol becomes normal, but in these cases there may be some overlapping of the characteristics of the two stages and hypercholesterolemia may still be present when the vascular changes and threatening uræmia herald the termination of the disease. Estimation of plasma cholesterol aids diagnosis in those cases of contracted kidney where no history can be obtained of the previously occurring stages, for if hypercholesterolemia is found the renal lesion must be a sclerosis secondary to a diffuse nephritis, which was not recognised because the sum of the factors which usually produces the oedema in these cases had not reached a sufficient value. Hypercholesterolemia is not found in cases of interstitial nephritis or in arterio-sclerotic kidney, or in arterio-sclerosis. The presence of hypercholesterolemia generally signifies a grave prognosis. The cause of the hypercholesterolemia is not known, but is possibly related to the disturbance of the plasma proteins which results from the proteinuria. The kidney does excrete traces of cholesterol in the urine, but even in "nephrosis," where the excretion is much increased, the amount does not exceed 40 to 50 mg. per day.

Myxœdema.—The total cholesterol of the plasma in this condition may be increased by nearly 50 per cent. over normal values, and after administration of thyroid gland the values generally become normal. Epstein and Lande thought that blood cholesterol was inversely proportional to the basal metabolic rate and they found an analogy between myxœdema and pure "nephrosis," where the basal metabolic rate is also below normal; this argument was then used to explain the occasional beneficial results of thyroid medication in "nephrosis." However, this relationship of basal metabolic rate and blood cholesterol does not exist in states of hyperthyroidism where, as in exophthalmic goitre, the blood cholesterol is within normal limits.

Biliary Stasis.—Hypercholesterolemia has been stated to occur in cholelithiasis and in affections of the liver, but there can be little doubt that in all the earlier investigations the hypercholesterolemia noted was due to the biliary stasis and not to the pathological condition which preceded this. Hypercholesterolemia is not a feature of uncomplicated cholelithiasis. When, however, biliary stasis occurs, as for examples from impaction of a stone in the common bile-duct or from catarrhal jaundice, the blood picture shows interesting changes. In the early stages the cholesterol ester rapidly diminishes and may almost disappear from the blood plasma, while the free cholesterol may remain normal or show slight increase. This characteristic change in the plasma cholesterol can also be observed in those cases of cholecystostomy where none of the bile is reaching the intestine. This change consequently must be due to the disturbance of fat and cholesterol absorption from the intestine which results from the absence of the bile. If complete biliary obstruction persists for many weeks then the plasma cholesterol

steadily increases as regards both forms till marked hypercholesterolemia occurs, but the ester to total ratio remains low, averaging 30 to 40 per cent. If the biliary obstruction is not quite complete or is intermittent the hypercholesterolemia does not appear. It is usually considered that the increase of plasma cholesterol is due to the retention of biliary cholesterol, but this explanation is by no means satisfactory. To explain this hypercholesterolemia no hypothesis would be acceptable which ignored the very close chemical relationship of the bile acids and cholesterol.

Diabetes.—True hypercholesterolemia occasionally occurs in severe cases of diabetes. It is stated that plasma cholesterol determinations are of value in diabetes as an index of prognosis, and that if the hypercholesterolemia persists despite insulin treatment the prognosis tends to be more serious in the sense that treatment is more difficult. The increase of plasma cholesterol in diabetes mellitus is possibly due to the disturbance of fat metabolism and transport. Hypercholesterolemia in diabetes (and also in biliary obstruction) may lead to deposition of cholesterol in the skin as xanthoma.

NATIONAL HEALTH INSURANCE IN SCOTLAND.

THE serious effect of the present industrial depression in health insurance finance is the subject of comment in the first annual report just issued (Cmd. 3529) of the Scottish Department of Health. In 1929 the numbers insured under the Unemployment Insurance Acts had only increased by 0.16 per cent. over those in 1927, contrasting with an increase of 4.76 per cent. in the Midlands and North of England. Reduction in the iron and steel, and coal-mining industries was mainly due to migration, but lack of new entrants was an increasing factor. Juvenile unemployment was rife. Of the 1,837,000 members of approved societies in Scotland, 43 per cent. were insured in industrial assurance companies, 48 per cent. in friendly societies, and only 7.4 per cent. in trade-union societies. The total membership of the new insurance section among deposit contributors was only 341.

The work of departmental inspectors continues to increase. Establishments visited numbered 25,044, and arrears collected amounted to £11,951 for health insurance and £12,836 for unemployment insurance. A feature of contribution irregularity in recent years has been the prevalence of illegal use of stamps. Prosecutions for this class of offence resulted in 25 convictions, with fines amounting in all to £158, and one term of six months' imprisonment. The judicial decision of questions of employment under the Act has often proved difficult. Of 70 cases submitted during the year, no fewer than 37 were pension cases in relation to past employment. Many cases turned on the question of an existing contract of service. Sixty-four disputes between societies and their members were referred to the Department: 22 were decided in favour of the member, 21 in favour of the society, and ten were withdrawn.

About 2000 practitioners and 1400 chemists are under contract with insurance committees. During the year there were 21 complaints against practitioners but no question arose of the removal of a doctor or chemist from the panel lists. The Department had to deal with seven appeals only against decisions of insurance committees in complaints against doctors and chemists. The complaints against chemists arose out of the operation of the drug-testing schemes.

rash on face, back, and forearms, which was diagnosed as toxic erythema at Marseilles on the 27th, where he was landed and died in hospital, the diagnosis then being changed to hæmorrhagic small-pox. The 450 passengers who landed at Marseilles were notified to the medical officers of health to whose districts they were travelling, and the ship was informed, when the crew and passengers, 900 in all, were vaccinated. On March 18th a greaser had reported sick, and on the 20th developed a rash on the face and elsewhere; this was diagnosed as chicken-pox on the 22nd with the concurrence of the quarantine medical officer at Suez; nothing is said about him at Marseilles, but at Liverpool on April 1st he was removed from the ship with small-pox. The ship reached Glasgow on April 14th, 15 days from the appearance of the first rash, when further cases of small-pox were discovered. Of the total 53 cases reported, two were these early cases, 45 were contracted on board, and there were six later infections. Twelve cases were fatal. Another ship, the *Appam*, had a case of small-pox at Calabar, which was recognised at once, landed, and properly controlled, with the result that there were no other cases. Much attention was given at Liverpool to the destruction of rats on ships as well as in the port and city. In 1929, 22,309 rats were caught or killed on ships (20,189 in 1928), 1405 about the port (2250), in the city 10,398 (16,004), in all 40,172 (48,103); the figures suggest that the anti-rat campaign is achieving something. To kill cockroaches, it seems, requires a higher concentration of hydrocyanic acid than to kill rats. Estimating the number of rats on a ship by inspection is a skilled employment, requiring training and constant practice, but it can be done pretty accurately; in a group of ships in which over 500 rats were expected, 000 were found. Seamen account for half the new cases of venereal disease in Liverpool, and half the total attendances at clinics; at the Seamen's Dispensary there are in proportion more cases of soft chancre and fewer of syphilis than in the city. Electrical treatment (not particularised) has shortened the period of gonorrhœal cases. Lectures on venereal diseases have been well attended and appreciated. Of anthrax, nine cases were notified, with three deaths; two cases were connected with South American hides, three with East Indian wool, and four from tanneries at Runcorn. Cases are to be sent direct to Fazakerley hospital for early serum treatment. Disinfection of the raw material is carried out at the Government Wool Disinfecting Station; a model of the plant in use there may be seen at the Home Office Industrial Museum in Horseferry-road, London. Many shipping companies now fumigate crew's quarters after every voyage to get rid of vermin. Less unsound meat is being received at Liverpool; 1804 (1907 in 1928) tons were "utilised under supervision," including 127 tons of mutton, largely condemned on account of epizootic lymphangitis. Inspection is being improved in the countries of origin. Meat from Waterford and Cork has also had to be seized, but a certain amount of inspection is now carried out by the Irish authorities. More care has been given this year by countries abroad to packing of fruit.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 3RD, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 300 (last week 353), scarlet fever 1829, diphtheria 1198, enteric fever 87, pneumonia 1054, puerperal fever 45, puerperal pyrexia 112, cerebro-spinal fever 10, acute poliomyelitis 5, acute poliomyelitis 1, encephalitis lethargica 18, continued fever 1, dysentery 3, ophthalmia neonatorum 136. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on May 6th-7th was as follows: Small-pox, 548 under treatment, 33 under

observation (last week 483 and 31 respectively); scarlet fever, 2030; diphtheria, 2541; enteric fever, 33; measles, 1025; whooping-cough, 64; puerperal fever, 28 (plus 10 babies); encephalitis lethargica, 119; poliomyelitis, 1; "other diseases," 19. At St. Margaret's Hospital there were 18 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (0) from enteric fever, 112 (53) from measles, 7 (0) from scarlet fever, 28 (2) from whooping-cough, 42 (13) from diphtheria, 50 (8) from diarrhoea and enteritis under two years, and 40 (5) from influenza. The figures in parentheses are those for London itself.

The three deaths from enteric fever outside London were reported from Southport, Burnley, and Sunderland. Fatal cases of measles were widely distributed with larger numbers at Liverpool and Salford each 6, Middlesbrough 4. Three deaths from whooping-cough were reported from each of Birmingham, Liverpool, Bradford, and Middlesbrough. Rhondda reported 4 fatal cases of diphtheria, Liverpool 3. Diarrhoea was credited with 8 deaths at Liverpool, 4 at Manchester. No great town attributed more than 2 deaths to influenza.

The number of stillbirths notified during the week was 321 (corresponding to a rate of 40 per 1000 births), including 70 in London.

MEDICINE AND THE LAW.

Hospitals and Rates: the Basis of Assessment.

WHAT may prove an important test case on the rating of hospitals was heard on May 6th before the County Assessment Appeal Committee of Hertfordshire. The local rating authority, the Barnet Urban District Council, appealed against the Barnet and District Assessment Committee and the Barnet Victoria Cottage Hospital on the point whether the hospital should be assessed at £80 a year (the figure recently fixed by the local assessment committee) or at the former figure of £250. A brief report in the *Times* indicates that the appellants contended that the value of the hospital was £14,000 and that, if a new hospital had to be built to take its place, the cost would be £20,000. The assessment, it was stated, had been £250 for the past five years, but, recently, all the Hertfordshire hospitals had been assessed on a basis of between 30s. and £2 per bed; the Barnet Hospital having 40 beds, the assessment had thus been reduced to £80. The chairman of the tribunal announced that the Appeal Committee did not accept the view that hospitals should be assessed on the basis of so much per bed; the proper basis was the rent which a hypothetical tenant would pay for the property. The figure, said the chairman, must necessarily be low in the case of a hospital; though not accepting the basis of assessment, the Appeal Committee accepted the figure of £80 as reasonable and proper. The appeal was therefore dismissed, the hospital being allowed costs but the other respondents (the Barnet and District Assessment Committee) being directed to pay their own costs. The unsuccessful appellants asked the tribunal to state a case for the High Court.

It is interesting to observe that the basis of assessment by the number of beds was rejected. This basis has furnished a convenient method for calculating hospital expenses and for classifying the size of an institution. A low assessment is of vital importance for hospitals, and, as Parliament declined to exempt them from the burden of rates, it has been essential for them to succeed in avoiding heavy assessments at the hands of the local assessment committees. What the case fails to reveal is the reasons which have prompted the local rating authority to undertake the ungenerous task of attacking the cottage

hospital and to seek to overthrow the arrangement reached throughout the county for hospital assessment.

Guaranteed Cures and Fraud.

Two men, described as manipulative masseurs, were recently found guilty at Nottingham Quarter Sessions of obtaining money by false pretences and of conspiracy to defraud. They were said to have undertaken to cure, by means of massage and by the use of an oil which they sold, cases pronounced incurable by doctors. The accused protested that they had not guaranteed cures. The Recorder, in passing sentence, said it was difficult to see any extenuating circumstance; they had been found guilty of heartless and cruel conduct. The elder of the two men was sentenced to 12 months hard labour in respect of the false pretences and 15 months in respect of the conspiracy, the sentences to run concurrently; the younger was sentenced to 9 and 12 months imprisonment in the same way. They were also ordered to pay £250 towards the cost of the prosecution.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Proprietary Preparations in Prescriptions.

OWING to competition between manufacturing chemists the number of proprietary preparations has greatly increased. This increase is detrimental to the pharmacists, because in recent years their profit on the sale of such preparations is considerably less than that accruing from making up prescriptions. The Hungarian Pharmaceutical Law allows for a good fee for preparing mixtures according to prescriptions, but allows only 30 per cent. profit on the sale of proprietary drugs. The widespread use of these, moreover, does not do the doctors much good, since patients are apt to try to treat themselves. It is not uncommon, in the present depressed financial state of the people here, for patients suffering from grave heart trouble to omit to call in a doctor because they have been advised by friends to buy a bottle of some preparation which was prescribed for a relative suffering from heart disease. The fact that large advertisements appear in the daily papers detailing the indications for the administration of this or that patent remedy is an additional reason why these are to be found in almost every household. The National Pharmaceutical Association has now circularised every doctor, pointing out the harm that proprietary medicines can do when they get into the hands of laymen. The pharmacists, it is said, have been brought to the verge of bankruptcy, and are forced to take collective action. They have no quarrel with sound preparations which are the products of scientific research, but deprecate the use in prescriptions of drugs which are merely mixtures which could equally well be prescribed separately. They request the medical profession to abstain, in the future, from prescribing proprietary drugs when they can get the same mixture made up by the pharmacist. When it is necessary to prescribe special preparations the wrappers and the enclosed literature should be removed, so that the patient will not be led to believe that the medicine is a sure remedy of all the diseases which are enumerated, and will seek advice from the proper quarters.

A Clinic for Civil Servants.

Some weeks ago Mr. A. Wekerle, Minister of Finance announced in the Houses of Parliament his intention to establish a sanatorium in the vicinity of the University Clinics for civil servants. He wishes to solve the problem of medical attendance for these officials by enlisting the service, gratuitous, or at nominal salaries, of the doctors of the neighbouring clinics. This scheme naturally provoked indignation among doctors, and the president of a Budapest

medical corporation, Dr. Rosenak, voiced their protest. The medical profession, he said, is well aware of the financial position of civil servants, and their claim to reduced medical fees has always been met. Not only do doctors attend them for minimal fees, but in cases necessitating exact investigations also the public hospitals are at their disposal. The Budapest Medical Corporation has resolved to apply to the Hungarian Medical Association to do everything in its power to prevent the erection of the proposed clinic.

Protective Immunisations against Diphtheria.

A well-elaborated report on prophylaxis against diphtheria was recently contributed by B. Johan and J. Tomcsik to the Medical Society. They said that the rate of morbidity in Hungary was fairly high. Although the statistical data available were not quite reliable, still some conclusions might be drawn from them. One of the tasks of public health authorities was to cope with carriers. A very extensive search for carriers had been made in Szolnok county, but their isolation did not appear to have had much influence on the rate of morbidity in 1928. That schools are of very great importance in the spread of epidemics is best shown by the fact that during epidemics a diminution in incidence tends to follow the closing of schools. Among the substances recommended for use in active immunisation against diphtheria, the T.A.F. preparation of the German Behringwerke, and the protective ointment of Loewenstein, of Vienna, have been tried in Hungary, but the Ramon anatoxin has been more widely used than either. Most of the anatoxin immunisations have been made with the inoculation material prepared in the National Public Health Institution, where, with a slightly altered technique, some highly efficient immunising serum has been produced. Up to the end of 1929 more than 20,000 children had been inoculated, and in January of this year a further 25,000 children were immunised. No severe reactions, lasting over one week, were encountered. In children ranging in age from one to five no inoculation reaction was observed, and fever was rare. In older children moderate fever, lasting for two or three days, occurred, and in adolescents high fever, but no disquieting symptoms made their appearance. After the second inoculation more local and general reaction occurred than after the first one, while the third inoculation was followed by less reaction. The immunising value of the inoculating material was controlled in a few cases by the Schick reaction. The results of protective immunisation are estimated from the morbidity-rate. About ten months ago in Szolnok county 10,181 children were given protective immunisation. Out of these, up to now, only four have been attacked, with very mild infections. Among a corresponding group of non-immunised children during the same period 248 fell ill with diphtheria. Although the immunisations were made at the season when the incidence of diphtheria is at its height, the number of cases occurring after the first immunisation did not confirm the belief that the first inoculation may produce a rise of susceptibility of short duration (negative phase).

Artificial Abortion on Sociological Grounds.

Owing to the critical economic conditions prevailing in Hungary, the number of artificial abortions is on the increase. The Government has found it desirable to take up the matter, and the medical profession has been warned to interfere only in the most urgent cases. Lectures designed to enlighten the public on the dangers of procuring abortion are being held. Dr. Lajos Göczy, lecturer to the University of Budapest, has raised the question whether any social indications for abortion exist. From the individual point of view, he argues, an obvious indication is the danger of aggravating previously existing diseases by pregnancy or by labour at full term. Even here, however, economic considerations

cannot be ignored, since, for example, patients suffering from tuberculosis or heart disease may not be able to afford prolonged sanatorium treatment or that extra care which will spare effort during childbirth. In such cases the interruption of gestation is recommended after consideration not only of the disease but also of the social conditions of the patient. Certain authorities go still further, and are prepared to admit the principle that abortion may be induced for such reasons as the decreased earning power of the pregnant women, or the fact that the critical financial state of the family does not justify the expense of bringing up and educating more children. According to this school, so long as the State is not in a position to prevent the social evils brought about by large families among the poor, the only escape from the dilemma is artificial abortion performed on social grounds.

Dr. Göczy pointed out, however, that it is not the doctor's business to ascertain the economic position of his patients and that he might be misled by false statements or gross exaggerations, and thus connive at unnecessary abortions. Moreover, even if the investigation were to be done by some competent authority deputed by the State, the performance of artificial abortion for sociological reasons would still be outside the province of a doctor, whose task is to protect pregnancy and not to interrupt healthy gestation. If he allowed himself to be placed in a position of producing abortion on demand, the authority, not only of the individual doctor, but that of the whole medical profession, would be undermined. On these grounds Dr. Göczy would deplore the acceptance of any indications for abortion other than medical ones.

Mushroom Poisoning.

The Mushroom Section of the Royal Hungarian Plant Life and Pathological Station has issued a questionnaire to all doctors practising in Hungary, asking for information, from records or from memory, of any cases of mushroom poisoning which they have come across during the last ten years. The most important data required are the names of the patients and the kind of mushroom with which they were poisoned; also the way in which the mushrooms were prepared for consumption. In Hungary there are some species of fungi which, stewed in an enamelled iron pan, are very poisonous, while if they are cooked in the form of soup they are much less harmful, causing only slight indigestion and nausea.

A Congress on Diseases of Digestion.

The German Society for Diseases of Digestion and Metabolism will hold its tenth meeting at the Medical Clinic of the Budapest University, under the presidency of Baron Alexander Korányi, from Oct. 6th-8th. The chief subjects for discussion are as follows: Changes in Form and Posture of the Digestive Organs, with Special Reference to Ptoisis and Diverticula (Prof. Vogt of Munich, Prof. Bergmann and Prof. H. H. Berg, of Berlin, and Prof. Verebelyi, of Budapest); The Organisation of the Dietetic Kitchens of the Budapest Clinics (Dr. Soós, of Budapest); Diseases of Bones in their Relation to Calcium Metabolism, Internal Secretion, and the Vitamins (Dr. Fürth, of Vienna, Dr. Pick, of Berlin, Dr. Alvens, of Frankfurt, and Dr. Wieland, of Basle); The Etiological Problems of Inflammatory Diseases of the Digestive Organs (Dr. Kuttner, Dr. Löwenberg, and Dr. Kaufmann of Berlin, and Dr. Löhr of Kiel). In connexion with the meeting there, an exhibition of pharmaceutical preparations will be held.

A MILLION FROM A CONTRIBUTORY SCHEME.—At the annual meeting of Sheffield Royal Infirmary recently it was stated that by the end of the present year the Sheffield hospitals would have received a million sterling from the penny-in-the-pound scheme since its creation. The average cost per bed has been reduced from £134 to £125. Last year there were 5000 in-patients, 38,242 out-patients, an increase of about 5500, and 23,286 casualties.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Social Hygiene in New York.

THE New York State Department of Health founded its division of Social Hygiene in 1918. During that year lectures were delivered to audiences aggregating 2200. Since then the yearly attendance has varied between 50,000 and 125,000 persons. By the middle of January of the present year the total attendance for 12 years had passed the million mark, rather more than half of the audiences being men. As many educators and civic leaders have been included in these audiences it is believed that the essential instruction must have penetrated to all people in the State. An important research is to be published shortly as Reprint No. 1365 of the Public Health Reports. It comprises the results of a joint undertaking by the American Social Hygiene Association, the New York Tuberculosis and Health Association, the Welfare Council of New York City, and the U.S. Public Health Service. The report is the result indirectly of international conferences on health and welfare of seamen and is entitled "Seamen with Venereal Disease in the Port of New York." Of the 961 men studied 840, or 87 per cent., were single and of the remainder only 67 were living with their wives, while 30 were divorced and 23 widowers. In religion, 440 were Protestants, 386 Roman Catholics, 46 had no religion, and only 18 were Jews. The proportionate representation of the religions among seamen generally is not stated. The effects of penalties and of charging for treatment are shown to be a reduction in the number of cases applying for medical care. The provisions for treatment and the results of treatment are described at length with numerous interesting tables. The men admitted freely that the first thought on entering port is "drinks and then girls." It is significant that in 676 cases out of the 961 the first infection is attributed to a commercial prostitute. Ignorance of these diseases is astonishingly widespread; 264 men had knowledge, 388 only "vague" knowledge, while 195 admitted to knowledge of preventive methods. The need for instruction on the subject of venereal diseases is said to have been "conclusively demonstrated." The remainder of the report deals with the social facilities for seamen in the port.

Sanitary Survey in Nicaragua.

A news release from the War Department states that as a result of negotiations between the medical corps of the U.S. Army and the director-general of health in Nicaragua a sanitary survey is to be undertaken of the "Nicaragua Canal Zone." The primary purposes of the survey are "to determine the sources of diseases prevalent in the area with special attention to human carriers, prevalence of insects, and the breeding places of those known to transmit diseases; the extent to which the present inhabitants of the zone of the canal are infected by these diseases; and the water-supply for domestic purposes available in the zone, and the incidence of disease conveyed by its present use." What the secondary purposes of the survey may be is not definitely stated. One might hazard a guess that the building of the Nicaragua canal is one of them.

New Coccus Isolated in Meningitis Epidemic.

The Hygienic Laboratory reports (Public Health Reports, April 18th, 1930, p. 845) the discovery of a new form of meningococcus present in the spinal fluid of 14 cases occurring during the course of an epidemic of cerebro-spinal meningitis in Chicago in 1928. During the same epidemic 33 other specimens showed typical meningococci distributed among the four Gordon types. Morphologically the new micro-organism is indistinguishable from other members of the genus *Neisseria*. Culturally it differs in

producing a yellow pigment, and in its lack of fermentative action. It is also distinct in its antigenic relationships. The 14 strains derived from the 14 cases form a homogeneous group culturally, biochemically, and serologically. The name *Neisseria flavescens* is proposed for the new form. The Laboratory points out that this form is not represented in any of the polyvalent serums now manufactured and that it is of clinical importance, since the fatality-rate in the cases from which it was derived was not less than 30 per cent.

Antinarcotic Organisation.

Speaking recently at a banquet of the Physicians and Surgeons Society of New Jersey, Dr. Stuart Thomson gave some account of the work of the International Narcotic Education Association, an American propaganda organisation on the committee of which he serves. He said that America plans to attend the convention in London "with firm feet and clenched fist." But before making demands there the American is going to clean up his own house by putting out of business the two factories in this country which manufacture synthetic opiates. Another speaker asserted that, while most of the smuggled narcotics enter through the port of New York, an increasing quantity is crossing the border from Mexico.

IRELAND.

(FROM OUR OWN CORRESPONDENT).

"Handy-Women."

At the annual meeting of the Irish Nurses' Union, held last week, a resolution was passed calling upon all supervising authorities to take action against the so-called "handy-women," as unregistered midwives are popularly called, in view of "the very grave consequences which have lately occurred in maternity cases where unqualified women were acting in the capacity of midwife." It is somewhat surprising to find that twelve years after the passing of the Midwives (Ireland) Act such a protest is necessary. That the evil is a real one was borne out by Mr. T. Hennessy, who suggested that in some cases a medical man had a kind of agreement with an untrained nurse because the trained nurse in the district was unfriendly to him. He advised nurses to report any such cases that came to their knowledge. It is possible that some medical practitioners are not aware that any practitioner who in any way gives countenance or assistance to an unqualified woman to enable her to practise as a midwife is running the risk of having his name removed from the Register. The General Medical Council has issued a warning notice to this effect, and there is little doubt that the Irish Medical Registration Council would take a like view of such an offence.

Motor Accidents and Voluntary Hospitals.

The daily papers in Dublin have recently given a good deal of attention to the burden that is thrown on the voluntary hospitals by the great increase in the number of accidents due to motor transport. The fatal accidents in Dublin, most of them due to motor vehicles, were 27 in number in 1927, 42 in 1928, and 66 in 1929. In almost every case the injured are brought to the nearest voluntary hospital, and rarely does the hospital receive any payment in return for the treatment given. Mr. A. B. Clery, assistant surgeon to the Richmond Hospital, calculates that, in 1929, in-patients suffering as the result of motor accidents cost the hospital between £400 and £500, while the total payments received on their behalf amounted to £82. He estimates that motor accidents cost the Dublin hospitals a sum of about £5000 annually, without taking any account of the cases treated in the extern departments. Sir James Craig hopes for some relief from the Traffic Bill which will be before the Dail in the autumn.

If third party insurances are rendered compulsory by this measure, it would be easy to introduce a provision that the hospitals should have a first claim on insurance payments.

Although no cases of psittacosis have yet been reported in Ireland the Minister for Local Government and Public Health in the Irish Free State, in view of the frequent occurrences of the disease in England and other countries in close touch with Ireland, has thought it right to issue an order prohibiting the introduction of parrots.

The Sweepstakes Bill, as it is familiarly called, the measure introduced to the Dail by Sir James Craig for the purpose of legalising the holding of sweepstakes in aid of hospitals and certain other charitable institutions, passed its third reading in the Dail last week without opposition, and has gone on to the Senate.

Mr. R. V. Slattery has been appointed one of the surgeons to the House of Industry Hospitals in place of Sir F. Conway Dwyer, resigned. Mr. Slattery has been one of the assistant surgeons to the hospitals for several years.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. V. F. Walsh and J. A. Cusack to be Surg.-Lt. Comdrs.

ROYAL ARMY MEDICAL CORPS.

Maj.-Gen. H. P. W. Barrow, Dir. of Hygiene, War Office, relinquishes his appointment.

Col. P. H. Henderson, late R.A.M.C., to be Dir. of Hygiene, War Office.

ARMY DENTAL CORPS.

Capt. B. W. Tyson to be Maj.

TERRITORIAL FORCE.

Cpts. E. L. Elliott and J. McCulloch resign their commissions.

Supernumerary for Service with O.T.C.: Lt. J. H. Strahan resigns his commission.

ROYAL AIR FORCE.

The undermentioned Flying Officers are promoted to the rank of Flight Lt.: R. E. Alderson, A. R. French, J. H. Cullinan, and P. J. Nyhan.

Flight Lt. W. Heron is transferred to the Reserve, Class D.ii.

INDIAN MEDICAL SERVICE.

Capt. D. R. Thapar to be Maj.

The undermentioned appointments are made:—To be Cpts. (on prob.): J. McM. Wilder, E. G. Hurd-Wood, and W. T. Taylor.

To be Lts. (on prob.): A. K. M. Khan, F. H. A. L. Davidson, J. H. Gorman, R. T. Hicks, S. M. Kharegat, R. C. Dracup, A. B. Guild, and W. Fleming.

The undermentioned officers retire: Col. A. B. Fry and Lt.-Col. F. H. Salisbury.

COLONIAL MEDICAL SERVICE.

The following appointments have been made: Dr. L. Milburn, Medical Officer, Supernumerary, Leeward Islands; Dr. L. P. Younglao, Medical Officer, Dominica, Leeward Islands; Dr. J. A. P. Cameron, Medical Officer, Malayan Medical Service. Dr. D. S. Johnston has been appointed Medical Officer on the West African Medical Staff.

RADIUM FOR CHESTER INFIRMARIES.—An amount of radium worth £2200 has been handed over to representatives of the Chester Royal Infirmary and the Wrexham Infirmary at Chester. This comes from the £140,000 which has been raised towards the Cancer Campaign Fund through a joint appeal from Manchester, Liverpool, Cheshire, and North Wales. Mr. Joseph Banks, of Hallow Park, Worcester, has given £1000 toward a new theatre at the Chester Infirmary.

Correspondence.

"Audi alteram partem."

A UNIVERSITY DEGREE FOR THE
GENERAL PRACTITIONER.

To the Editor of THE LANCET.

SIR,—As a general practitioner of over ten years' standing, may I say that your correspondents, Dr. Franklin and "M.D., M.R.C.P.," have rendered a great service to the general practitioner and the status of general practice? Their reasoned and valuable contributions to the subject of medical degrees for general practitioners must surely command the serious attention of all those who are interested in the future of the proposed post-graduate hospital at Hammersmith. The need is urgent to encourage general practitioners, who, as your correspondents so rightly emphasise, have to deal with the bulk of the sick community, to undertake systematised clinical research. For such research general practice provides rich material, and the advantages to practical medicine as a whole will be enormous.

The University of Durham has for years granted its M.D. degree to medical practitioners—that in itself is nothing new—but with the introduction of a new post-graduate hospital medical school in London, the very heart of the British Empire, the University of London has a unique opportunity of encouraging the general practitioner to continue his studies and to remain a student of medicine. The standard should, as your correspondents point out, remain high, but surely the requirements suggested:

- (a) clinical research in general practice,
- (b) a prescribed course of study at the post-graduate hospital,
- (c) a practitioner of at least seven to ten years' standing, are high enough. It is sincerely to be hoped that a matter of such importance as has been raised by your correspondents—long since overdue for consideration—will not be brushed aside, but will be brought directly to the notice of the responsible authorities for their serious consideration. By so doing they will be helping to raise the status of general practice, one of the most important branches, if not the most important branch, of medicine.

I am, Sir, yours faithfully,

JOHN L. BOOKEY, M.B., B.Ch., B.A.O.

London, E., May 12th, 1930.

ANGINA PECTORIS AND CORONARY DISEASE.

To the Editor of THE LANCET.

SIR,—In his article on this subject, published in THE LANCET of April 26th (p. 908), Dr. Douglas Hubble referred to a theory that I put forward in the last edition of Taylor's "Medicine" in these words:—

On the analogy of œsophageal and gastric pain, cardiac pain would be due to a toneless and consequent stretching of the muscle, and amyl nitrite may possibly act by stimulating the muscle to contract down on its contents.

Although I still agree with the general truth of the statement, I should not at the present day use the word tonelessness; but as I have discussed the subject at length in my Oliver-Sharpey lectures (THE LANCET, 1928, ii., 1282 et seq.) I need only give a summary of my views at present, and attempt to answer Dr. Hubble's objections.

In the first place I should like to protest against his regarding myocardial anoxæmia as an alternative explanation to myocardial exhaustion or myocardial distension. I think it is quite possible that the myocardial anoxæmia hypothesis may be correct—there is, in fact, some further evidence in its favour in my lectures; but it provides no explanation of the mechanism of the pain. Anoxæmia can only provide a stimulus that brings the pain mechanism into action.

Now to deal with two objections (a) and (b). In my lectures I brought forward some experimental evidence that pain in one particular patient was associated with acute left-sided failure, while the right side of the heart was still active, so that within a few minutes a considerable amount of blood accumulated in the lungs. This might mean that the right side of the heart was working against increased resistance, and in its efforts to push on the blood the diastolic pressure rose so that the pain nerve-endings in the wall were stretched. A more vigorous contraction produced by some stimulation—e.g., amyl nitrite—might drive on the blood and stop the pain; but when gross cardiac failure has set in the muscle may be so dilated that there is not enough increased tension during diastole to cause any pain, in spite of feeble contractions. As Dr. Hubble points out, nothing is more striking than the fact that angina pectoris disappears in gross cardiac failure. The above is only meant as a picture of how pain may be produced, and I certainly do not want to be dogmatic on the subject considering the scanty evidence at present available.

Objection (c).—The evidence that amyl nitrite stimulates the cardiac contractions was obtained in a personal communication by Dr. Anrep to the writer as the result of his study of the heart-lung preparation. But there is also a clinical observation that amyl nitrite relieved the pain in an anginal attack without any lowering of the blood pressure; but with a great increase of the heart-rate. Of course, there was superficial vaso-dilatation; but I suppose this was compensated for by some deep-seated vaso-constriction, and it cannot have helped the heart. Dr. Hubble himself suggests that amyl nitrite causes dilatation of the coronary arteries which would on physiological principles lead to more vigorous contraction.

Objection (d).—While structurally plain and striped muscle are different, the pain nerve-endings in the muscular walls of the heart and œsophagus are presumably the same, and these and not the muscle are responsible for the sensation of pain. I am surprised that Dr. Hubble considers that there is no condition occurring in the stomach and œsophagus which is at all comparable to angina pectoris, when Dr. Walter Verdon introduced his œsophageal and gastric theory of angina pectoris because the conditions are so similar. Sir Clifford Allbutt also thought it reasonable that pseudo-angina might result from the œsophagus, quoting the work that Dr. W. W. Payne and myself were carrying on at that time. I believe myself that it may be very difficult to distinguish the two, and that people who suffer from angina commonly also get pain from reflex œsophageal disturbances. The best way of separating the pains clinically is to ask the patient to make one swallowing movement. If the pain is due to the œsophagus, it may be increased or it may be diminished some seconds after swallowing owing to the passage of the peristaltic wave. But the presence of œsophageal pain is not proof that the patient does not also suffer from angina, because the heart and the œsophagus are so closely related to one another.

I am, Sir, yours faithfully,

London, W., May 12th, 1930.

E. P. POULTON.

FEE-CUTTING IN PATHOLOGICAL SERVICES.

To the Editor of THE LANCET.

SIR,—At the annual meeting of the Governors of Charing Cross Hospital Pathological Institute, Mr. George Verity is reported as having stated that "the Pathological Institute was doing untold good in examining patients who are not of necessity eligible for treatment in hospital" but that "the work will be in jeopardy unless £1000 is quickly subscribed towards it."

May I beg the courtesy of your columns to point out that similar work with similar results is being done in the pathological departments attached to most of the voluntary hospitals throughout the country;

none of these hospitals has, however, as yet found themselves under the necessity of appealing to the general public for funds in support of this work. The fees charged by the Charing Cross Hospital Institute of Pathology for pathological examinations are below those charged by any similar institution in this country, and are set at a level at which, without subsidies from outside sources, it is impossible for them to be performed other than at a loss. It is not surprising to anyone engaged in similar work that the authorities of the Charing Cross Institute of Pathology having set their fees at this low level should find themselves in need of a subsidy.

As to the justification for an appeal to the public for funds to enable the continuance of this policy of fee-cutting in competition with the pathological services conducted by other voluntary hospitals, I leave to your readers to judge.

I am, Sir, your faithfully,

S. C. DYKE.

Secretary, the Association of Clinical Pathologists.

Wolverhampton, May 7th, 1930.

CALCIFIED PERICARDIUM.

To the Editor of THE LANCET.

SIR,—Having read Dr. Vilvandre's article in THE LANCET of March 15th (p. 564) on calcification of the pericardium I wish to record a case to which I was urgently called two years back. When I reached the house I found the patient dead, and was told that death had occurred about half an hour back, because before informing me they tried household remedies to restore him. The patient was a cook of about 65 years. His master had given him only light work, as he was an old servant and unable to do hard work. Before death he was doing light work, sitting and chatting with other servants, who noticed him to fall back suddenly and die. His only disability was that he took a long time to walk even a short distance, owing to difficulty of breathing.

As soon as I arrived, noting the heart had stopped beating, I gave an intracardiac injection of adrenalin, and to my surprise I found difficulty in making my needle enter the heart, and could distinctly feel the needle point touch a stony hardness. Persisting I thought I could with difficulty enter the heart, and I injected twice about 5 c.cm. of adrenalin solution. It was of no avail, as the duration of cessation of life was too long, and perhaps the adrenalin entered partly the calcareous myo-pericardium. I diagnosed the case at the time as calcareous adherent pericardium. There was no autopsy.—I am, Sir, yours faithfully,

Fort Bombay, April 17th. SHAPURJI A. BANKER.

INCOMPATIBLE BLOOD.

To the Editor of THE LANCET.

SIR,—In your issues of May 3rd and 10th Dr. S. C. Dyke refers to direct matching as the only safeguard against introduction of incompatible blood. I should like to point out that recipients often have diluted serum, weak in agglutinins, and should the donor have weak agglutinogens the direct test may not detect an incompatibility which may all the same result in disaster.

Personally I always first perform this test and, if satisfactory, test the red cells of both recipient and donor with 2 and 3 type sera of good titre; as a result of this test a further test is made in each individual, unless he is group 1, by putting up his serum with known type red cells of good agglutinin content, either type 2 or 3 or both, with the object of obtaining a double positive result.

The method is not unduly long, as there is no need to watch to be certain that an apparent negative is really negative; the positives usually occur rapidly; if they do not, one knows at once that one of the reagents or the red cells or serum of the individual is weak, and that a closer examination is necessary, possibly with titration and absorption tests. Another

advantage is that one can deal with confidence with those patients whose sera show apparent agglutination, not always easily demonstrable as due to rouleau formation, with red cells of their own group and even their own red cells. The positives obtained by the "double positive" method are usually with ease distinguished from these pseudo-reactions, which can then be disregarded.

I am perhaps fortunate in being group 3, but if search be made in any hospital staff a member can usually be found who is of this group, and does not mind an occasional drop of blood being taken. If taken in citrate saline, "packed" by centrifugalisation, and kept in an ice safe, not frozen, red cells will usually keep in quite good condition for a week.

I am, Sir, yours faithfully,

C. RICKWORD LANE.

Pathological Department, Hampstead General Hospital,
May 9th, 1930.

A HANDY CENTRIFUGE.

To the Editor of THE LANCET.

SIR,—Dr. Dyke's reference to the delay that occurs in obtaining the speedy separation of serum from a recipient's blood when the patient is at some distance from a laboratory centrifuge prompts me to say that this difficulty can be surmounted readily by using the radiator fan of a motor-car. If a Wright's capsule of blood is attached firmly, by means of adhesive plaster, or better, is placed in an easily contrived appliance, at the end of the shaft of the fan, so that the capsule lies along its length with the straight sealed end pointing outwards, a few minutes revolution by the car engine gives an adequate supply of serum. If the capsule of blood is kept in contact with the warm radiator for a short time before attaching it to the fan, a better yield of serum is obtained.—I am, Sir, yours faithfully,

Harley-street, W., May 12th, 1930. ARTHUR DAVIES.

PRACTICE IN SOUTHERN RHODESIA.

To the Editor of THE LANCET.

SIR,—May I draw the attention of men who are well qualified in medical and surgical practice to the excellent opportunities offered by the posts in Southern Rhodesia now advertised in the medical journals. The position carries a salary of £500, rising to £650 per annum as Government medical officer, with the right of private practice, a feature which, of course, makes all the difference to these posts. Southern Rhodesia has a delightful and healthy climate and the country is a most attractive one in which to settle. There are very good schools. Medical men who have been in practice there for a number of years speak very highly of the prospects afforded by Southern Rhodesia, both from a professional and social point of view.

I am, Sir, yours faithfully,

R. A. ASKINS, M.D.,

P.M.O. Elect.

Office of the High Commissioner for Southern Rhodesia,
Aldwych House, London, May 10th, 1930.

THE WATER OF TREFRIW.

To the Editor of THE LANCET

SIR,—In your issue of May 3rd (p. 984) the interesting account of the mineral wells at Belle Vue Spa, Trefriw is a little misleading in one important point. Comparison is made with the famous Matchless wells at Alabama. It should be noted that the iron in Belle Vue Spa water is entirely in the bland non-oxidised ferrous form, appropriate for internal use. As far as can be judged from published analyses it is the strongest water of this variety so far discovered in Europe or America. The water of the Alabama wells contains a considerable proportion of irritant and astringent ferric salts.

I am, Sir, yours faithfully,

Cavendish-square, W., May 8th. N. MUTCH, F.R.C.P.

CÆSAREAN SECTION UNDER SPINAL ANALGESIA.

To the Editor of THE LANCET.

SIR,—We are interested to read in your last issue (p. 1012) that Mr. J. W. Burns of Liverpool agrees that spinal analgesia is a valuable aid to the safety of Cæsaean section. In 1923, we drew attention¹ to the advantages of this method, and emphasised the following points: the powerful contraction of the uterus causing ischæmia, and conducing to a strong suture line; the immediate activity of the child; the satisfactory general condition of the patient after operation; and the special value of the method, in Cæsaean section, for cases of diabetes mellitus, phthisis, toxæmia of pregnancy, heart disease, and fibroids requiring myomectomy. We agree with Mr. Burns that morphia should be withheld before operation in order that the child may not suffer from the depressing effects of the drug. These facts have been confirmed by other observers in Great Britain and elsewhere.

The retching to which Mr. Burns draws attention, is, in most cases, produced by the pressure of the firm uterus on the abdominal contents. Usually it ceases as soon as the child has been extracted.

With but few exceptions patients are tolerant and helpful with the necessary technique, and several have willingly consented to "spinal" at a subsequent Cæsaean section.

We are, Sir, yours faithfully,
BECKWITH WHITEHOUSE.
HENRY FEATHERSTONE.

Birmingham, May 13th, 1930.

THE FIRST INTERNATIONAL CONGRESS ON MENTAL HYGIENE.

(FROM A SPECIAL CORRESPONDENT.)

THE First International Congress on Mental Hygiene was held in Washington, D.C., from May 5th to 10th. Its object was to bring together for the first time all those interested in the various aspects of mental hygiene—medical, legal, and social.

The mental hygiene movement was started in America 22 years ago by Mr. Clifford Beers and has since spread to every country in the world. The aims of the congress were to give the fullest possible ventilation to the many medical and social problems with a mental hygiene basis, and to bring together representatives from all over the world in the hope that a fuller coördination and coöperation in the field of mental health would be thereby attained.

The first session for discussion was held on May 6th, when Dr. HAYEN EMERSON, Professor of Public Health Administration, College of Physicians and Surgeons, New York City, dealt with the magnitude of

MENTAL HYGIENE AS A PUBLIC HEALTH PROBLEM.

He said that resources for interpreting mental limitations, for helping human beings in adaptation to circumstances, for guiding them, and treating them with discrimination through episodes of emotional mal-adjustments have greatly expanded.

No longer could the health officer satisfy his community or the sciences and arts of preventive medicine through the traditional development of programmes to control communicable diseases, to detect the physical defects of school-children, to protect maternity and infancy, and to teach the health rules of nutrition, rest, and physical recreation. He must give account to his population for the incidence of suicides, showing correlations, perhaps, with unemployment, the prevalence of divorce, nativity, sex, and occupation. Was it not at least as important that

the suicide-rate had risen from 4.9 to 10.7 for each 100,000 of our people in seventy years as that the diabetes death-rate had done about the same? Was there a greater need to report upon a rising death-rate from appendicitis or to analyse, publish, teach, and if possible prevent the conditions that have brought about a rise in the divorce-rate from 26 per 100,000 to 68 per 100,000 in less than 60 years? If the Traveller's Aid stations at city railroad terminals revealed the incidence of runaway children, unwholesome homes, the too-heavy hand of discipline, the misunderstood errant child, were they not as essential to our plan of public health as the collecting depôts for diphtheria smears and typhoid cultures at drug stores and hospitals? Among unselected children of four years of age, considered by their parents to be normal, coming from self-supporting families of various economic levels in a medium-sized industrial city of New England, and showing by the standard tests a range of intelligence of from 75 to 150, 36 per cent. were found to have characteristic behaviour problems that were likely to develop into personal or family embarrassments. These unadapted or badly trained or ill-adjusted little folk were found to be distributed with considerable uniformity among the dull, the average, and the bright. The bulk of the problems presenting at this age were included under the rather general categories of fears, extreme shyness, severe speech difficulties, and the more precise phenomena of tantrums, interference with appetite for and use of foods, and enuresis. These evidences of deviation from good health appeared with an incidence higher than that of any other defect or disorder of apparently normal childhood of this age, unless it be in the realm of dentition. So far as the problems of pre-school childhood brought the boy or girl to the brink of social failure, they called for professional diagnosis, aid, and prevention.

The problem for public health, for the avoidance of behaviour problems in children under school age, was to include in the plan of service to parents such personnel as could be trusted to notice evidences of deviation from normal conduct in the home, to advise parents to seek professional guidance, when necessary, for themselves as well as for the child, and to deal with early and mild disturbances in this field, as was done with physiological errors in the field of growth, nutrition, and infection. The community was beginning to realise that the typhoid carrier and the small-pox patient were no more dangerous in the community than was the partly well mentally disordered patient. To be immune to the buffets of social intercourse was as important for a child as to carry a certificate of a negative Schick test. Failure of emotional adjustment might at any time become a communal hazard. Dr. Emerson said that the health officer must begin to ask himself such questions as: Will the psychiatrist get to the mean, lazy, ne'er-do-well before the policeman does? Will the bully the fearful child, the miserable man, meet a wise social worker before he is forced into an institution?

Evidence obtained from various studies indicated that with a population of 120,000,000, 4,560,000 under five years of age could probably show some behaviour problems which, if not noted and in some measure dealt with, would lead to personal or family dilemma or disturbance; 250,000 between five and fifteen years of age would be suffering from major speech defects, and a similar number would need special class training because of mental defect; 3,135,000 would develop some behaviour problem that calls for professional assistance. 250,800 school-children before they were fourteen years of age would be held at least temporarily as delinquents; 70,000 young men and women from twenty to twenty-four would suffer damage or distress as a result of emotional difficulties. Without counting adult delinquents or inmates of mental hospitals, one could assume that at least 288,000 could need a psychiatrist's advice within the year, and of the 1,443,000 who would become major dependency problems 210,450 would be in families in which there is a case of mental disorder.

For these 104 million of the people at various ages who would not be listed among the insane or the criminal, but whose lives would be narrowed, warped, tangled, and lacking in happiness or gentleness, something in the way of prevention could at least be attempted. System, method, and the persistence of organised effort by trained and understanding representatives of the sciences and of society, could and surely would show results, first among the little children and later among the army of school youth.

Discussion.

This paper was followed by a discussion, opened by Dr. GUSTAV KOLB (Germany) who said that in Germany it had not been possible to develop many new institutions since the war owing to financial considerations.

¹ Proc. Roy. Soc. Med. (Sect. Obst.), 1923, xv, 55; Jour. Obst. and Gyn. Brit. Emp., 1923, xxx, No. 4; Jour. Med. Jour., 1923, ii, 878.

but that a great deal had been done towards improving those already in existence. Social work directed to the after-care of patients who had been in institutions for the mentally diseased was being greatly extended and the principle of prophylaxis of mental illness had come to be fully accepted. There was great need for more uniformity in respect of nomenclature and classification, and he hoped that this congress would do something towards the achievement of this ideal.

Sir HUBERT BOND, who was attending the congress as the official representative of H.M. Government, hoped that this congress might be of signal service in relation to the administration of the new Mental Treatment Bill which he hoped would soon become law in England. This Bill would realise the vision expressed many years ago by Sir Clifford Allbutt who believed that the more static mind of the lawyer must necessarily come to terms with the dynamic mind of the biologist. Medicine in relation to mental hygiene had been much hampered in the past by lack of elasticity both in regard to legal and lay opinion. Elasticity was essential not only for them but for the doctor, nurse, and the social worker, who are all coöperating in the work of mental health.

Dr. GENIL-PERRIN, General Secretary of the French League of Mental Hygiene, read a paper on

SYPHILIS IN RELATION TO MENTAL HYGIENE.

He summarised the current data concerning the rôle played by syphilis in determining various mental disorders, and pointed out that the mental disorders arising indirectly from syphilis were worthy of as much attention as those which are due to its direct action. He wished to emphasise the moral trauma produced by syphilis.

Through the fear syphilis inspired it was a cause of moral disturbance, even among those who were not contaminated by it. Syphilophobia was a kind of hypochondriacal preoccupation, or phobia which was not distinguishable from the other phobias from the point of view of its psychological mechanism, but which was particularly dreadful in its consequences, since it influenced the sexual and even the social behaviour of the patient. To the conscientious individual, the discovery of syphilis in himself constituted a tragedy. The new syphilitic was in need of moral support, and this was one of the most dramatic points of contact between mental hygiene and syphilis.

Just as it was necessary to ferret out syphilis in the psychic abnormal on account of his disposition to catch and to transmit it, it was necessary, also, to look for psychic abnormality in the syphilitic because it increased inordinately his social danger.

Individuals who married against medical prohibitions must be considered psychically abnormal, and needed moral re-education.

Moral education, sexual education, prophylactic education all implied the coöperation of the mental hygienist, since he was better qualified than anyone else to decide on the best methods to employ.

In the course of the discussion Dr. WILLIAM F. SNOW (United States) spoke of the numerical magnitude of the problem. He estimated that by far the commonest age of incidence of syphilis was from 20 to 25 years and that it occurred chiefly among the relatively indigent. Dr. Snow was opposed to any compulsory control of prostitutes, who should receive treatment on the same terms as any other member of the community. It was wholly inadvisable to mark them out as a group. Any person who refused to be treated for syphilis must be suffering from some kind of mental abnormality. Mental hygienists must work in coöperation with educators and social workers in developing the right attitude of mind on the part of the public towards this great problem.

A representative from Hungary was interested to find that the statistics relating to syphilis in such a comparatively eastern country as Hungary approximated so closely to those obtaining in France and the United States.

THE CONGRESS DINNER.

The International dinner inaugurating the congress was held on May 5th at Hotel Willard. Nearly 1000 people were present, including foreign delegates from 53 different countries. The principal speakers were Dr. William A. White, President of the congress, who took the chair; Dr. Frankwood E. Williams, the chairman of the committee on the programme; Mr. Clifford W. Beers the secretary-general of the congress, an official representative of each of the six continents, and the Hon. Ray Lynman Wilbur, M.D., Secretary of the Interior, who spoke on some aspects of the world movement for mental health. Dr. Wilbur stressed the shift from the physical to the mental aspects of life and said that it was a sign of the advance of civilisation. The power of the mind in national and international affairs was everywhere coming to be recognised as of more importance than big battalions. Even in the war it became obvious that organised propaganda was more potent than bullets. He believed that the hope for the world's future welfare and progress lay in the development of right thinking and controlled emotion, and that these questions were essentially those which came under the aegis of mental hygiene.

(To be continued.)

HOSPITAL COÖRDINATION UNDER THE LOCAL GOVERNMENT ACT.

THE LONDON VOLUNTARY HOSPITALS COMMITTEE.

Section 13 of the Local Government Act, 1929, provides that:

The council of every county and county borough shall when making provision for hospital accommodation in discharge of the functions transferred to them under this Part of this Act, consult such committee or other body as they consider to represent both the governing bodies and the medical and surgical staffs of the voluntary hospitals providing services in or for the benefit of the county or county borough as to the accommodation to be provided and as to the purposes for which it is to be used.

"The London Voluntary Hospitals Committee" is the title that has been taken by the committee elected by the hospitals in the County of London for the purpose of consultations with the London County Council under this section. There has not hitherto existed in London any suitable body for this purpose, and a scheme of representation was therefore drawn up and submitted to the hospitals, for their comments and approval, by a joint committee consisting of representatives of the Voluntary Hospitals (Local Government Bill) Committee of the King's Fund, the Conference of Teaching Hospitals, and the London Regional Committee of the British Hospitals Association. The scheme provides that every hospital in the area shall have the right to nominate at least two representatives, one representing the governing body and one the medical and surgical staff, upon an electoral body which is divided into six sections for the purpose of representing five areas (north-western, northern, north-eastern, south-eastern, and south-western) and the special hospitals whose work cannot be localised in relation to any particular area. Each of these five area committees and the non-localised special hospitals committee in turn elects its own representatives upon the central committee, the method of representation being such as to ensure that teaching, non-teaching, and special hospitals are each given proportionate representation. Meetings of the various electoral bodies were convened in the latter part of March by members of the joint committee, to which reference has been made above, and the central committee was able to hold its first two meetings during April.

Personnel of the Committee.

Lord Riddell is chairman of the committee, Dr. Geoffrey Evans its hon. secretary, and the other members are as follows:—

Mr. A. Lawrence Abel, F.R.C.S., Mr. F. S. A. Baker, Lady Barrett, M.D., Mr. O. N. Chadwyck-Healey, Mr. Thomas Clapham, Lt.-Col. Clement Cobbold, Dr. Edmund H. Colbeck, Capt. the Rt. Hon. C. C. Craig, D.L., Mr. Robert Davies-Colley, F.R.C.S., Prof. L. S. Dudgeon, F.R.C.P., Mr. Arthur G. Ferard, Mr. Charles Gibbs, F.R.C.S., Sir Henry Gooch, J.P., Mr. E. L. Pearce-Gould, F.R.C.S., Dr. A. M. H. Gray, Capt. A. M. Hughes, Sir Henry Jackson, Dr. J. M. H. MacLeod, Sir George Makins, F.R.C.S., Mr. M. S. Mayou, F.R.C.S., Mr. E. Vernon Miles, Mr. Arthur Morley, Mr. E. W. Morris, Mr. Gilbert G. Panter, Mr. D. Denham Pincock, F.R.C.S., Dr. Arthur Porter, Dr. Harold Pritchard, Mr. D. W. Roy, F.R.C.S., Dr. T. H. G. Shore, Dr. E. Bellingham Smith, Mr. H. S. Scuttar, F.R.C.S., Mr. Widdrington Stafford, Mr. Thomas G. Stevens, F.R.C.S., Mr. Austin Taylor, Sir William H. Wells, F.S.A., Mr. J. P. Wetenhall, Mr. Francis P. Whitbread, Dr. C. M. Wilson.

The address of the committee is 23, Park Square East, London, N.W.1.

Obituary.**JOHN EDWARD SANDILANDS, M.C.,
M.D., D.P.H. CAMB.,**

LATE EXECUTIVE HEALTH OFFICER, BOMBAY CITY.

John Edward Sandilands was born in 1872. He was educated at Harrow (E. E. Bowen's House), where he reached the Vith Form and represented the school in the Public School boxing championships before he left in 1890. After six months in Paris he went up to Trinity College, Cambridge, where his exploits will be long remembered. He read natural science and medicine, having made up his mind early in life to become a doctor, and obtained second-class honours in the Natural Science tripos. At Cambridge he made many friendships which lasted through his life. He began his clinical work at St. Bartholomew's Hospital in 1893, and qualified in 1897, taking his medical degree at Cambridge in 1918 and the M.D. and D.P.H. six years later. He held the post of house physician to Sir Lauder Brunton at Bart.'s and that of house surgeon at the Metropolitan Hospital. In 1900 he went out to India to help combat a plague epidemic; from there he was transferred to Aden, and then proceeded to South Africa to serve as a civil surgeon during the

DR. SANDILANDS.

[Photograph by Clifton, Bombay.]

concluding months of the Boer War. On his return to England Dr. Sandilands became assistant medical officer under the Metropolitan Asylums

Board on the small-pox ships at Dartford (the old Castalian or Calais Douvres) where he found the hygienic conditions far from satisfactory. Determined to gain experience in public health work he obtained an appointment under Dr. (now Sir George) Newman in Finsbury, and in 1905 he was appointed medical officer of health for Winchester, where he stayed till 1909, when he was appointed medical officer of health of Kensington. These were the days when baby clinics and various measures for child welfare were being brought into being, and he took a keen interest in their development. In the spring of 1914 he joined the Territorials, mainly in order to get the opportunity for some horse riding on economical terms. Within a few months he was called up for war service and probably welcomed the change of occupation. He went to France with the 5th Field Ambulance of the 47th Division until 1916, when he was forced to undergo a severe operation. As soon as he was moderately fit he returned for a short time to his duties in Kensington. When his health was restored he again offered himself to the Territorial Force and was refused; but he obtained a commission as a temporary officer in the regular R.A.M.C. and returned to his old ambulance in France just in time to act as a bearer officer in the great attack on Messines in 1917. For his work during this period he received the Military Cross. He continued to serve in the same field ambulance until after the retreat in March, 1918, and it was characteristic that the more risky job of bearer officer attracted him more than any other. Later he was placed in command of a motor ambulance convoy with which he remained until demobilised. Now in full health, Dr. Sandilands returned once more to Kensington, but after barely a year's work was appointed executive medical officer to the Municipality of Bombay where he stayed for nearly ten years. His work at Bombay tried his natural ingenuity and tact to the full. He was faced with the task of reconciling Western ideas of sanitation with Eastern religious beliefs—and he had some measure of success in the task.

Dr. Sandilands was very popular in Bombay. There, as elsewhere, he was known as "Sandy" to a large circle of friends, and was frequently to be seen at the Yacht Club, and at the Willington Club where he played golf. He was very tactful, and got on well with Indians. As regards his work, he had an uphill furrow to plough. His views on public health were eminently sound, but he was unable to carry out many measures which he would have liked to see in force. Examples of these are the big drainage scheme which was much overdue, and more rigid enforcement of anti-malarial measures. He was a firm supporter of Lady Lloyd's efforts for child welfare in India. Ill-health compelled him to return home last summer, a few weeks before his appointment expired. He underwent another severe operation in the autumn, from which he had reached convalescence when he died quite suddenly on May 8th.

Dr. Sandilands had numberless friends outside his profession as well as within it. He was full of wit and humour, often seeing events from the most unexpected points of view, and he was possessed of the most arresting and fascinating powers of narration. It is the more unfortunate that his published work is scanty. In 1904 he married the eldest daughter of the late W. L. Courtney, editor of the *Fortnightly Review*, and he leaves a widow, two sons, and three daughters.

**THE LATE DR. C. J. BATTLE,
OF KLERKS DORP, S.A.**

Dr. Charles John Battle, who died at the General Hospital in Johannesburg on March 16th in his fifty-first year, was the oldest son of Charles Key Battle, of Lincoln, and qualified from St. Thomas's Hospital, London, in 1903. Soon afterwards he went out to

South Africa, where he practised first in Natal and then on the East Rand. During the late war he served in East Africa as Captain in the South African Medical Corps under Lieut.-Colonel H. J. Orford, whom he joined in practice at Klerksdorp when the war was over. Dr. Battle was medical superintendent of the hospital there, and held office as district surgeon, railway medical officer, and medical officer of health. He had the reputation of a careful and accurate diagnostician, and five years ago came to England for post-graduate study, acting as assistant house surgeon at the Bristol Royal Infirmary. His last illness was an insidious lung infection which later became pneumonic in character and resulted in an abscess requiring incision. Dr. Battle married in 1921 Peggy, daughter of E. S. Lawlor, and leaves a widow with a boy of eight.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

DEBATE ON MINISTRY OF HEALTH VOTE.

(Continued from p. 1044.)

THE HEALTH SERVICES: MALINGERING.

Dr. MORGAN said that every day he was engaged in administering the Act. They had been told by a Member who was the representative of one of the industrial approved societies that the malingerer was made and not born. That was to say, he was made apparently either in his own house or in the doctor's surgery. Sir Kingsley Wood had said that lax certification was due to the fact that new doctors came along and wanted to make their practices very quickly out of the National Health Insurance Act. As one who administered the Act every day he said that from the medical point of view there was no general laxity of certification on the part of the medical profession. There was no general malingering going on. Every day he had patients coming to him to whom he had given a certificate of incapacity, and they asked him to certify them as fit. He might say, "No, in my opinion you are not fit to be taken out yet, and I will give you a certificate of incapacity still." They always agreed, and left it to the doctor to decide whether they should come off. People were gradually getting to have a knowledge of their rights, and were demanding them more and more. Some approved societies for years had been trying to educate the insured persons as to his rights against the doctor, and trying to get him to make charges against the doctor. The doctor's job was difficult enough at any time, but certain societies and their agents had tried to excite a feeling against the medical profession for what they thought was laxity. They forgot that, at the same time, the insured person was being educated in his rights against approved societies, and he knew now what he was entitled to, and that when he was ill he could receive the benefits for which he had paid. What was more, his employer was much more keen now that his employee should come under the Act and get its benefits. The Government actuary made it perfectly clear that it was a wider number of persons claiming benefit for a shorter time, and not persons claiming benefit for a long period that was responsible for the increase. A larger number of the population were taking advantage of the Act. They were ill, and the plea that the increase was due to malingering or laxity on the part of the doctor was not true. He had found, as a doctor, that it was to the benefit of himself and the insured person that the patient should come on the panel early. Many said "Shall I come on the panel or not." He used his judgment and if he said "You should," he kept them there as long as he thought they should be there. The Insurance Act was not brought into existence for the sake of the approved societies, the doctors, the chemists or the State, but for the benefit of the insured person, and the individual insured person had enough to suffer! There was equality of payment, but not of benefit. A man might be registered in Manchester, become unemployed, go to London, choose another doctor, and get ill. Then there was a whole series of performances to go through—sending certificates to Manchester, and so on, before he could get the benefit. The whole system was riddled with anomalies to the disadvantage of the person for whose benefit the Act was introduced, and part of the criticism of the doctors was employed to hide criticism of

the approved societies. Because approved societies wanted to hide the charges against them for the administration of the Act they levelled charges against other people. Increased cost was not due to the change of doctor, which the patient had a perfect right to do. It was due to more than that.

The Protection of the Insured.

The doctors were organised, the State was organised, the chemists and the approved societies were organised. The one person not organised was the insured person. The sooner somebody in the country called for a league of insured persons and made them pay, say, a penny a month to see that they got their benefits and rights under the Act, the better it would be. They required to be protected not only from the doctors, but from the chemists, the societies and the State. The sooner that was done the quicker there would be a change in the administration of the Act, and the full benefits recommended by the majority of the Commissioners would be brought in. The sooner, too, would be brought about the changes recommended by the minority—hospitals and convalescent treatment, dental treatment, eye treatment, not only for those who happened to be in favoured rich societies or favoured rich occupations, but all insured persons. Seeing that they paid equal contributions, they should also have equal benefits. The Minister of Health had given a very impartial view of the situation, and when certain allegations and charges were being made, it was their duty to investigate departmentally or otherwise those allegations. What he had said was perfectly correct, that there was a gradual lowering of physique due to unemployment. They did not find that in the year the unemployment started. It took some time, owing, perhaps, to a lack of nutriment and the proper vitamin content in the lowered dietary. But after a series of years of unemployment people gradually deteriorated in physique, and when they were ill they had a tendency to ask for the benefits of health insurance. He had what he called the "in-and-outers" on his list. There were the women with varicose veins. At any time these people, if they so wished, as any doctor knew, could ask for certificates of incapacity, and he defied any doctor, specialist, medical referee, or regional referee to refuse them a certificate of incapacity. They ought never to be at work. The same thing happened with bronchitis and asthma, and he had cases of men hanging on to work when really they should not be about. These "in-and-outers" under a decent system of society would not be at work at all, but would be treated as sick and invalid. There were Members of the House of Commons who were not administering the Act, and had only a secondary knowledge of it. They had not got to go into dark, dismal buildings, barking their shins and hurting their hands on doors, and seeing the conditions under which people were living every day. Doctors had to treat pneumonia in damp dwellings, and maternity cases in disgraceful conditions. The members of the public of whom he spoke sat in comfortable offices and said "lax certification." Frequently they telephoned to know if the certification was correct or not, as if a doctor would sign a certificate without knowing what he was doing. He did not say doctors did not make mistakes; they made grave mistakes. But he was sure, from discussion with medical men all over the country, that there was no malingering on the part of the insured person and no lax certification on the part of doctors. Many changes were necessary in the Insurance Act, and he was sure that the approved societies would have to be changed. They would have to have national amalgamation and a pooling of surpluses. The insured person would insist on an equality of benefits for an equality of contributions, and when that time came approved societies with a large number of members in sheltered occupations would be up against it. He hoped that the House would allow the Minister of Health to go on and do his business without hindrance, that the committees would be allowed to do theirs, and that the medical profession would carry on the provisions of this onerous Act with the least possible difficulty.

Views of Regional Medical Officers.

Lieut.-Colonel FREMANTLE said they were much relieved to hear that the question of excessive claims for insurance benefit was under further examination. It had been suggested that the experience of the first three months of this year indicated that this phase of things was coming to an end, but he (Colonel Fremantle) doubted very much whether such a steady rise going on year after year would be terminated as quickly as had been freely suggested. And he would lay emphasis on the views of some of the regional medical officers, and more especially one opinion from one of the chief medical schools of London who took a detached line, wished to make the scheme run smoothly, and was used to dissecting and analysing such records. This review of the factors in the situation showed that there were to blame both those who took advantage of the scheme

as receivers of benefit and those who took advantage of it in administration of benefit. Both among medical men and insured persons there were a certain number who had less conscience than others. An hon. Member put the number of malingerers as high as 1 per cent.—that was to say, out of 17,000,000 persons there would be 170,000 potential malingers. He would not have put the figure so high, but they must all recognise that malingers existed. Ordinary human beings tried to get the most out of a State service; in fact it came natural to them. As his friend the regional medical officer said in his review, that state of affairs was not confined to any one class. No one was more responsible for this attitude towards national insurance than Mr. Lloyd George who managed to send the cry “nineteen for fourpence” throughout the country—a most immoral doctrine which had its vogue. Now the disadvantages of it were receding on the insurance scheme. If there were a deliberate attempt to defraud the scheme he did not think there would be any difficulty in detecting and preventing such definite frauds. But it was generally not fraud either on the part of the insured person or the doctor. He asked hon. Members who had been trying to make the doctors the scapegoat to recognise that the facts of the case were the other way round. Here was one of the most vivid descriptions he had seen as to how this affected the individual—

“The patient, feeling desirous of a rest, goes to his panel doctor and practically says, ‘I do not want a prescription but only a certificate.’ The doctor, knowing the result will be a refusal, would, I am sure, rarely dares to disclose. It is no trivial annoyance for an angry patient to remove his name from the doctor’s list, because it does not stop at that; he tells his friends and acquaintances and the doctor gets a bad name in the neighbourhood, which is detrimental to his income.”

That was the way in which this regional medical officer summed up the situation. Naturally it was his business to please his patients, whether they were private or panel patients. He remembered one doctor summing up a busy practice in this way: “My practice is to give the patient the benefit of the doubt, and if after some time there are still doubts, then I give my partner the benefit of the doubt, and if the last resort I refer the case to the regional medical officer, and give him the benefit of the doubt.” That was the way medical men carried on a very busy practice, and if they had a rule-of-thumb method of carrying out their duties that was very serious. Although there might be a setback in the first three months of the year, he (Colonel Fremantle) believed that the real fault was inherent in the system, and was due to the fact that it was a State system supported by the notion of the Labour party that the nation had a bottomless purse, and the Government always had the idle right to draw upon. Let them contrast that with the old system of the friendly societies, as summed up in the societies’ reports over and over again, for this induced a spirit of loyalty among the members. There was then a tendency among the members to make the best of things and come on the funds as little as possible. Owing to the effort to spread the principle so as to go into every nook and cranny and relieve every form of hardship in every form of sickness, they had done away with the voluntary principle which once attached to the separate and dependent entity of the friendly societies, and they now had ended up on what was regarded as a bottomless national purse. They could not reverse the hands of the clock; they had to try to encourage the old spirit which formerly attached to friendly societies. They had to cultivate the spirit of loyalty in friendly societies on the one hand and among medical men on the other in order to get through the difficulty. It was no use trying to coerce any body of professional men, most of all medical men, because they had always got the whip hand in the end. They alone understood the technicalities and with necessary sympathy with them. The Ministry of Health had been extraordinarily sympathetic towards medical men in understanding their difficulties and helping them through. There was now a scheme under which a medical practitioner whose action was called in question could submit his case first of all to the judgment of the regional medical officer, and then to a jury of medical men. This would have the greatest effect upon medical practitioners. It was suggested that medical men were too lenient in these cases, but the last thing medical men wanted to do was to cover up the misdoings of those who were letting them down. The chief difference between private practice and insurance practice was that there were penalties in the latter if doctors did not thoroughly examine their patients and gave certificates for sickness benefit without discrimination. Those were the doctors they wanted to catch. The Minister of Health was trying to devise a method by which they could be caught and penalised, because they had no use for them. Those were the opinions of those who spoke with the experience of the British Medical Association, and they represented the opinion of the great majority of the doctors.

Excessive Prescribing.

Two particular cases of excessive prescribing had been brought to the notice of the Ministry of Health, and they had been referred to the referees. In one case the referees upheld the decision of the Minister, but not in the other. It was shown, however, that excessive prescribing did exist. Some of those who wished to support the idea of giving benefit at any price had taken the line that medical men were justified in prescribing to any extent so long as they were doing what they considered was best for their patient. In this particular case it was a firm of four men who, as reported by the referees, were all men of very high principle, who wished to do the best for their patients; but the amount of prescribing in that case could not possibly be countenanced. This question was obviously a very delicate one. The ordinary doctor, certainly in his day, was brought up to be fairly regardless of cost in regard to prescriptions, dressings, equipment, and so on, in the hospital, but it was a very different matter when one had to provide these things for himself in private practice. The natural tendency was for a man to do these things without regard to cost, and that tendency must be restrained, but not damaging the effect of the advice. The only way to do that was to take the profession generally into confidence, and get their cooperation. He believed that good machinery had been devised now which would meet this case. It was necessary to watch the tendency, which was liable to be a fatal one, on the part of people to fall back into the arms of the State in order to get everything done for them. The idea was futile in the matters of the prevention of ill-health that the State could do things for the individual. Prevention was only possible so far as the community would do its part. A very remarkable statement was made last November at the National Conference of Friendly Societies. The chairman said:

“There is in evidence, however, another development less desirable in its reaction upon the life of the nation. Useful though these schemes of national health insurance are, there is a very real danger in their over-development. Any scheme, however good, which removes the incentive to provide for the future, and encourages all and sundry to look to the State to make provision for that future, forgetting all too often that they themselves are the State, must tend to weaken the national fibre, which thrives and develops in an atmosphere where thrift is fostered and where self-reliance and independence are fostered.”

He (Colonel Fremantle) could not believe that excessive prescribing was in any way associated with the increase of sickness, owing to the industrial difficulties through which the country had passed. They had seen the death-rate figures steadily coming down year after year from 1921, and an even more definite indication of health conditions was the fact that infantile mortality had steadily gone down. It was quite true that there was a small rise in this very accurate index of the health of the nation during 1924 and 1925, but the decline after that continued, the figures being 75, 70, 70, and 65, respectively. Yet another index of sickness was the tuberculosis death-rate. The number of deaths from pulmonary tuberculosis had gone down from 33,000 to 29,000 per annum, and the number of deaths from other forms of tuberculosis had gone down from 10,000 to 7000. He did not believe that there was any real increase of sickness among the people. Some of the very best and most useful health work done throughout the country was done by voluntary societies and voluntary hospitals, and he hoped that every effort would be made to encourage these schemes in the future administration of local government and of the health services of the country, not least in connexion with the post-graduate hospital which had been so warmly commended on every side, though, he thought, a little without regard to the difficulties that there must be in enlisting the voluntary skill and experience and efficiency which were at present associated with the medical schools in London and elsewhere in the country. He hoped this new post-graduate hospital, founded with such excellent intentions after so many difficulties and failures, would manage in some way—though it was difficult to realise how—to enlist the best sympathies and efforts of all the 13 medical schools in London, and that they would expect the creation of the greatest post-graduate medical school in the world, and certainly in the Empire.

Treatment at British Spas.

Mr. PENN appeared to the Minister of Health to sanction the inclusion in additional insurance benefits of treatment at British spas for rheumatism and allied diseases. At present the cost of such treatment was beyond the means of the vast majority of the workers. The British Spas Federation had drawn up a scheme for the consideration of the Ministry and the approved societies. They had come to an agreement with the British Medical Association in regard to the scale of fees under which exactly the same medical service and treatment now given to private patients would be

available for insured persons. It was approximately 18s. a week for the baths and course of treatment. The medical fees worked out at 7s. a week, or a guinea for a course of three weeks' treatment. At the moment no hostels or institutions were provided, but he believed that arrangements had been made whereby at a cost of 35s. a week good, high-class accommodation could be provided for those attending and taking treatment. That meant that at an approximate inclusive cost of £3 or 3 guineas a week, if approved societies were encouraged to make this one of their additional benefits, treatment at English spas, similar in every way to that enjoyed by those who had the means to undergo it, would be at the disposal of insured persons.

REPLY TO THE DEBATE.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health), replying to the debate, said that taking the total increase of £216,573 for administration in England and Wales, this was accounted for as follows: £50,000 in automatic increments, £18,000 due to the cost of living increase, £118,000 due to the administration of new services, £11,000 in respect of the increase of the whole-time dental staff, and £11,000 due to various increases in regard to initial expenditure on medical staff. It was under Sir Kingsley Wood's administration that the men's sickness claims rose from 76 to 107 per cent. of expectation and disablement claims went up from 54 per cent. to 100 per cent. It was also under the right hon. gentleman's administration that the regulation allowing panel patients to change their doctors at very short notice was begun. But she did not intend to follow the right hon. gentleman in the manner and temper of his speech. This was really a very big and somewhat obscure question, and it was not new. The truth was that these claims had risen steadily from 1921 to 1928; 1928 was the peak year. The number of claims had not been analysed for the two later years, but she would give some figures as to the total amount paid in benefits. In this total she was adding in for the last two years for comparison the £2,000,000 transferred to the Widows', Orphans' and Old Age Pensions Fund. In 1927 the amount rose to £18,135,000. In 1928 it went down by nearly £1,000,000—adding in the £2,000,000—and then rose again in 1929 to £19,600,000; but in the opinion of the experts the increase was wholly due to the lamentable influenza epidemic of the earlier months of the year. The figures were dropping now in the earlier months of this year. It was very remarkable that the duration of sickness had hardly risen at all, but there had been an increase in the number of claims in respect of short illnesses. If that were due to improper certification, the practice might increase, but it was not so, because the statistics were almost unaltered during those years. That led one to believe that there were other reasons besides those which had been stated. She asked the Committee not to pass any rough-and-ready judgment on this mass of very confused statistics. The report which had been issued was one of the most valuable things that either the medical profession or the approved societies had ever had. The Ministry proposed to follow up the report and to give the information year by year. The approved societies and the medical profession had now rather changed their mind and were inclined to think that a somewhat longer period within which a patient might change his doctor was necessary. The British Medical Association and the Council of Approved Societies had drawn up a scheme under which they would be able to review the case of any one of their professional brethren.

Dr. MORGAN: Will the hon. lady consider the possibility of a doctor who is unpopular, not for medical reasons, being dealt with unjustly by his colleagues who differed from him not medically but for other reasons?

Miss LAWRENCE said that she thought that the general medical opinion of the district was very much better and more acceptable for correcting any eccentricity in a medical man, because the representatives of all the persons concerned were considered.

Sir KINGSLEY WOOD asked if Miss Lawrence would give a little more information to the Committee about the new regulation in relation to the penalisation of doctors and the method of dealing with the matter?

Miss LAWRENCE said that the British Medical Association, the Conference of Panel Committees, and the Consultative Council of Approved Societies had agreed that where there was anything abnormal in a doctor's certification a panel committee should be chosen from the panel doctors in his own area to review the case.

Mr. MCSHANE: Is it not true to say that every one of those doctors who are going to sit in judgment is an interested person?

Miss LAWRENCE said that was so in a sense. The panel practitioners in a district have a common interest in maintaining the professional prestige of their brethren, and they also have a pecuniary interest in not cutting down too much

the fees of any member of their body. They would report to the Minister who would have in reserve the usual powers where a case was proved of deducting something from the remuneration of the practitioner concerned.

Dr. MORGAN: Will the practitioner have the right of appeal?

Captain GUNSTON: Would the hon. lady say what action is going to be taken if it is found that a doctor has behaved wrongly? Is he going to be debarred from practice?

Miss LAWRENCE said the usual method was to make a certain deduction from the remuneration of the doctor concerned.

Mr. T. LEWIS: Will the approved societies or insurance committees have any part in this review?

Miss LAWRENCE: No. It has been agreed that it shall be the panel doctors in the locality who will investigate such matters.

The debate was adjourned.

MINISTRY OF AGRICULTURE VOTE.

ON Monday, May 12th, the House of Commons went into Committee on a vote of £2,312,310 for salaries and expenses of the Ministry of Agriculture.

Mr. BUXTON (Minister of Agriculture) stated that the sum devoted to research and education had now risen to £750,000. A survey ship for fishery research was to be built at a cost of £80,000. This work was also of great importance in connexion with river pollution. It was undoubtedly a public scandal that so many of our delightful rivers were being turned into open sewers. In regard to the Royal Veterinary College, the Treasury had sanctioned a grant of £100,000 from the Development Fund on a £1 for £1 basis. The Colleges ought to be rebuilt at the earliest possible moment, and the Ministry would be prepared to help in every possible way.

Tuberculosis in Cattle.

Dr. HASTINGS drew the attention of the Minister of Agriculture to the question of tuberculosis in cattle. He said that the question was an important one for farmers, because the cattle most affected were milch cattle, and they did not contract the disease in their early years, but when they had reached the milk producing age. He asked the Minister if he could give any accurate estimate of the number of cows so affected. It had been suggested that they numbered nearly 1,000,000, or 40 per cent., of the milch herds of this country. Something between 4 and 8 per cent. of the samples of milk exhibited for sale were found to contain tubercle germs. About 2000 deaths occurred each year among human beings as a result of infection by the bovine bacillus. As far as they knew the germs reached the human subject in nearly every case by means of milk. Apart from deaths, 20,000 persons were affected by the disease. It affected young children more than adults, and was the cause of 46 per cent. of the cases of glandular tuberculosis, 60 per cent. of the cases of lupus, and 66 per cent. of the cases of tuberculous meningitis. He would like to know what was being done to mitigate and cure this terrible evil. It had been suggested that by pasteurising milk everything necessary was done, but by pasteurising an impure article they did not make it pure; the toxins and bacteria were not destroyed. There was also clear evidence that certain changes took place in milk as the result of pasteurisation. There was clear evidence that the calciums contained in milk were changed by heating and became less digestible and less easily absorbed. Experiments showed that children did not do so well on pasteurised milk. So in the interests of mankind, as well as those of the citizens and farmers of this country, it was desirable that the Ministry of Agriculture should do everything in their power to eradicate tuberculosis from the cattle of this country. So far as he knew their chief activity in the matter centred round the Tuberculosis Order, 1925. From a report issued for 1928 he noticed that something like 1700 cattle have been slaughtered; 162 cattle, or 1 per cent., were so bad that they died before there was time to slaughter them. It was also interesting to note that out of 347 cattle reported as giving tuberculous milk, 204 had no lesions of the udder at all. Did the Minister believe that the eradication of tuberculosis in cattle was going to be effected by merely destroying animals which were so badly infected that 1 per cent. of them died before there was time to slaughter them? In his opinion nothing short of the complete eradication of the disease in cattle would do what was necessary. It seemed to him that what was being done under the Tuberculosis Order was merely to destroy cattle after a good deal of mischief had already been done. Were the cowsheds in which these animals lived disinfected, and were experiments being carried out by the Ministry in regard to the immunisation of calves against tuberculosis or the rearing of stock which was not susceptible to that disease? Another point was that farmers in this country had to pay for the T.T. certificates, and also the fees of veterinary

surgeons who tested their cows. In Denmark, he understood, the services of veterinary surgeons, and the tuberculin used for testing, were given free, and it would be very useful if the same thing could be done in this country. There was another method which he suggested might be adopted by the Ministry—namely, the method of "accredited" herds. Under that method which was in use in America, farmers were assisted to have their herds tested, and as soon as "accredited" herds were produced in any number in a district, an attempt was made to establish what was known as an "accredited" area. Where 75 per cent. of the farmers wished to form an "accredited" area, compulsion was used on the rest, so that the herds might be made free from tuberculosis.

Reply to the Debate.

Dr. ADDISON (Parliamentary Secretary to the Ministry of Agriculture), replying to the debate, said that the position of this country with regard to agricultural research was a discredit to an intelligent community. For the last few years we had been spending millions in compensation for animals which had been burned in connexion with outbreaks of disease. It was only the other day that we began to spend any substantial amount on research in the cause of prevention of foot-and-mouth disease, after we had spent at least £10,000,000 in compensation for animals which were destroyed because they were thought to be infectious. That remark applied to our attitude with regard to many other animal diseases. Some years ago, in regard to medical research and scientific industrial research, the then Government, of which he was a Member, got together a committee to exercise a general oversight, and to give comprehensive advice as to the lines which that research might take, the type of cases where research might be undertaken, and so on. They were now engaged in considering a provisional report with the idea of seeing whether they could adapt that kind of suggestion to agricultural research. It seemed to him, without being committed at this stage to the recommendations, which they had only seen for a few days, that the committee offered the most helpful possible suggestions. It was quite evident that if they were going to have organised, well-directed research, designed to remove the chief causes of waste and loss in agriculture, they must have some machinery of that kind. That was the committee had been investigating the matter during the last few weeks. The vote was agreed to.

HOUSE OF LORDS.

WEDNESDAY, MAY 7TH.

Workmen's Compensation (Silicosis) Bill.

The Committee stage was concluded, and the Bill was reported without amendment to the House.

HOUSE OF COMMONS.

WEDNESDAY, MAY 7TH.

Health Insurance in Scotland.

Mr. STEPHEN asked the Secretary of State for Scotland if he would consider the introduction of legislation to protect the rights of employed men and women on the lines of the prolongation of Insurance Acts, in view of the fact that otherwise thousands of men and women would cease to be eligible for health insurance benefit at the end of this year.—Mr. JOHNSTON (Under Secretary for Scotland) replied: I am aware of the position mentioned by my hon. friend, and the matter is being considered by my right hon. friend, the Secretary of State, in consultation with the Minister of Health.

THURSDAY, MAY 8TH.

Notification of Psittacosis.

Mr. MANDER asked the Minister of Health whether it was the intention of the Government to make psittacosis a notifiable disease, in accordance with the recommendations of the health section of the League of Nations.—Mr. GREENWOOD replied: In view of the obscure nature of psittacosis I am advised that it is unlikely that any useful purpose would be served by compulsory notification of the disease. Medical practitioners and others have already been invited to report suspected cases of psittacosis to the local medical officer of health, or to my department, and I have no reason to suppose that this procedure is not being followed. The recommendation in favour of notification to which the hon. Member refers is, so far as I am aware, only an expression of opinion by the compiler of a recent review of psittacosis published in the monthly Epidemiological Report of the Health Section of the Secretariat of the League of Nations.

Progress of Housing.

Mr. SIMON asked the Minister of Health if he would state what was the total number of houses completed since the termination of the war up to the latest convenient date; and what proportion of these houses were for letting.—Mr. GREENWOOD replied: The total number of houses completed in England and Wales since the termination of the war up to March 31st last, including houses of a rateable value not exceeding £78 (or £105 in the metropolitan police district) erected by private enterprise without State assistance, is approximately 1,463,000. I regret that I am unable to say what proportion of these houses are for letting; the number of houses erected by local authorities was 62,769, and the great majority of these were built for letting.

Child Mortality in India.

Mr. FREEMAN asked the Secretary of State for India how many children, per 1000, born in India died during their first year; and to what extent this was estimated to be due to the effects of opium.—Mr. WEDGWOOD BENX replied: The rate per 1000 of deaths of children under 1 year old in 1927 (the latest year for which figures are available) are: males, 174.1; females, 159.30. I am not aware of any attempt having been made to estimate to what extent, if any, this death-rate is due to the effects of opium.

Preservatives in Cream.

Brigadier-General CLIFTON BROWN asked the Minister of Health whether he would withdraw the order forbidding the use of preservatives in cream which had caused a reduction of that article with a consequent loss to agriculture and an increase of unemployment in the business concerned.—Mr. GREENWOOD replied: Representations on this subject were recently made to my right hon. friend, the Secretary of State for Scotland. I am considering the question in consultation with him, and a decision will be announced as soon as possible.

Maternity Accommodation.

Dr. HASTINGS asked the Minister of Health the number of maternity beds recognised by his department for grant in voluntary and municipal institutions respectively.—Mr. GREENWOOD replied: On April 1st, the date on which grants for such purposes were placed on the new basis under the Local Government Act, there were 1638 maternity beds in voluntary institutions, and 1023 such beds in municipal institutions, in respect of which grants were paid by my department.

National Medical Services.

Mr. FREEMAN asked the Minister of Health whether his attention had been called to the proposals of the British Medical Association to nationalise the medical services of this country; and what steps, if any, he proposed to take to give them practical effect.—Mr. GREENWOOD replied: I assume that my hon. friend refers to the proposals described by the Association as proposals for a general medical service for the nation. These proposals have only recently been published, and I have not yet had an opportunity of considering them closely; but I do not gather that they are intended to have any such effect as is indicated in the question.

Health of Teachers.

Dr. VERNON DAVIES asked the President of the Board of Education (1) if he had any statistics as to the health of men and women teachers; and if there was any evidence to show that the health of women teachers was not as good as that of men teachers; and (2) if he could express in percentages of the number of teachers employed in either sex the 347 men and 1000 women teachers who were granted infirmity allowance for the three years ending March 31st, 1930; and if these allowances were for life or for a limited period of time.—Sir CHARLES TREVELYAN replied: The infirmity allowances awarded in the three years ended March 31st, 1930, represent in the case of men 0.2 per cent. of the total number of teachers employed, and in the case of women 0.4 per cent. These allowances are awarded for life. These figures show that a higher percentage of women qualify for infirmity allowances; but I have no other evidence which would justify me in drawing a comparison between the sexes in the matter of health.

MONDAY, MAY 12TH.

Dangerous Drugs in India.

Mrs. HAMILTON asked the Secretary of State for India whether the Government of India had recently authorised the cultivation of the coca plant and the manufacture of cocaine.—Mr. WEDGWOOD BENX replied: No, Sir. The facts of the case are that recently the Government of India, in order to strengthen the means at their disposal for carrying out their obligations under the Geneva Convention, placed before the Indian Legislature a Bill to control the traffic of

dangerous drugs. One clause of the Bill prohibited the cultivation or gathering of the coca plant, and to this clause the select committee added the proviso that the prohibition did not apply to the cultivation or gathering of the plant by Government, the object being to allow Government to grow the coca plant and to experiment in the manufacture of cocaine if at any time it were thought desirable that the cocaine required for proper medicinal uses in India should be produced in India. This appears to be the foundation of the incorrect report that the Government of India have authorised the cultivation of the coca plant, and the manufacture of cocaine. No action in this direction has been taken nor, so far as I am aware, is any contemplated. The Dangerous Drugs Act, which has passed into law, merely makes this legally possible.

Medical Examination of Pensioners.

Dr. HUNTER asked the Minister of Pensions whether he would arrange forthwith that no further medical boards should be held on pensions (except on deterioration claims, errors of final awards, Article 9 claims, or setting aside cases), and that the present assessment, whether on a deterioration or current award basis, should be made as current for the next three years.—Mr. F. O. ROBERTS replied: The number of cases in which further medical examination is requisite is now reduced to very small proportions. I have full sympathy with the hon. Member's desire, that medical re-examination should be reduced to the minimum possible, and it is the practice of the Department to give prolonged awards wherever justifiable. But I have no power to authorise awards which are not covered by medical certification, or to refrain from awarding a permanent settlement in those cases which are suitable for it.

Dr. HUNTER asked the Minister of Pensions whether he was prepared to take the necessary steps to make statutory all awards, whether errors of final awards, or on over seven years' claims, so as to give the same rights to these pensioners as to others.—Mr. ROBERTS replied: Legislation of the kind referred to is not contemplated as either necessary or desirable. The mere grant of statutory powers to make awards of the two classes referred to would not, of itself, confer material rights which pensioners do not already possess.

TUESDAY, MAY 13TH.

Merchandise Marks Orders.

In reply to Sir Nicholas Grattan-Doyle, Mr. WILLIAM GRAHAM (President of the Board of Trade) stated that the classes and descriptions of imported goods in respect of which Orders in Council had been made under the Merchandise Marks Act, 1926, requiring them to bear an indication of origin, included surgical, medical, dental, and veterinary instruments and appliances; aseptic hospital and dental furniture, and dental supplies; cotton-wool, gauze tissues, sanitary towels, spring balances, and scientific glassware.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A meeting of the Council was held on May 8th, with Lord Moynihan, the President, in the chair.

Prof. L. G. Parsons and Mr. Seymour Barling attended, and on behalf of the medical staff of the Birmingham General Hospital presented a replica of Partridge's portrait of Joseph Hodgson, president of the College in 1864.

Diplomas of Membership were conferred on 130 of the candidates whose names we gave on May 3rd as recipients of the L.R.C.P. (excepting A. H. Baker, C. C. Bryson, W. W. Gerrard, C. C. Kapila, J. I. Rennie, and Samuel Scher) and also upon Julia A. Boyd, Royal Free, and Laura M. Hollingsworth, University College.

Lord Moynihan was reappointed representative of the College on the Court of Governors of the University of Sheffield for three years from July 1st.

The President also reported that a vacancy on the Court of Examiners occasioned by the retirement of Mr. Graham Simpson would be filled at the next meeting of the Council.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—A quarterly meeting of the College was held on May 6th, with Sir Norman Walker, the President, in the chair.

Dr. James Kirkwood Slater, Dr. John Henry Douglas Webster, and Dr. Sydney Watson Smith were introduced and took their seats as Fellows.

Lieut.-Colonel William Frederick Harvey and Dr. Herman Petrus Gunnar were elected to the Fellowship.

Dr. John Orr was elected a representative of the College on the committee of management of the triple qualification

The Parkin Prize was awarded to Prof. R. J. S. McDowall.—The award of the Lister Fellowship was divided equally between Dr. Ralph Stockman Begbie and Dr. Donald Stewart.—Dr. W. A. Alexander was granted recognition as a lecturer on the practice of physic.—The College decided to celebrate the 250th anniversary of its foundation on St. Andrew's Day, 1931.—Intimation was made of a bequest by Mrs. Isabella Kirk Duncanson for the foundation of a Fellowship in medical research.

ON May 10th Dr. H. B. Brackenbury, chairman of the Council of the British Medical Association, was admitted to the freedom of the borough of Hornsey. He was mayor of Hornsey in 1905 and has been a member of its council for 26 years.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—The next series of lectures and demonstrations on tropical hygiene, which are intended for those outside the medical profession who are going to the tropics, will be given by Lieut.-Colonel G. E. F. Stammers, between May 28th and June 6th. The lectures will be from 5.30 to 7 P.M., and full particulars may be had from the Secretary of the school, in Keppel-street, W.C.1.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held at Blackburn on May 30th and 31st. Dr. J. J. Buchan will open a discussion on the Reorganisation of Poor-law Hospitals under the Local Government Act, and Dr. V. T. Thierens will speak on the Need for Further Legal Powers with Respect to Ice-cream.

LONDON HOSPITAL MEDICAL COLLEGE.—The distribution of prizes in this college will be made by Lord Rayleigh, F.R.S., on Tuesday, June 24th, at 3 P.M.

BIOCHEMICAL SOCIETY.—A meeting of this society will be held at the School of Medicine, Leeds, to-day, Saturday, May 17th, at 3 P.M.

NATIONAL PHYSICAL LABORATORY.—The President of the Royal Society, as chairman of the General Board, is holding a reception at the National Physical Laboratory, Teddington, on the afternoon of Friday, June 27th.

WEST SURREY HOSPITAL LEAGUE.—Last year the Royal Surrey County Hospital at Guildford received £6831 from this League, which is equivalent to one-third of the year's ordinary expenditure. The League, formed only two years ago, has a membership of 20,000.

UNIFORMITY OF HOSPITAL POLICY.—It has been arranged that the Birmingham General Hospital and the Queen's Hospital shall interchange representatives at the meetings of the respective boards of management. It is hoped thus to secure greater uniformity of policy.

KING'S COLLEGE HOSPITAL.—Last year there were 7006 in-patients, and the daily average of patients received was 349; in addition, 674 babies were born in the maternity ward. At the end of the year the hospital had a debt of £25,867.

HERTFORD BRITISH HOSPITAL, PARIS.—At the request of the committee of management Lord Tyrrell, the British Ambassador, who is honorary president, has appointed a commission of inquiry to report on the necessity of modernising and enlarging this hospital. The members are Lord Linsithgow (Chairman), Sir Basil Mayhew, Mr. Herbert L. Eason, Mrs. Loch, Mr. Evelyn M. Toulmin, and Mr. R. H. P. Orde, honorary assessor to the commission. The accommodation of the hospital has become insufficient to meet the growing demand for admission by members of the British community in Paris and British subjects from all parts of the Empire.

BRISTOL HOSPITALS.—On May 1st Lord Moynihan opened a new operating theatre at the Bristol General Hospital. He had come to Bristol a few years ago, he said, and had inspected a theatre in this hospital which he had described as the worst theatre in a first-class teaching school in this country. He had now come back to open one that was as good as any that he had seen anywhere. On his previous visit he had come as a friend and critic, and had judged the institution by the very high standard which modern surgery demanded. Judged by such standards it still fell short. In Bristol there were two hospitals, and he thought it a mistake that they had not amalgamated. It was not right that the General Hospital and the Royal Infirmary should be separated, and unless they amalgamated themselves they would find that someone outside would do it for them—and less satisfactorily. The university should be the centre of research, and all the work that the hospital was capable of doing. Lord Moynihan concluded by congratulating his audience on what they had done, and by fervently hoping that they would do much more.

LEBANON HOSPITAL.—Dr. Bedford Pierce will take the chair at the thirty-first annual meeting of this hospital, to be held in the vestry hall of St. Martin's-in-the-Fields, at 3.30 p.m. on Friday, May 23rd. The hospital is at Asfuriyeh, near Beirut, and is the only one of its kind in Syria.

MALARIA IN SOUTH AFRICA.—The Union Government, having definitely decided to start a scientific investigation into the malaria menace in South Africa, has appointed Prof. N. H. Swellengrebel, of Amsterdam, to conduct the necessary research. He is expected to go to South Africa in September. It is stated that Colonel S. P. James, of the English Ministry of Health, was invited to undertake the work, but was unable to do so.

LEPROSY RESEARCH IN SOUTH AFRICA.—The committee appointed to advise the Union Government regarding leprosy research and other matters relating to leprosy in the Union was gazetted on April 11th, as follows: Dr. J. A. Mitchell, Secretary for Public Health and Chief Health Officer for the Union, chairman; Sir Spencer Lister, Director of the South African Institute for Medical Research, or his deputy, Prof. A. W. Falconer; Prof. O. K. Williamson; Dr. A. Pijper; Dr. A. J. Orenstein; Dr. Karl Bremer, M.P.; Dr. F. C. Wilmot, Assistant Health Officer for the Union; and Dr. G. W. Robertson. The appointments are for the period ending December, 1935, and the Committee is to meet annually or more frequently as convened by the chairman.

NORTHAMPTON GENERAL HOSPITAL.—Mr. Thomas Singhurst, of Northampton, has offered £10,000 for the provision of an in-patients' ophthalmic department of this hospital. Mr. Singhurst gave an out-patients' ophthalmic department to the hospital six years ago.

STUDENTS' BEDS AT BIRMINGHAM.—As the result of their annual carnival on behalf of the hospitals of the city the students of Birmingham University last week endowed, at a cost of £1250 each, two more beds at the Queen's Hospital. Fifteen beds have now been endowed from this source. The carnival produced a total of £6700.

QUEEN'S HOSPITAL FOR CHILDREN.—Patients' contributions have risen from £3121 in 1925 to £6605. The first part of an extension scheme, which is about to be begun, will include accommodation for nursing mothers in connexion with a ward for babies, which is to be built with money from the Children's Jewel Fund. Sir James Carmichael is building an extension of the Little Folks' Home at Bexhill which will provide room for ten more children and accommodation for the nurses.

DESTROYING AN ISOLATION HOSPITAL.—Following the recent example of the Tcevil town council the corporation of Doncaster have set fire to their old isolation hospital which has just been replaced by a new institution. Most of the buildings were of wood and corrugated iron, and it was feared that if they were preserved they might spread infection. Carr House, the original hospital, was formerly the residence of the Childers family, and there, in the middle of the eighteenth century, was bred the famous racehorse, "Flying Childers."

UNIVERSITY COLLEGE HOSPITAL.—Last year 8374 in-patients and 77,129 out-patients were treated. The cost per occupied bed was £181, a reduction of £4. The patients' dietary has been revised and supplemented by adding meat broths and soups of milk and jam, and the prejudice of patients against even the best quality of margarine "has been partly overcome" by the issue of a half ration of butter. The provision of these extras will cost an additional £2000 a year. According to the annual report the new diet kitchen is "proving an invaluable aid to medical treatment, more especially in relation to specific diseases, such as pernicious anaemia, diabetes, &c."

A RHEUMATIC CLINIC IN BRIGHTON.—At a conference at Brighton on April 30th a resolution was carried unanimously favouring the establishment of a rheumatic clinic in the town. The gathering comprised representatives of the Brighton and Hove corporations; British Medical Association; Brighton and Sussex Friendly Societies' Council; Brighton Insurance and East Sussex Insurance Committees; Industrial Approved, British Red Cross (Sussex Branch), and Brighton and Sussex Mutual Provident Societies; Brighton and Hove Chamber of Commerce; and Brighton and Hove Hotels Association. The resolution recorded that the representatives of these organisations were strongly in favour of the establishment of a clinic locally, urged Brighton corporation to take the necessary steps at an early date, and appointed a subcommittee of one representative from each of the associations to arrange the details.

EXTENSION OF NELSON HOSPITAL.—Princess Mary has laid the foundation-stone of a new maternity wing and other extensions of Nelson Hospital for Wimbledon, Merton, and district. The Princess "proved" the stone with an oak mallet made of wood from the *Victory*.

EDENBRIDGE COTTAGE HOSPITAL.—On Saturday last Prince Arthur of Connaught laid the foundation-stone of the Edenbridge war memorial cottage hospital. The existing hospital was founded in 1920 in a temporary building; it is said to have been the first in England to start a contributory scheme, and it has never been in debt. A scroll was placed within the foundation-stone inscribed with the names of those to whom the hospital is a memorial.

MIDDLESEX HOSPITAL CHILDREN'S WARD.—This new ward, given by the late Mr. Bernhard Baron, came into use last week, when it was visited by Prince and Princess Arthur of Connaught. The ward, which is for surgical and medical cases, is brightly decorated, and the walls are covered with tiles upon which nursery rhymes are depicted; there is a deep blue dado and the cots are a bright blue. Upon arrival patients are placed in isolation wards separated by glass partitions where they remain for three or four days unless they have a clear medical history.

STAFFORDSHIRE MENTAL HOSPITALS.—Reports presented to the annual meeting of the Staffordshire Mental Hospitals Board showed that overcrowding exists in each of the three asylums—Stafford, Burntwood, and Cheddleton. At Stafford the excess over the authorised numbers is 98; and at Burntwood, where there are 417 patients, it is 30. The asylum visiting committee are pressing for the erection of an admission hospital at the latter institution. At Cheddleton (1133 patients) there is an excess of 34 females.

TRIBUTE TO A MEDICAL MAN.—Sir Garrod Thomas, M.D., who, for the last 25 years has been Chairman of the board of Directors of the Royal Gwent Hospital, at Newport, Mon., has been presented with a life-size bronze bust of himself, the work of Mr. L. S. Merrifield, and an album containing an illuminated address with 5000 signatures. Sir Garrod, who formerly sat in Parliament for South Monmouthshire, presented the bust to the hospital.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, Wimpole-street, W.

TUESDAY, May 20th.—5.30 P.M. GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8 P.M. PATHOLOGY. Special General Meeting. To consider the suggested change in the times of the meetings of the Section—viz., 5 P.M. instead of 8 P.M.

THURSDAY.—8.30 P.M. UROLOGY. Annual General Meeting. Election of Officers and Council. Discussion on The Technique and Results of Prostatectomy. Operative: Mr. Kenneth Walker. Followed by Mr. Swift Joly, Mr. John Everidge, Mr. Clifford Morsen, Sir John Thomson-Walker, and others.

FRIDAY.—8 P.M. EPIDEMIOLOGY. Annual General Meeting: Election of Officers and Council. Paper: Dr. P. Stocks: Infectiousness and Immunity in regard to Chicken-pox, Whooping-cough, Diphtheria, Scarlet fever, and Measles.

CHELSEA CLINICAL SOCIETY.

TUESDAY, May 20th.—7.30 P.M. Dinner at the Hotel Rembrandt, Thurlow-place, S.W., followed by a discussion on Sleep, to be opened by Dr. S. A. Kinnier Wilson and Mr. P. Seymour-Price.

LONDON CLINICAL SOCIETY.

TUESDAY, May 20th.—8.45 P.M. (at the London Temperance Hospital), Dr. A. Remington Hobbs: Puerperal Sepsis: Early Symptoms and Signs and Treatment by Drainage.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 19th, to SATURDAY, May 24th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Special Course, Lectures on Tuesdays and Fridays at 8.30 P.M. Tues., Dr. L. S. T. Burrell: Intrathoracic Tumours. Fri., Dr. L. S. T. Burrell: Bronchiectasis and Abscess of Lung. WESTERN OPHTHALMIC HOSPITAL, Marylebone-road, N.W. Wed., 11 A.M., Mr. Rugg-Gunn: Clinical Demonstration. No fee.—PRINCE OF WALES'S HOSPITAL, Tottenham, N. Fri., 2 P.M., Dr. L. R. Yealland, Clinical Demonstration. No fee.—CENTRAL

LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C. Last week of clinical course.—CENTRAL LONDON OPHTHALMIC HOSPITAL, Judd-street, W.C. Afternoon course, continuing for four weeks.—MAUDSLEY HOSPITAL, Denmark Hill, S.E. Course in Psychological Medicine. Clinical practice of hospital in addition to lecture-demonstrations.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon course, clinical instruction and lectures.—CITY OF LONDON HOSPITAL FOR DISEASES OF HEART AND LUNGS, Victoria Park, E. Second week of course. All day can be spent at hospital.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, May 19th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations. 4.30 P.M., Mr. N. B. Fleming: Some Fundus Conditions (Special Lecture).
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.
FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M., Medical, Surgical, and Children's Diseases Clinics. Operations.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, May 19th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Wards.
TUESDAY.—10 A.M., Medical Registrar: Medical Wards. 2 P.M., Mr. Hamblen Thomas: Throat, Nose, and Ear Dept. 2.30 P.M., Sir Henry Simson: Gynaecological Operations.
WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards. Dr. Scott Pinchin: Medical Out-patients.
THURSDAY.—11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department. 2 P.M., Mr. MacDonald: Genito-Urinary Department.
FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Department. 2 P.M., Mr. Sinclair: Operations.
SATURDAY.—9 A.M., Mr. Vlasto: Throat, Nose, and Ear Operations. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Children's Department.
Daily, 10 A.M. to 5 P.M., Medical, Surgical, and Special Out-patients, Operations, Ward Visits, Anaesthetic Courses.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

MONDAY, May 19th.—5 P.M., Dr. H. Haldin-Davis: Drug Eruptions.
TUESDAY.—5 P.M., Dr. J. E. M. Wigley: Napkin Area Eruptions in Infants.
THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Leprosy.
FRIDAY.—5 P.M., Dr. W. Griffith: Bullous Eruptions.
MONDAY, May 26th.—5 P.M., Dr. J. A. Drake: Streptococcal Infections of the Skin.
TUESDAY.—5 P.M., Dr. W. J. O'Donovan: Tuberculosis of the Skin.
THURSDAY.—5 P.M., Dr. W. N. Goldsmith: The Nervous System in Relation to Skin Diseases.

UNIVERSITY COLLEGE, Gower-street, W.C.

WEDNESDAY and THURSDAY, May 21st and 22nd.—5.30 P.M., Prof. F. J. Cole: The Early History of Generation and Comparative Anatomy. (Last two of six free lectures.)

ST. MARY'S HOSPITAL INSTITUTE OF PATHOLOGY, W.

THURSDAY, May 22nd.—5 P.M., Prof. C. A. Lovatt Evans: Stages in the Investigation of the Physiology of the Heart.

GREAT NORTHERN HOSPITALS POST-GRADUATE LECTURES.

WEDNESDAY, May 21st.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. Saxby Willis: Bronchiectasis.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

TUESDAY, May 20th.—5 P.M., Mr. A. L. Walker: The Causes of Maternal Mortality.

NATIONAL HOSPITAL POST-GRADUATE COURSE, Queen's square, W.C.

MONDAY, May 19th.—12 noon, Dr. Greenfield: Cerebro-spinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Collier: Subacute Combined Degeneration.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Mr. Armour: Spinal Injuries.

THURSDAY.—2 P.M., Dr. Rinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Julian Taylor: Trigeminal Neuralgia.

FRIDAY.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmqvist: Demonstration of Re-educative Methods (in Exercise Room).

UNIVERSITY OF BIRMINGHAM.

THURSDAY, May 22nd.—4 P.M., in the Medical Lecture Theatre, Edmund-street Buildings, Sir John Bland-Sutton: The Blood Trail. (Ingleby Lecture.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, May 20th.—4.15 P.M., Dr. R. S. Paterson: Radiology in Compensation Work.

FRIDAY.—4.15 P.M., Mr. W. R. Douglas: Demonstration of Surgical Cases.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

WEDNESDAY, May 21st.—4.15 P.M. (at the Western Infirmary), Dr. J. G. Tomkinson: Skin Cases.

Appointments.

HALLER, B. C., L.R.C.P. & S. Edin., D.P.H., has been appointed Medical Officer of Health and School Medical Officer, Bilston.

MURRAY, E. F., M.D., Ch.B. St. And., F.R.C.S. Eng., Hon. Gynaecologist, Royal Victoria Infirmary, Newcastle.

WILSON, EDWIN FRANK, F.R.C.S. Eng., Honorary Assistant Surgeon to the South Devon and East Cornwall Hospital, Plymouth.

Royal Infirmary, Manchester: RAYNER, H. H., F.R.C.S. Eng., Hon. Surgeon: SOUTHAM, A. H., M.D., M.Ch. Oxf., F.R.C.S. Eng., Hon. Assistant Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: DAGGER, R. L., M.D., B.S. Durh. (Morpeth); and SHANKEY, P. J., M.B., B.Ch. Belf. (Rhayader, Radnor.)

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital. H.P. £120.
Berkshire C.C.—Asst. Tub. O. and General Med. Asst. £600.

Birmingham P.H. Dept., Tuberculosis Section.—Temporary Asst. M.O. 7 gns. a week.

Birmingham, Queen's Hospital.—H.P., Res. Anesth., and Cas. H.S. Each £70.

Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.

Bolton Infirmary and Dispensary.—Res. Surg. O. £250.

Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.

Bristol, Clifton Dispensary, Dower-square.—Res. M.O. £300.

Bury St. Edmunds, West Suffolk General Hospital.—Jun. Res. M.O. £120.

Cambridge, Addenbrooke's Hospital.—Res. Anesthetist. Also H.P. At rate of £180 and £130 respectively.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Chelmsford Borough.—M.O.H. &c. £800.

Chingford, Hospital for Infectious Diseases.—Res. M.O. £200.

City of London Hospital for Disease of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

City of London Maternity Hospital, City-road, E.C.—Asst. Res. M.O. At rate of £80.

Colchester, Royal Eastern Counties Institution for Mental Defectives.—Jun. Asst. M.O. £350.

Cumberland C.C.—Asst. County M.O.H. £600.

Derbyshire Education Committee.—Asst. School M.O. £600.

Doncaster Royal Infirmary.—2nd H.S., 3rd H.S. Each £150.

Also two Hon. Anesthetists. 50 gns.

Dreadnought Hospital, Greenwich.—Anesthetist. At rate of £160.

Durham County Hospital.—Sen. H.S. At rate of £125.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. Also H.P. Each at rate of £125.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Med. and Surg. Regs. Each £100.

Elvelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

Fleetwood, Rossall School.—Res. M.O.

Gloucestershire Royal Infirmary and Eye Institution.—H.P. and H.S. At rate of £135 and £100 respectively.

Gl. Barrow, nr. Chester, East Lancs. Tuberculosis Colony, Barrowmore Hall.—Asst. M.O. £250.

Great Yarmouth General Hospital.—H.S. £125.

Guildford, Royal Surrey County Hospital.—Res. Med. and Surg. O. and Reg. £250.

Halifax Royal Infirmary.—3rd H.S. At rate of £125.

Herford County Hospital.—H.P. At rate of £150.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Psychiatrist. Two Med. Regs. Also Clin. Path.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. Also H.P. Each at rate of £100.

Huddersfield Royal Infirmary.—H.S. At rate of £150.

Hull Royal Infirmary.—H.S. At rate of £150.

Liverpool School of Tropical Medicine, Pembroke-place.—Research Asst. £400.

London Hospital, E.—Cardiographic Dept. Paterson Research Scholar. £400.

London Lock Hospital, 91, Dean-street, W.—Hon. Surgeon to Out-patients.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester City.—M.O. for Maternity and Child Welfare Centres. £600.

Manchester Royal Children's Hospital.—Sen. M.O. to Out-patient's. £300.

Manchester Royal Eye Hospital.—Jun. H.S. £120.
Manchester Royal Infirmary.—Surg. O. to Out-patients. £35.
Manchester, W. Thimpton Hospital, &c., Neth-lane, West Didsbury.—
 Three Jun. Asst. M.O.'s. Each at rate of £275.
Miller General Hospital, Greenwith-road, S.E.—Pathologist.
 £600. Out-patient Office. At rate of £150. H.P., and
 H.S. Each at rate of £125.
Milham Junction Isolation Hospital.—Asst. R.M.O. £200.
Nottingham General Hospital.—2nd Cas. O. At rate of £150.
Perth, County and City Royal Infirmary.—Jun. H.S. Also H.P.
 Each £100.
Perth Prison and Criminal Lunatic Dept.—M.O. £440.
Plymouth, City of.—Deputy M.O. £1750.
Plymouth City Hospital.—Res. Med. Supt. £1000.
Plymouth Royal Hospital.—H.P., 3rd H.S. Each at rate of
 £130. Also Cas. O. At rate of £100.
Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—
 Asst. Res. M.O. At rate of £80.
Rotherham County Borough.—Asst. M.O.H. &c. £700.
Rotherham Hospital.—Sen. H.S. £200.
Royal Free Hospital, Gray's Inn-road, W.C.—H.P.'s and H.S.'s
 to Special Depts. Obstet. H.S. £150. Also District
 Obstet. Asst. £100.
Royal London Ophthalmic Hospital, City-road, E.C.—Nine
 Out-Patients Officers. Each £100.
Royal National Orthopaedic Hospital, St. Portland-street, W.—
 Hon. Anesthetist.
St. Bartholomew's Hospital, E.C.—Physician.
St. Mary's Hospital, W.—Surgical Registrar. £200.
Saint Pancras Dispensary, 39, Oakley-street, N.W.—Res. M.O.
 £185.
Salford, Lancs., Hope Hospital.—Asst. M.O. At rate of £250.
Salford Royal Hospital.—H.P. Also Cas. H.S. Each at rate of
 £125.
Sheffield, Jesson Hospital.—Res. M.O. £175.
Sheffield Royal Hospital.—Res. Ophth. H.S. Also Res. Anes-
 thetist. Each at rate of £300.
Southampton Borough Hospital.—Res. M.O. £275.
Southampton, Royal South Hants. and Southampton Hospital.—
 Asst. H.S. and Cas. O. Each £180.
Stratham Babies Hospital, Leigham-court road, S.W.—Res. M.O.
 £100.
South-Eastern Hospital for Children, Sydenham, S.E.—Asst. and
 Res. M.O.'s. At rate of £100 and £75 respectively.
Sussex General and Eye Hospital.—H.S., Cas. O., and H.P.
 Each at rate of £150.
**Warwickshire, King Edward VII. Memorial San-
 atorium, Herford Hill.**—Med. Supt. £300.
West Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.
West London Hospital, Hammer-smith, W.—Hon. Surg.
West-Sussex, More General Hospital, Brighton, S.—H.S. £130.
Weymouth and District General Hospital.—H.S. £180.
Wilkes General Hospital, N.W.—H.P. £100.
Windsor, Ethel Hedley Hospital for Crippled Children.—
 Res. H.S. At rate of £150.
York Dispensary.—Res. M.O. £150.

Births, Marriages, and Deaths.

BIRTHS.

LEWEN.—On May 14th, at 83, Telgmoor-road, N.W., the wife of Dr. S. Charles Lewen, M.R.C.P., of a daughter.
O'NEILL.—On May 17th, at British Forces' Hospital, Karachi, the wife of Squadron Leader C. T. O'Neill, R.A.F. Medical Service, of a son.
PIDCOCK.—On May 8th at The Friary, Winchester, the wife of B. Henzell Pidcock, M.D., B.S., F.R.C.S., twin sons.
PUMPHREY.—On April 29th, at Kodai Kanai, India, the wife of Major Cyril M. Pumphrey, F.R.C.S.E., I.M.S., of a daughter.
SANDFORD.—On May 6th, at St. Barnabas Hospital, Saltish, the wife of Mr. F. Rossa Sandford, of a son.
WORSLEY.—On May 7th, at Black Torrington, Devon, the wife of Dr. R. Carmichael Worsley, of a daughter.

MARRIAGES.

SIMPSON-BEACH.—On April 29th, at the Church of the Holy Trinity, Prince Consort-road, Kensington, Charles Walter Simpson, M.B., B.Ch., of Beaconsfield, Bucks, to Margery Jean, second daughter of Mr. H. G. Beach, of Fordingbridge.

DEATHS.

BAKER.—On May 5th, at a nursing home, Frederick Grenfell Baker, M.R.C.S., L.R.C.P., L.S.A.
BRIDGMAN.—On May 10th, at Broomfield, Dawlish, Henry Edward Bridgman, M.R.C.S., L.R.C.P., formerly of Burton-on-Trent, aged 81 years.
HELM.—On May 12th, at Bradshaw-street, Moss Side, Manchester, William Alexander Helm, M.B., Ch.B., aged 58 years.
LANG.—On April 13th, 1930, at Jansenville, Cape Province, Arthur Joseph Lang, M.R.C.S., L.R.C.P., second son of the late Dr. and Mrs. John Lang (formerly of Southport, Lancashire).
MCCOWAN.—On May 2nd, Gladys, wife of Peter K. McCowan, M.D., M.R.C.P., Velindre, Whitechurch, Dr. Cardiff.
THOMAS.—On May 8th, at Bank House, Brecon, Thomas Price Thomas, M.A., M.R.C.S., L.R.C.P.
WEIGHTMAN.—On May 2nd, at Mylor, Cornwall, Edward John Weightman, M.B.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Notes, Comments, and Abstracts.

SHOULD MEDICINE BE A MENDICANT?

A REVIEW OF OUR HOSPITAL SERVICE.

Harveian Lecture delivered at the Harveian Society of London on March 13th

By ERNEST W. HEY GROVES, F.R.C.S. ENG.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL.

(Concluded from p. 1051.)

Voluntary System not Adaptable to Modern Developments of Medical Science.

MEDICAL practice used to be founded on the teaching of ancient masters, and it consisted in the empirical administration of drugs to sick people. Some handling of the patient was necessary to let out his poisoned blood, or to cover his sores, and his rather menial handiwork was relegated to the barber or chironom, whilst the inefficiencies of childbirth were relegated to the midwife. In such practice there was obviously no advantage in, or necessity for any institution, except for the feeding and lodging of the poor. The tradesman and well-to-do patient was attended at home. But for 300 years this crude application of empirical knowledge has been gradually replaced by scientific study of disease, and within the past century the rate of advance has been so much accelerated that in its last quarter everyone of us can look back on his own student days as a time when the science of medicine was comparatively simple and knowledge of disease restricted.

But however much medical science may grow as the mysteries of infinite nature are discovered, the practice of medicine still has to be carried out by human beings of very finite capacities. Therefore it is that the growth of knowledge has necessitated subdivision of labour—in other words, medical specialism. First of all there was the separation of surgeons, as a separate class from physicians, and their attainment of an independent status, then a long time later some physicians became accoucheurs and midwifery was accepted as a necessary specialism, whilst the development of optical science and optical instruments called forth the ophthalmic surgeon. The segregation of infectious fevers and of mental cases became necessary for protection of the rest of the community.

Thirty years ago specialism had not got much further than this. The general hospital had physicians, surgeons, physician-accoucheurs, and ophthalmic surgeons, whilst fevers and mental diseases were placed in isolated institutions with medical attendants of their own. But since that time scarcely a decade passes without some corner of the territory of medical knowledge being so enlarged as to demand special workers and explorers for its investigation and utilisation. Physician-accoucheurs have taken off their coats and scrubbed their hands and become surgeons and gynaecologists. Diseases of the ear, nose and throat have acquired a domain of their own; dental surgery, anaesthesia, pathology, bacteriology, public health, tuberculosis, radiology, and venereal diseases have established undisputed claims to separate recognition. Orthopaedic surgery has established an overwhelming claim which for various reasons has not been fully granted. Such subjects as neurology, cardiology, and genito-urinary diseases show a tendency to departmental segregation, but still for the most part form only subsections of the parent medical surgery. At the moment we are considering whether radiology and roentgen therapy is to be a new department or merely a new agent to be used by physicians, surgeons, and gynaecologists.

Some subjects—e.g., radiology—involve so much technical knowledge and apparatus that they become special departments very quickly. Others, such as orthopaedics, difficult of definition and being founded on general surgical principles, are very slow to be segregated. But I think no one will dispute that advance of knowledge and accuracy of treatment always follow the intensive study and teamwork, which is involved in making the war, both in regard to fractured femurs and facial injury. The treatment of gunshot fractures of the femur, which was a matter of terrible failure at the beginning of the war, became satisfactory just so soon as it was treated as a special subject, the patients being brought together, a team of surgeons and nurses trained to carry out the treatment, and a proper continuity of after-treatment secured. So whether we like it or not, we must face the fact that the giant growth of medical science, unaccompanied by a corresponding giant growth of supermen, can only be practised and

advanced by groups of men, taking each a special study and accumulating special experience. But, on the other hand, the patient, the sick or injured man, is only one, and his ailment must be studied as a whole, or at any rate by several men working in coöperation with one another.

Fission and Fusion.

Therefore both for the healing of the individual and for the advance of knowledge, it becomes necessary to provide for some living fusion of the parts of the medical organisation to counteract the necessary fission which every day differentiates its units more and more from one another.

A simile may be borrowed from the development of animal life. Both in growth of an individual from the ovum to the adult, and in the evolution of the race from the amoeba to man, two great processes take place in measured harmony. The cells divide and become differentiated from one another, both in structure and in function, so that at last a great variety of tissues and organs are produced. But this division and differentiation is accompanied by a coördination of all parts, controlled by a central nervous system. I think it may be fairly claimed that medical science in its growth and development must conform to these two natural and immutable laws: differentiation and coördination, or fission and fusion. It would be easy to push this analogy further. The team of students, doctors, and nurses working in any special department may be likened to one organ in the body, the hospital unit to a group of organs carrying out one special vital function, whilst the medical service of the country represents the living body as a whole. The general practitioners may be likened to the free and roving cells of the blood, constantly visiting each organ of the body in turn, giving to and taking from each.

But enough of a fanciful analogy, and let us return to plain facts. The growing complexity of medical science with its vital necessities of differentiation and coördination necessitates quite a different grouping of patients and doctors from that which sufficed 100 years ago, and was fairly satisfactory even at the beginning of the present century. Then it was reasonable to treat the rich man at his own home, and to collect the indigent in poor-houses of which the voluntary hospital was one variety. Now, not only has the distinction between poor and rich become less marked, but medicine has become a science which can only be applied under scientific conditions, and the classification should no longer be between rich and poor, but between one type of disease and another. If elaborate apparatus, special laboratories, expensive operating theatres, and a team of medical men and nurses are necessary to investigate the disease and to treat the injury of a poor man, then these are equally necessary in the case of the rich or middle classes. The middle classes have enough common sense to understand this quite well, and they do now actually form the bulk of the patients in our voluntary hospitals, whilst the unfortunate rich man has still to make shift with some arrangement improvised in his own mansion, or with the scanty resources of a small nursing home.

The general hospital of the future must take in patients of all social classes if they are suffering from disease which requires investigation and expert treatment. It must be large enough to include all the special departments of medicine and surgery. It must also be large enough to give the greatest economy in overhead charges, equipment, and personnel. In large centres of population, 600 bed hospitals would probably represent the best size of unit. Where multiple small hospitals exist, these should be amalgamated into groups with a single administration and a united staff. Isolated hospitals must be retained for certain types of cases—e.g., mental diseases, fevers, tuberculosis, and venereal disease.

Probably diseases of an essentially chronic and incurable nature in poor patients will also require special hospitals. But diseases of slow course but curable nature such as surgical tuberculosis and poliomyelitis, which necessitate special country hospitals, certainly should not be made on a class basis. All the arguments adduced above can be urged here for making centres of maximum efficiency, where patients of all social classes can be received.

In country districts and small towns where the ideal big hospital is not possible, small hospitals are a necessity, but they ought to be all brought into coöperation with the big hospital service scheme. Even the most remote country districts ought to be linked up with the county town or big city, so that medical practitioners can easily get the services of consultants, and patients can readily be transferred who require special treatment. A ten bed cottage hospital may be an inestimable boon to a country district, but that is no justification for trying to make it do the same work as is possible in the primary general hospitals, nor is it any justification for expecting the medical men who staff it to be experts in every branch of medical science. There should be no such thing possible as an isolated small hospital independent of supervision and control. Every such

hospital should be definitely linked with a large one, so that the freest exchange of consultation and patients can take place between one and the other. I believe that a system of this sort has already been adopted, with excellent results in the Highlands and Islands of Scotland.

Obstacles in the Way of Accomplishment.

The two first great obstacles which hinder the attainment of an ideal hospital service in this country are the voluntary or mendicant system upon which the great and teaching hospitals are dependent, and the lack of any central body with the knowledge and power to control and direct. The action of both these obstacles is well illustrated by the happenings in a large city with which I am well acquainted. Ten years ago it was urged that there existed in the district a pressing need of an open-air school hospital for chronic and curable disease, chiefly affecting children. This need is now being met by three perfectly independent bodies. The municipal authority is completing a hospital for surgical tuberculosis, a charitable organisation is opening a hospital for non-tuberculous diseases, whilst an existing children's hospital is enlarging its premises and making open-air wards in order to cope with exactly the same type of case as the other two. So that before long there will be three institutions each of 100 beds competing instead of coöperating, requiring three sets of administrative officials, three sets of apparatus, and, what is worst of all, three sets of experts. This lamentable and indefensible absurdity was foreseen, and an attempt made to prevent it, but when the promoters met together it was evident that they only really agreed about one thing, and that was the determination to maintain their independence, each one of the other, and so long as they depended upon independent sources of income no outside authority could be brought to bear upon them in order to force amalgamation, however much this might be for the common good. The Local Government Act of 1929 has gone a long way towards making possible a general unification of the hospital system. We await with interest its results. In its broad outline it brings together the municipal and voluntary hospitals. It removes the stigma of pauperism from the former institutions. It sets up a machinery whereby a local committee can bring about some coöperation between the two classes of hospitals. But it leaves untouched the fundamental error of regarding the great voluntary hospitals as institutions for the care of poor people which have to be maintained by the donations of the rich. And in its provision for coöperation it is rather permissive than authoritative. If in any locality there exists a broad-minded wish for amalgamation and coöperation, it provides the machinery by which this can be brought about. It is instructive to notice that up to the present Aberdeen seems to have gone furthest in adopting this plan of voluntary coöperation between the different types of hospitals. Aberdeen, which has gained a world-wide reputation for a canny care for money and of avoidance of waste! Just as you can tell an Aberdeen boat at a distance because no sculler thinks it worth while to follow in its wake to pick up what is thrown away, so Aberdeen leads the way in substituting coöperation for competition, so as not to waste money or skill in the provision of the best hospital service for the sick and injured.

It is often assumed that if we give up our cherished voluntary or mendicant hospital system, we shall have no alternative but that of State service, but this assumption is quite unjustified by the facts. There is no other country in which the voluntary hospital system is adopted to the same extent as in England. There are many countries in which the mendicant system does not exist at all, and in which a very nearly perfect hospital system does exist. Countries like Switzerland and Denmark have fine hospitals, but I suppose that in these it might be claimed that a State service is really responsible for them. But it is in the English-speaking countries, the United States of America, Canada, and other Colonies where modern hospital developments are most instructive to us. For all these places began with the English tradition of voluntary hospitals, but in all of them, although voluntary bequests for buildings and voluntary efforts in social service are utilised, yet in the main the finest hospitals in the world are maintained without resort to mendicancy and yet without State control. The guiding principles of these hospitals is that of making the institution one which admits all classes of the community and in which the middle-class patient pays for himself, whilst the rich patient not only pays for himself and the poor, but incidentally pays for the medical staff.

How to Overcome these Obstacles.

There are two obvious courses by which in England the evils of mendicancy can be abolished. One is by making the hospital suitable for all classes, and the other is by an extension of the insurance system, whether it is that effected by the State or that known as the contributory scheme.

There would still be a certain proportion of destitute persons who could not afford to pay for themselves and who were not insured. These would be paid for by the county or municipal authorities, as is now done when such patients have to be treated at the municipal hospitals. But many of the old hospitals which have invested endowments would be able to continue gratuitous treatment of indigent patients if once they were relieved of the unreasonable burden of treating the middle classes. To the really charitably minded persons who think that we ought to give hospital treatment freely to the genuinely destitute sick, the present system can afford but little comfort. For although the voluntary hospitals profess to be for poor people, yet in reality the pressure upon their accommodation is so great and financial stringency so urgent that the destitute person who cannot pay £1 a week is often pushed aside, whilst hospital beds are filled by tradesmen and professional classes. On the other hand, if the well-to-do and middle-class patient were adequately paid for by private fees or an insurance scheme, then the original funds bequeathed for the poor could be used for the purpose for which they were intended.

The patients who pay for themselves would also pay ordinary professional fees to the members of the medical staff who attend them. The staff would also receive a fixed salary in respect to the insured patients and those of no means, which would be met by money received from the insurance fund and from the profits made by the treatment of the paying classes. The practicability of this plan is beyond question because it is in actual existence in America, several of the Colonies, Switzerland, and elsewhere, although the financial details vary in each place. With us, the only real difficulty is the sentimental idea of the beauty and holiness of the voluntary system. I wonder how long this sentiment will survive the criticism of considered reason and the contemplation of the lengths to which mendicancy has been driven.

Appeals from the pulpit and from the press, through the wireless and at street corners recur with a wearisome monotony which makes us marvel that the term voluntary can still survive. Students and nurses are sent out to conduct a ribald harlequinade in the streets, in aid of the good cause, citizens are raided and held to ransom or offered the blackmail choice of purchasing an immunity ticket, the hoardings of the streets are covered by pitiful appeals, mechanical contrivances are set up in shop windows to lure subscriptions from the curious. A spotted dog offers to wink an eye for a shilling, or wag his tail for 2s. 6d. Lotteries, which the pious have declared to be immoral, are yet allowed in aid of this cause. Champagne supper parties are held at the Club in aid of military and charitable 1. And all this in the name of sentiment, which is revolted at the idea of reducing the conduct of hospitals to a decent self-respecting matter, of well-to-do patients paying for themselves and middle-class patients being provided for by insurance.

The adoption of a self-supporting system instead of mendicancy would at once solve the difficulty of maintenance, and there would be enough margin, too, to cover the provision and replacements of apparatus, but it would not meet the need of new buildings. We have drifted so far behind the times in the present generation that there is a great need for new and modern buildings. Quite apart from the replacement of several small hospitals by one large one, of bad old buildings, in unsuitable sites by good new ones in good sites, the new hospital system would be obliged to provide many more beds, because if the artisan and his family are insured for hospital treatment, then this would have to be provided, so that the scandal of waiting-lists with people kept out of work for months and years whilst they wait for their turn for a hospital bed would have to be abolished forthwith. The capital outlay on building would have to be met out of county and treasury funds, as would also be proper for the execution of work which would give employment to many who are now on the dole. The hospitals should be like the universities, in receipt of State aid, which does not involve State control

The Controlling Body.

But the solution of the financial difficulty by no means gives us any assurance of the ideal hospital system for which we are pleading. It merely removes the first and greatest hindrance to the realisation of our ideal. Once sweep away the mendicant principle, and then present hospital managers will no longer have any excuse or justification for behaving as though they controlled a proprietary institution. There will be no force tending to prevent hospital units from being organised into a hospital system. This raises a second great problem to be faced and that is, the constitution of the controlling and directing body, which shall organise and supervise the hospitals. The Hospitals Advisory Committee, set up by the recent Act,

might form useful local bodies, if once the voluntary hospitals gave up their independent position.

At present the committees are of unwieldy size. They contain representatives of all hospitals of the district, the majority being managers of voluntary institutions, whose first duty would seem to be to maintain the rights and prestige of the hospital they represent, rather than to evolve a system which shall serve the district as a whole. But in addition to the local committees there must be a central body under the guidance or control of medical experts, which shall be able to shape, direct, and supervise the hospital policy of the whole country. The Ministry of Health is not suitable to undertake this work any more than the medical officers of health are capable of undertaking all the responsibilities laid upon their shoulders by the Local Government Act. The Health Ministry represents experts in only one branch of the healing art—namely, that of preventive medicine. In the days of the war there was a council of consultants which worked in co-operation with the Army Medical Service. In like manner a council of consultants should be associated with the Ministry of Health, to direct the hospital policy of the country.

Only in this way will it be possible to adopt a progressive programme of reform, and to bring into one harmonious whole the big teaching hospitals, the municipal hospitals, the special hospitals, and the small hospitals in town or country districts. Every honest man, whether lay or medical, who has travelled abroad and seen hospitals in other countries must know that we have much ground to make up in respect of hospital construction and organisation, medical research, and education. The demand for reform and advance should come from the medical profession, and not be forced upon the country by party politicians, nor be compelled by a mere breakdown of that voluntary system which once was a noble philanthropy, but which now has degenerated into an indecent mendicancy, unjustified either by morals or necessity.

IDENTIFICATION BY TEETH.

FIRE, injury, or decomposition often make bodies unrecognisable after death, and in these circumstances the teeth afford useful means of identification. They nearly always bear marks by which their owner can be distinguished; they are more resistant to destructive agents than any other structure, and are well protected. Dr. Alexander Klein, of Vienna, says that a tooth which is suddenly exposed to intense heat will split into fragments, but if heated slowly it chars, the enamel cracks, and finally all organic components are destroyed, and only white ash is left. In the body, however, the overlying structures nearly always protect the teeth from complete destruction, especially when the victim of the fire, though unrecognisable through smoke and scorching, is not calcined. Moreover, fire spares most of the work of the dentist. According to the work of Wachholz and Lepkowski, quoted by Klein, amalgam and gutta-percha disappear completely, but gold and platinum remain unaltered. Phosphate and silicate cement fillings retain their shape and consistency, and are merely blackened; porcelain, metal plates, crowns, and bridges are unharmed.

Apart from dentistry there are many distinguishing marks a mouth may bear: few persons have no gaps, almost everyone has some teeth which are not in their right position or of the right height, and a certain small percentage have definite malformations, such as fused and supernumerary teeth or peg-teeth. It is obvious that the chief value of this method is to verify or contradict a suspicion. Klein, in an interesting if somewhat discursive account of the Kinchester disaster of 1881, relates that a mere description of the teeth enabled the relatives to identify some of the corpses, but when there is one calcined body and it is desired to know whether it is or is not that of a particular person, the dentist can nearly always clinch the matter beyond doubt.

Klein adds another to the stories of detection which depend on examination of the teeth. A diplomatic official in Chile complained of the wretched letters, and one night the embassy was burnt down and his charred body was found in the ruins and buried with great public lamentation and eulogy. The director of the Chilean dental school had his doubts and examined the jaws of the corpse an hour before burial. The next day he announced that the deceased was not the missing official; within a few days the latter was arrested on the frontier with the whole negotiable wealth of the embassy. The body was that of the night porter, who had never been to the dentist: although the murderer had been in particular pains to mutilate the teeth, they were easily distinguishable from his own as described in his dentist's records.

RED NOSE.

This distressing stigma, which is hardly mitigated by calling it erythema nasalis, has many origins. Dr. J. C. Warbrick enumerates¹ 13 causes which could be more conveniently classified as (1) local or intranasal, (2) reflex, as in rosacea, and (3) metabolic, as in renal and cardiac cases.

Any intranasal abnormality, whether mechanical or infective, or both, can give rise to passive congestion which in a terminal and exposed structure such as the nose will soon cause manifest and disturbing symptoms. The patient should be questioned about signs of nasal obstruction and referred to a rhinologist if there is evidence of such common conditions as a deflected nasal septum, chronic nasal catarrh, mucous polypi, or furunculosis in the atrium nasi.

Reflex causes are probably the most common of all those responsible for the red nose. A history of dyspepsia—associated, according to some authorities, with pronounced hypochlorhydria—and of concomitant facial flushing, can often be elicited and may explain the condition at once. There is no doubt that disorders of the uterus and adnexa are sometimes at the bottom of the symptom. Alcoholic excess, again, is an undoubted cause of erythema nasalis, but its existence is seldom admitted by the patient—probably because people whose red nose is a result of alcoholism do not usually bother to ask a doctor about it. Dilated veins are most apt to recur in this "reflex" group.

In the metabolic category we should have to consider such factors as the "chilblain circulation." In these cases the patients are mostly young girls with bluish rather than red noses. Cardiac and renal back-pressure may play a part in causation, but such cases are not likely to present themselves for the disfigurement alone. Dyspepsia due to a gouty diathesis or hepatic dysfunction—not necessarily causing hypochlorhydria—may explain why an apparently normal gastric content is sometimes revealed on analysis. Constipation, doubtless, acts in a similar way, and it always needs attention when present.

A recurrent cutaneous infection, such as a low-grade erysipelas, although difficult to imagine in a form localised to the nose, is mentioned by Warbrick. There is also the possibility of localised infection of the sebaceous glands, with or without acne, and that exceedingly rare affection of the adolescent youth known as hyperidrosis rubra nasi. Adenoma sebaceum, first classified by Pringle, and sometimes associated with a deficient mental development, is in the nature of a nevus and confined to girls.

These are the main causes of a red nose, although the list is by no means exhausted. The symptom may be part of a seborrhoeic tendency, with erythema and greasiness of the nasolabial sulcus and a scurfy scalp. It can also occur as part of the clinical picture in lupus erythematosus, psoriasis, and lupus vulgaris. It follows that all who aspire to success in treatment must possess a fairly extensive knowledge in the domain of general medicine, as well as the special experience that can only be acquired in the out-patient department of a dermatological clinic.

GIDEON MANTELL.

ON May 8th, at a house in Old Steine, Brighton, a tablet was unveiled bearing the following inscription:—"Here lived from 1833 to 1838, Gideon Algernon Mantell, Geologist." Besides being one of the pioneers of geology, Gideon Mantell was a medical practitioner. Born at Lewes, he served there an apprenticeship to a surgeon named James Moore, and afterwards qualified at St. Bartholomew's Hospital. Returning to Lewes, he practised medicine for 20 years, and at the same time carried on exhaustive researches in the surrounding district. He published a volume entitled "The Fossils of the South Downs, and the Geology of Sussex." He made a great collection of fossils and geological remains, and these were acquired by the British Museum. In 1833, Dr. Mantell was induced to go to Brighton in the hope that he would find easier conditions of practice, but he did not succeed, and died in 1852. The tablet was unveiled by Sir Arthur Smith-Woodward, who, as a former keeper of the geological specimens in the British Museum, had for 42 years Dr. Mantell's collection of fossils under his care.

STAINS ON THE HANDS.

Prof. Paul Delmas, of Montpellier, advises² the use of commercial ammonia, diluted to one half or one quarter with water, for the removal of iodine stains from the hands after the first intensity of the discoloration has been reduced with alcohol. The stains turn a rusty black, and subsequently disappear. Bloodstains, which are occasionally persistent on the hands, can be removed by washing in a solution of tartaric acid and warm water.

² Quoted in Semaine Médicale, April 20th, p. 596.

HOSPITAL STAMPS.

Mr. A. G. Galloway writes: The recent appeal for foreign postage stamps to be sold in aid of Charing Cross Hospital recalls the part philately has played in assisting other medical causes. There have been many special issues of stamps sold for the benefit of charity at a price above their face value. Thus as long ago as 1897 New South Wales and Victoria both issued two special postage stamps which although possessing franking powers of only 1d. and 2½d. were sold for 1s. and 2s. 6d., the difference going towards a home for consumptives. Many of the smaller British colonies, such as the Bahamas, Jamaica, and Trinidad, have either had Red Cross stamps or have issued semi-official labels. A unique method of collecting funds was adopted by South Africa in 1918, when for two months special aeroplane flights were made round the Cape of Good Hope and in the Transvaal, souvenir cards being sold at 6d. each, bearing the inscription "By Aerial Post—make your Sixpence Fly."

It is, however, in foreign countries that we find more elaborate methods to assist the Red Cross cause. In Belgium in 1914 a handsome set of postage stamps was placed on sale at Antwerp; but they had only a brief existence, for they appeared but two days before the German occupation. In 1928 a complete set of pictorial stamps bearing views of the Belgian Cathedrals was issued in that country for the benefit of the Anti-Tuberculosis Fund. Apart from producing several charity stamps, France has lately recognised bacteriology by putting the portrait of Pasteur on a number of her recent issues.

"THE T.B. PATIENT'S GUIDE."

Dr. F. J. O. Blackmore, who, as tuberculosis officer for the Metropolitan Borough of Woolwich has great experience in the management of consumptive patients, has long been aware that many failures in treatment are due to the fact that the patient fails to appreciate the gravity of the disease until it has reached an advanced stage. In a little book recently published¹ he has succeeded in warning the patient against possible dangers without being unduly alarming. The reason for various methods of treatment is described, so that the patient can understand why he should rest in one stage and work or take exercise in another. In a chapter on complications, hints are given for dealing with night sweats, indigestion, insomnia and other troubles. Advice on clothing, food, employment, and the general mode of life is also given. The tuberculous patient who wishes to work in co-operation with his doctor without worrying him with too many questions will appreciate the information here set out.

PROGRESS OF CONTRIBUTORY SCHEMES.

At a county conference in connexion with the Norwich hospitals contributory scheme it was decided that, in view of the increasing needs of the many institutions aided by the scheme, it is desirable to make the minimum contribution 2d. instead of 1d. The scheme, which started in 1910 with an income of £600, last year produced £30,000. It was argued that only in this way can long waiting-lists be avoided.—The annual report of the Royal Buckinghamshire Hospital, Aylesbury, shows that the income of the contributory scheme has increased from £804 in 1923 to £4176 in 1929.—A voluntary hospitals council has been established at Hull composed of representatives of all the local hospitals and dispensaries, which is putting into operation a contributory scheme on the now familiar model. Contributions are twopence or threepence weekly, according to wages, and should a member fall ill while away he will be treated at the local voluntary hospital at the cost of the fund. It is hoped to obtain an income of £55,000 a year.

CONTINENTAL LABORATORIES, LTD., of Lower Belgrave-street, London, S.W., inform us that their address from May 19th will be 30, Marsham-street, S.W.1. (Tel.: Victoria 2041).

A MEMORIAL COTTAGE HOSPITAL.—The Haddington Vert Memorial Cottage Hospital was recently formally opened by Mr. John Vert, of Pendleton, Oregon, U.S.A., a native of the town, and the son of a former provost, and the donor of £10,000 towards the cost of its erection and equipment. The hospital, which will serve a dozen surrounding parishes, is built of red sandstone obtained from the demolition of Amisfield, a former residence of the Earls of Wemyss, about a mile from Haddington. It is primarily a memorial to Mr. Vert's parents, but a wing will be known as the Elcho Ward, in memory of the eldest son of Lord Wemyss, who fell in the war; the Jessie McLean ward commemorates Mr. Vert's late wife. There are, in addition, a maternity ward, two private wards, and a theatre.

The Linacre Lecture

ON

THE AUTONOMIC NERVOUS SYSTEM:

AN INTERPRETATION.

Delivered at Cambridge on May 6th, 1930,

By WALTER B. CANNON, O.B., M.D., Sc.D.,
LL.D.,GEORGE HIGGINSON PROFESSOR OF PHYSIOLOGY, HARVARD
UNIVERSITY.

THERE is a distinctive appropriateness in considering here at Cambridge some recent developments of our knowledge of the autonomic nervous system and its interpretation, for here the firm foundations of our knowledge of that system were laid. The careful researches of Gaskell, and of Langley and Anderson—how readily the names are spoken, so often did they appear together in published papers!—the careful researches of these physiologists taught us not only the physiological effects of autonomic nerve impulses, but also the morphological organisation of autonomic neurones. Indeed, the names which they, as pioneers, devised to designate both the new structures and the new functions which they discovered have gone forth from this place and are now employed throughout the world. It was a difficult and intricate problem which confronted them. Happily, their investigations went far towards untangling the complex maze of fibres and responses to stimulation, so that later workers in this realm of physiology have had relatively easy tasks.

In the organisation of the autonomic system a number of features are so peculiar that they at once attract attention and challenge explanation. First there is its field of influence, its typical government of the activities of smooth muscles and glands; and associated therewith the intercalation of an extra neurone between the central nervous system and the peripheral organ. What is the significance of the outlying neurone? Again, there is the arrangement of the connexions between the outlying neurones and the brain and spinal cord in three divisions; and commonly associated therewith a double innervation of the peripheral organs, one nerve-supply from the mid-division and another from either of the end divisions. Why this double innervation? Furthermore, there is the striking fact that the mid- or sympathetic, division can cause the discharge of an internal secretion, adrenalin, which in nearly all respects is capable of producing the same effects on the peripheral organs as the sympathetic nerve impulses themselves. What is the service of adrenalin? And, finally, there are the special conditions under which the several divisions of the autonomic system are brought into action. What do these natural modes of stimulation indicate as to the uses of the autonomic system in the organism? I propose that we discuss these questions.

THE SIGNIFICANCE OF THE OUTLYING NEURONES.

First, then, the question as to the significance of the outlying neurones. It appears certain that one function of these structures is to multiply the channels of distribution. Ranson and Billingsley have counted in the cat the number of pre-ganglionic fibres in the cervical sympathetic trunk and the number of cell bodies in the superior cervical ganglion and they report that the ratio is as 1 to 32. Obviously, if a similar relation exists generally, any single pre-ganglionic axone would bear impulses having extensive effects because of the multiplicity of its contacts with the final distributing agencies.

But does multiplication of the discharging paths tell the whole story? Is there not perhaps a service

which the intercalated neurones perform that is peculiarly related to the tissues which they affect? Smooth muscle, for example, rarely responds to a single brief stimulus, though that is highly effective when applied to skeletal muscle; and furthermore, smooth muscle has a much longer latent period and a much slower contraction than skeletal muscle. May not the nerve impulses as discharged from the central system be quite appropriate for skeletal muscle but not for smooth muscle? And may not the outlying neurones, which differ in some respects from all other neurones in the body, act as "transformers," modifying the impulses from the central source and adapting them to the peculiar tissues which they innervate?

This suggestion, put forth about sixteen years ago, was the subject of an investigation in the Harvard Physiological Laboratory by Querido. Using as a test structure the smooth muscle of the nictitating membrane of the cat's eye he found that frequencies of stimulation above and below a certain effective range, when applied to post-ganglionic fibres, had no effect or caused submaximal contraction, whereas stimuli of the same frequencies, when applied to pre-ganglionic fibres, caused a maximal response. The conclusion was drawn, therefore, that impulses of widely varying frequencies, started central to the ganglion, induce there impulses which pass to the smooth muscle at an optimum frequency. This conclusion was checked by cooling the nictitating membrane and thereby slowing its response. Stimulation of post-ganglionic fibres could then be made effective, but only by selecting a frequency of the impulses which was much below the usual optimum. Under those conditions, when the pre-ganglionic fibres were stimulated, it was found that no matter what the rate of stimulation, the membrane failed to respond. It is difficult to explain this result except in terms of a relatively fixed frequency of discharge of nerve impulses from the ganglion in response to varying frequencies of impulses coming into it—a frequency of discharge which under the circumstances was too high for the cooled muscle.

Although the results obtained by Querido appear to be clear-cut and decisive, they have been criticised by Veatch and Pereira. Contrary to Querido, they obtained the same responses from the nictitating membrane, on both pre- and post-ganglionic stimulation, with impulses ranging in frequency from 3 to 142 per second. Veatch and Pereira did not, however, follow exactly Querido's method, which permitted rapid comparisons back and forth between the two stimulated regions. Also, they did not conduct their investigation by varying the rate of a continuous stimulation, as Querido did, but employed periodic stimulation at the different rates—a method which Querido tried and discarded because it yielded results dependent on the length of stimulation. That point Veatch and Pereira seem not to have carefully regarded. They showed, to be sure, that as induction shocks become more frequent they may become less effective because of overlapping, and they suggested that the lessened efficacy of high rates of stimulation in Querido's experiments may have been due to such effects; they did not note, apparently, that Querido explicitly stated that he had ruled out the possibility of that error by "galvanometric control"; further, they did not account for the differences which Querido found between pre- and post-ganglionic stimulation with the same frequencies, *whether fast or slow*; and although they proved that the overlapping effect can be overcome by increasing the strength of the primary current they seem not to have noticed that when Querido did precisely that the maximally effective frequencies were not raised but lowered. These tedious but pertinent details, though presenting a strong presumption in favour of Querido's results and inferences, still indicate that the question at issue is not settled, and that a clear verification is desirable.

It is surprising that Querido and also Veach and Pereira report that the optimum rate of stimulation of post-ganglionic fibres lies between 120 and 160 impulses per second. That rate is considerably higher than the maximum reported by Adrian and Bronk for the natural discharge of motor impulses to skeletal muscle. In an economical system it would appear that less rapidly acting smooth muscle might well be excited by less frequently recurring nerve impulses, and the less rapid conduction in post-ganglionic fibres, as compared with conduction in motor fibres of skeletal muscle, as well as the longer chronaxie, the longer absolutely refractory period and the longer duration of the action potential, reported by Heinbecker, is in accord with that idea. On the other hand, Kleitman and Chauchard's contradictory observation that the chronaxie of post-ganglionic fibres is much shorter than that of pre-ganglionic fibres could be significant of a more frequent discharge along post-ganglionic axones. We really ought to have, however, direct evidence on this point under natural conditions.

In the present state of our knowledge of the nature of nerve impulses in the autonomic system no decisive conclusion can be drawn regarding the possible function of the outlying neurones as "transformers," adapting the nerve impulses received from the brain and spinal cord to the peculiar visceral structures which are affected. More information is needed. May I venture the suggestion that here lies an attractive realm for research, which may yield highly interesting new facts.

THE DOUBLE NERVE-SUPPLY TO THE VISCERA.

As you have already been reminded, the viscera not uncommonly have a nerve-supply from two sources, from the mid- or sympathetic division of the autonomic system and from the cranial or sacral division. In the management of a skeletal muscle—the biceps, for example—it is quite possible to have all variety of change from extreme contraction to total inhibition by regulating the impulses which pass along its single nerve. Why not a similar control of an internal organ by way of a single nerve supplied to it? A possible answer to this puzzling question can be found by examination of the differences between the distribution of the pre-ganglionic fibres of the sympathetic division on the one hand and of the cranial and sacral divisions on the other.

The pre-ganglionic fibres of the sympathetic division pass out to two rows of ganglia lying each beside the vertebral column. These fibres give off branches to the cell bodies in the first ganglion which they reach, and then they continue to neighbouring ganglia, and thus they form the connexions of the so-called sympathetic "chain." At each successive ganglion the fibres passing through it give off branches to the cell bodies of the outlying neurones. This arrangement provides a highly effective device for multiplying contacts with discharging channels. But it does more than that. The overlapping connexions of the pre-ganglionic fibres, as distributed to the sympathetic ganglia, are such as to result in a *diffuse* discharge of nerve impulses. This view of the mode of action of the sympathetic division is supported by common observation. When a cat, for example, is subjected to excitement or to exposure to cold—conditions which call the sympathetic into action—its hairs are erected from head to tail tip. Deeper observation reveals that the general erection of the hairs is indicative of other general effects on large systems, such as inhibition of the activities of the digestive canal and constriction of blood-vessels. The view that the sympathetic division is organised for diffuse discharge of nerve impulses is confirmed also by the fact that sympathetic impulses evoke a secretion of adrenalin from the medullary portion of the adrenal glands. Since this substance is highly potent in producing, as a rule, the same effects in the organism as sympathetic impulses, and since it has a general distribution in the blood stream, it is clear that, if the sympathetic did not have diffuse effects by other means, it

would have them by way of adrenalin. The two factors, however—the nerve impulses and the hormone—commonly work together, as a sympathico-adrenal system, to produce widespread changes in smooth muscles and glands throughout the organism.

How different is the organisation of the cranial and sacral divisions. Here the pre-ganglionic fibres reach into or end near the organs which they affect, and the outlying neurones are merely local agents. Like the nerves supplied to skeletal muscles, therefore, the bundles of pre-ganglionic fibres in the cranial and sacral divisions are distributed in a manner favourable to separate and discriminating action. Thus, constriction of the iris, by discharge through the *motor oculi* when the light is strong, is not associated with an increased salivary flow produced by discharge through the *chorda tympani*, nor with slowing of the heart and increased tone of the alimentary tract by involvement of vagal activity. These various functions of the cranial autonomic nerves can be carried on quite independently of one another—indeed, there is little or no evidence of a diffuse discharge of impulses in them, such as is seen in the complex of nerves forming the sympathetic division.

Associated with the double nerve-supply to the viscera is the interesting fact that, as a rule, the two nerves are opposed in action. Thus, as you well know, the sympathetic influence on the heart is acceleratory, the vagal influence inhibitory; the sympathetic lessens the muscular tension of the stomach, and vagal stimulation increases it. Now, by means of the general *diffuse* action of the sympathetic division and the opposite *particular* action of the several nerves of the cranial and sacral divisions every variety of change is provided for both locally and temporally. All the viscera can be affected *simultaneously* in one direction or the other by varying, up or down, the tonic activity of the sympathetic division. And any *special* viscus can be *separately* affected in one direction or the other by varying, up or down, the tonic activity of the special nerve of the opposed cranial or sacral division that is supplied directly to the viscus. The sympathetic is like the soft and loud pedals, modulating all the notes together; the cranial and sacral innervations are like the separate keys. When we consider that the sympathetic, in emergencies, serves in a great variety of ways to preserve the stability of the organism, if that is threatened, the importance of its arrangement for simultaneous and unified action becomes evident.

THE SERVICE OF ADRENALIN.

As already emphasised, the general distribution of adrenalin in the blood stream would assure a general influence of the sympathetic division even if the neurones of that division were not so arranged as to broadcast impulses everywhere, simultaneously, throughout the organism. But the question has been raised, is extra adrenalin discharged into the circulation on special occasions and in amounts which influence the viscera? Over that question sharp controversy has raged for many years. Stewart and Rogoff, although admitting that splanchnic stimulation causes an extra discharge of adrenalin which can affect the viscera, have contended that normally the rate of discharge is fixed, and that it is not altered by asphyxia, afferent stimulation, or emotional excitement—natural conditions which cause splanchnic stimulation. And Gley and Quinquaud, after presenting evidence that the output can be varied—by asphyxia, for example—have declared that adrenalin does not reach the viscera in sufficient concentration to produce any physiological effect. It would be impossible to elaborate, on this occasion, a critique of that long polemic. That I have recently done (in an article in the *Ergebnisse der Physiologie*), and anyone may read the review. It is perhaps sufficient to state here that our claim for a discharge of adrenal secretion in pain and asphyxia has been supported by other investigators, who have used various methods, in England, Russia, Algeria,

Argentina, the United States, and Japan. No one has yet appeared who has confirmed the conclusion of Stewart and Rogoff that the secretion of adrenalin is uniform and invariable. Indeed, Japanese investigators, who have employed the method which Stewart and Rogoff employed, have confirmed our results. And furthermore, when we showed that asphyxia and afferent stimulation caused acceleration of the denervated heart, if the blood flow from the adrenal veins was uninterrupted, but did not do so if the flow was blocked, we used the same procedure which Stewart and his collaborators used to prove that the output of adrenalin is increased by splanchnic stimulation. Logically, therefore, they must either accept our evidence that asphyxia and afferent stimulation augment the output or surrender their own evidence that splanchnic stimulation augments it. Though our evidence was published about eight years ago, Stewart and Rogoff have not yet resolved the dilemma which was presented to them. I see no other conclusion to draw from the evidence in hand than that afferent stimulation, asphyxia and emotional excitement—as well as cold and hypoglycemia, as we shall see—cause a quick and abundant secretion from the adrenal medulla.

There are many observations which prove that adrenalin reaches the viscera in amounts or concentrations capable of influencing them. The effects of extra adrenal secretion on the denervated salivary gland, iris, heart, and kidney, and in experiments with a crossed circulation, need only to be mentioned to recall to your memories the wealth of this evidence. Indeed, Gley has himself admitted an "adrenalinemia" of an effective character. That aspect of the controversy, therefore, appears to be settled in principle.

Granted that adrenalin is produced in extra amount under special circumstances, what services does it perform? First, as is generally admitted, adrenalin cooperates with sympathetic impulses to produce the same effects which they produce. Though in some conditions the impulses can induce the changes quite as obviously without the aid of circulating adrenalin as with it—on the heart and blood-vessels, for example—the evidence is not yet clear that the impulses normally produce maximal effects without that aid or that they are not materially supported by it. There are indications also that circulating adrenalin prolongs the effects of sympathetic activity. We have reported a continued acceleration of the denervated heart, during nearly a half hour after one minute of excitement, although the animal, after the momentary disturbance, was resting serenely on a cushion. Furthermore, there are observations that in some respects the secreted adrenalin has an efficiency far beyond that of the sympathetic impulses. For example, apnoea, reflex stimulation, normal emotional excitement, and the sham rage which follows decortication of the cerebral hemispheres, are associated with hyperglycemia. This is fully as great in animals with the liver nerves severed and with the adrenal glands undisturbed as it is in animals normal in that respect. On the other hand, if the adrenal glands are removed or inactivated and the liver nerves left intact, the hyperglycemia is diminished or entirely lacking. Quite possibly the action of adrenalin in causing a faster coagulation of the blood and a faster metabolism, as well as its influence in abolishing the effects of muscular fatigue, is wholly independent of any coöperation with sympathetic nerve impulses. The relative services of adrenalin and the nerve impulses need to be studied further, however, before their respective rôles in the functioning of the viscera can be assigned.

THE GENERAL SERVICES OF THE AUTONOMIC SYSTEM.

As suggested earlier, we are likely to obtain insight into the various functions of the autonomic system in the organism by considering the special circumstances under which its several divisions are brought into action and also the special effects which each produces. We shall survey the three divisions separately.

The Sacral Division.—The functions of the sacral division may be summarised by the statement that they consist of a group of reflexes for emptying hollow organs which are periodically filled. Thus, sacral autonomic impulses cause contraction of the rectum and distal colon and also contraction of the urinary bladder. In both instances the effects are induced reflexly by a stretching of the tonically contracted viscera by their accumulating contents. Distension of the seminal vesicles, though associated with more elaborate reactions, stimulates the *nervi erigentes* of the sacral division, and may thereby result in behaviour which reflexly leads to a discharge of the accumulated fluid. To what degree the contractions of the distended uterus can be brought into this scheme is not quite clear. According to Langley and Anderson the sympathetic, not the sacral, division innervates the uterus. The fact that parturition can occur normally in the absence of the sympathetic division indicates either that there is an intrinsic government of uterine contractions which is quite adequate, or that there are influences working by way of sacral fibres which have not yet been traced.

Although simple distention, and reflex response thereto, is the commonest *modus operandi* of the sacral division there are other ways in which it is roused to action. Great emotion—fear, for example—which is attended by nervous discharges through the sympathetic division may be attended also by discharges over sacral pathways. The involuntary voiding of the bladder and lower gut in times of intense excitement is a well-known phenomenon both in man and other animals. And the power of sights and odours and libidinous thoughts to disturb the region controlled by the *nervi erigentes* shows that its function is subject to its own special affective states.

Cranial Division.—The functions of the cranial division, like those of the sacral, can be summarised as mainly a group of reflexes—reflexes protective, conservative, and up-building in their service. By narrowing the pupil of the eye the cranial division protects the retina from excessive light. By providing for the flow of saliva and gastric juice and by supplying the muscular tone necessary for the periodic contractions of the alimentary canal it assures the essential basis for proper digestion and absorption of the energy-yielding material required for all bodily activity. By vagus control of insulin secretion it may play a rôle in the storage of glycogen in the liver. Further evidence of its conservative value is seen in the assurance of time for rest and recuperation of cardiac muscle by the tonic vagal slowing of the heart-rate.

The cranial division, like the sacral, has uncomplicated reflexes, such as the narrowing of the pupil, and likewise activities associated with affective states. The pleasurable taste and smell of food are accompanied by the so-called "psychic" secretion of the digestive juices, and by a tonic contraction of the stomach and intestines. Furthermore, the two divisions—sacral and cranial—are similar in being largely subject to interference by striated muscle. Contraction of the bladder and rectum can be aided or frustrated by impulses from the cerebral cortex, much as the reactions of the pupil can be induced or modified by voluntary acts. Indeed, as a rule, the workings of the sacral and cranial divisions involve the coöperation of the cerebro-spinal nervous system to a much greater degree than do the workings of the sympathetic division, because they are much concerned with external orifices surrounded by striated muscles.

Sympathetic Division.—As preliminary to the discussion of the services of the sympathetic division to the organism I wish to recall a signal contribution to physiology made by Claude Bernard about 70 years ago. He pointed out that we do not live in the atmosphere that surrounds us—we are separated from that atmosphere by a layer of dead cells or by a film of mucus or of salt solution. All that is alive within these lifeless surfaces is immersed in the fluids of the body, the blood, and the lymph, which form an internal environment. Striking instances of the

dangers which arise when the internal environment, or *fluid matrix*, is markedly altered clearly demonstrate the primary importance of keeping it as constant as possible. A relatively small rise of body temperature, a reduction of blood sugar to half its common percentage, a shift of the pH of the plasma slightly up or down, may be attended by disaster. As Claude Bernard explicitly stated, the preservation of constancy is the condition for free and independent life. A glance at lower vertebrate forms reveals the truth of that statement. The amphibian, for example, is not free in either water or air; if it remains in water it asphyxiates; if it remains in air it desiccates. Furthermore, it cannot control its temperature, and therefore it is rendered inactive by the onset of winter. The next higher forms, the reptiles, are likewise dependent on external warmth for their activity. When winter approaches they become cold and sluggish. They have, however, acquired the ability to retain the bodily fluids and therefore can move away from water sources without promptly drying. In still higher forms, in birds and mammals, not only are bodily fluids readily conserved, but the temperature is maintained at a fairly constant optimum level. It is evident that in the course of evolution the internal environment has come more and more under control of agencies which protect it and keep it constant, and that concomitantly the evolving organisms have become more and more independent of the shifts of outer circumstance.

Freedom from External Influences.

Bernard and others laid particular emphasis on this freedom from external influences which is provided by assuring constancy of the fluid matrix of the body. It is well to recognise that as control of the fluid matrix is gradually attained the organism is freed not only from variations in the outer world, but also from disturbances arising from the intrinsic activities of the organism itself.

The comfortable and liberating constancy, or *homeostasis*, of our internal environment is secured only by the operation of nice devices which normally are ready at all times to prevent catastrophe. A brief survey will reveal the nature of these devices. External injury may open blood-vessels and allow the fluid matrix itself to escape. Coagulation of the blood appears, however, as a conservative agency. And by reason of pain, or the partial asphyxia which results from hæmorrhage, the sympathico-adrenal system is roused to action; thereby the efficacy of coagulation as a means of stopping the hæmorrhage is increased by an acceleration of the clotting process. If, perchance, hæmorrhage occurs to such a degree that there is considerable loss of blood, the sympathico-adrenal system is further serviceable; it constricts the peripheral vessels, thus diminishing the flow in regions where the bleeding is likely to be great, and thus assuring, also, a continuous supply of blood to essential and constantly active organs, the brain and the heart.

Again, there may be external cold which withdraws heat from the organism and thereby threatens a lowering of the temperature of the internal environment. The sympathico-adrenal system promptly acts to check the danger. It constricts peripheral blood-vessels and thereby lessens the exposure of warm blood to the surface. It causes erection of hairs and feathers, in animals provided with these means of protection, so that a layer of poorly conducting air surrounds the body. Furthermore, by discharging adrenalin into the circulating blood it increases the speed of the oxidative processes at a time when extra heat is needed to keep the temperature from falling.

Or there may be a reduced oxygen supply to the organism, either because of resort to high altitudes, or because of hæmorrhage, or because of the action of poisons, as, for example, carbon monoxide. Once more the sympathico-adrenal system comes to the support of homeostasis. The heart is made to pump the blood more abundantly into constricted vascular

areas in the splanchnic and peripheral regions, the blood pressure rises, and the flow becomes faster in essential and sensitive structures. In addition, as Barcroft has so beautifully proved, the spleen is made to contract and discharge myriads of extra red corpuscles for the service of the organism. By these activities of the sympathetic system what might be a serious disturbance is minimised to an important degree.

As I have mentioned above, however, homeostasis of the fluid matrix of the body may be altered not only by external conditions, but also by internal conditions, which, if not guarded against, result in profound disorders. Among the disturbing internal conditions vigorous muscular work stands forth prominently. Let us review the changes caused by intense labour and see how they are prevented from altering the fluid matrix.

Prolonged muscular activity, such as running, markedly reduces blood-sugar, and may deplete the liver of its store of glycogen. The blood-sugar must not be permitted to fall to a dangerous degree—if it is reduced to about 45 milligrammes per cent. (as shown by extirpation of the liver or by use of insulin) convulsions result; and if the reduction is not checked, coma and death follow. Before the convulsive stage is reached, however—and even in the absence of muscular work—the sympathico-adrenal system is brought into operation and sugar is liberated from storage. And so much sugar is thus set free that, if the condition producing hypoglycæmia is not overwhelmingly effective, the danger is passed, and then the sympathico-adrenal system subsides into inactivity. Thus, in spite of great demands for sugar from labouring muscles the glycaemic level is assuredly maintained above the region of serious danger.

Vigorous muscular activity is associated with the development of heat. In prolonged and supreme effort, when the great muscle masses of the body are employed, the amount produced may be very large. Unless this extra heat is dissipated, the temperature of the internal environment may rise to a perilous height. As a consequence of exertion temperatures in man have risen as high as 40.5° C. A rise of two degrees more, if prolonged, might bring serious results because of effects on sensitive cells in the brain. As an automatic protection against that danger the sympathetic system is called into service. Peripheral vessels are relaxed, sweating becomes profuse, and the discharge of heat is greatly accelerated. Thus, a rise of temperature is quickly met and counteracted and the harmful effects of hyperthermia are obviated.

When one engages in strenuous muscular work there is a tendency for the reaction of the blood to shift towards the acid side of neutrality, as a consequence of the metabolites resulting from contraction. This appearance of acid is not without danger. As is well known, in pathological states a condition of acidosis may develop to such an extent that the functions of the nervous system are impaired, and, if the situation is not rectified, coma and death supervene. Long before that stage is even approached, as an effect of muscular effort, corrective and protective processes are started and are vigorously maintained. The important features in the strategy are, first, a prompt supply of extra oxygen to burn non-volatile lactic acid (which otherwise persists, and makes trouble in the blood) to volatile carbonic acid which can be rapidly discharged; and second, a faster and deeper breathing so that carbon dioxide is driven away from and extra oxygen is drawn into the lungs. In short, the circulatory and respiratory mechanisms must work at their maximal capacity. Again, the sympathico-adrenal system steps in and saves the fluid matrix from grave disturbance. The circulatory adjustments—constriction of the splanchnic vessels, acceleration of the heart, discharge of extra corpuscles from the spleen—are all made by means of the sympathico-adrenal system. And in addition, this system probably plays a rôle in facilitating the respiratory processes, for, as has been

demonstrated, it can quickly and effectively cause dilatation of the bronchioles and thus reduce the frictional resistances of the to-and-fro movement of the expired air. By these various services the sympathico-adrenal system helps greatly to preserve the homeostasis of the acid-base relationship in the blood, at times when it is dangerously threatened.

The foregoing survey has shown that not only states of the *external* environment itself, but responses of the organism to situations in the external environment, are associated with disturbances of the *internal* environment. This personal, individual climate, which we each carry about with us, must not change if we are to continue to be effective. In order that the constancy of the internal environment may be assured, therefore, every considerable change in the outer world and every considerable move in relation to the outer world, must be attended by a rectifying process in the hidden world of the organism. The chief agency of this rectifying process, as we have just noted in many illustrations, is the sympathetic division of the autonomic system.

Removal of the Sympathetic Division.

Having laid emphasis on the great importance of the sympathetic, or sympathico-adrenal mechanisms, may I now tell you something about the physiology of animals from which this part of the autonomic system has been removed. The aggregation of the nutritive centres (the cell bodies) of the outlying neurones in ganglionic chains, especially in the chest and abdomen, where direct connexions with the spinal cord are present, permits a thorough extirpation of the sympathetic division. If the ganglia are removed, the post-ganglionic fibres must degenerate. And, as Langley showed, the pre-ganglionic fibres, coming from the central nervous system, are incapable of making effective connexion with organs normally innervated by post-ganglionic fibres. Removal of the sympathetic chains, therefore, must result in a permanent disconnection of these organs from central nervous control.

In removing the sympathetic chains we have used two methods. At first we took out the cervical, the thoracic, and the abdominal portions separately. The defect of that method lay in an occasional failure to excise one or two ganglia in the lower thorax, close to the diaphragm. To avoid that possibility we later removed the thoracic and abdominal portions, from the stellate ganglia to the ganglia beyond the rim of the pelvis, in an unbroken condition. There is no possibility of question that the entire sympathetic system, as a functioning agency, is thus extirpated. The qualification, "as a functioning agency," is used because the cervical sympathetic still remains in place. The pre-ganglionic fibres for the cervical sympathetic ganglia, however, pass through the stellate ganglia on either side, and consequently the removal of the stellates necessarily disconnects the cervical ganglia from the central nervous system. That the cervical sympathetic ganglia do not function under these circumstances is proved by extirpating the stellate on one side, and later exciting the animal or exposing it to cold. The hairs rise on only one side of the head; they do not rise on the side deprived of its stellate, although they are still innervated by the post-ganglionic fibres from the isolated cervical ganglia. It is clear, therefore, that removal of the thoracic and abdominal portions of the sympathetic strands over the range of their connexions with the spinal cord completely eliminates sympathetic control of the viscera.

The first fact which strikes the observer of sympathetomised animals—cats, dogs, and monkeys—is that they continue to live without apparent difficulty. It is immediately surprising that the so-called "Lebensnerven" can be so largely destroyed without producing marked and obvious changes and definitely jeopardising existence. Numbers of these animals have lived many months, some more than a year, before being sacrificed; and one of them, now

comfortable in the laboratory, has had no effective sympathetic system since Oct. 10th, 1927.

These facts definitely contravene certain views, put forth by previous workers, concerning the importance of some parts of the system. Meltzer, for example, removed the superior cervical ganglia from rabbits and cats, and because of the very high mortality he concluded that those ganglia contain a principle which is essential for the maintenance of life. His views receive no support from our observations. Later Spadolini declared that complete and extensive extirpation of the mesenteric nerves of the cat is incompatible with continued existence. He observed a general depression in his animals, grave wasting, the lowering of body temperature, and severe lesions of the gastro-intestinal tract. Although we have removed the abdominal sympathetic chains, including the splanchnic nerves, from more than one hundred cats, and although we have taken from some of them the semilunar ganglia and have even stripped the nerve strands from the coeliac axis and the superior mesenteric artery, we have never seen any serious symptoms as a consequence of the procedure. Finally, Abel has urged that chromophil tissue—possibly that which is associated with sympathetic ganglia—is essential to life. We have, however, removed all the sympathetic ganglia from the superior cervical to the pelvis, we have dissected out the semilunar ganglia, we have excised the right adrenal gland and sucked away the left adrenal medulla. The animal lived thereafter in evidently normal health for many months. At autopsy there was proof of the thorough character of the operations. No chromophil tissue could have remained. From all these observations we are driven to the conclusion that no part of the sympathetic system—superior cervical ganglia, mesenteric nerves, or chromophil tissue—nor the system as a whole is of vital importance for the individual.

You might think that the vegetative system would be important for growth. We have, however, performed unilateral sympathetomy in young kittens and permitted them to grow to adult size. Thereafter we have killed them and compared the weights of various bilaterally symmetrical organs and parts, including bones. There was no demonstrable difference between the two sides. It appears, therefore, that the sympathetic system is not concerned with the growth of the skeleton or of internal organs.

We have made careful observations on the basal metabolism before operation and after removal of each of the three portions—cervical, thoracic, and abdominal—of the sympathetic chains. Usually there is a slight fall of the metabolic rate after sympathetomy. In our experience this has been most persistently observed after excision of the cervical portion. As a rule, however, the operation does not reduce the metabolic rate more than 10 per cent. Indeed, the reduction may be regarded as negligible.

Recent discussion of possible sympathetic control of the tonus of skeletal muscle and of the service of the sympathetic in resisting fatigue raised the question as to the influence of sympathetomy on muscular function and performance. After unilateral sympathetomy the knee-jerks on the two sides were not demonstrably different. Also after unilateral extirpation of the lower abdominal chain in a dog which had been trained to run in a treadmill, there was no reduction in the total performance of the animal, nor was there any notable difference of action of the two hind limbs.

Defects shown by Sympathectomised Animals.

So much for the failure of sympathetomy to produce striking alterations in the body. Now let us turn our attention to the defects shown by animals after the operation.

In a paper published last year we reported that sympathetomy does not prevent the female from performing the functions of reproduction and lactation. The observation on which that report was based was

made on an animal from which the last portion of the sympathetic system was taken only a short time before the birth of her young. This animal did, indeed, nurse one of her two offspring until it was capable of foraging for itself. Later, however, another cat, from which the sympathetic had been removed about twenty months, gave birth to three kittens. The surprising fact appeared that the breasts were not prepared for lactation, and in spite of our efforts the young died from inanition; or from inanition and lack of maternal care, for the mother was utterly indifferent to her offspring. More recent observations have shown that in the dog also a belated effect of sympathectomy is a serious disturbance of the function of the mammary glands.

When animals are totally sympathectomised there is a great reduction of their ability to work. We have completely excluded the sympathetic system from action in a dog which had been trained to run in a treadmill until exhausted. With a standard rate of movement of the treadmill the running lasted approximately two hours, interrupted towards the end by brief periods of rest. After sympathectomy the capacity of the animal to work was reduced about 35 per cent. Of course, the vagus nerves were still intact, and by a reduction of vagal tone the heart could be moderately accelerated. Observations on another animal in which the denervated heart could be only slightly accelerated, and associated therewith there was a great reduction of the animal's ability to run, indicate that much of the retained ability of the sympathectomised animal was due to the cardiac acceleration. Nevertheless the redistribution of blood in the body, the rise of blood pressure, the dilatation of the bronchioles, and the liberation of adrenalin—all possible concomitants of muscular effort and all favourable to prolonged and efficient performance—had been rendered impossible by removal of sympathetic control; and the absence of these important factors must be added to the deficiency of the heart as determining the failure of the sympathectomised animal even to approach his former standard of achievement.

In addition to the lack of adaptive changes in the circulatory system, there is total paralysis of the mechanism for liberating sugar from the liver. This fact was brought out by determining the effect of emotional excitement on blood-sugar before and after sympathectomy. In our experiments excitement, varying between three and ten minutes, caused in normal animals an average increase of blood-sugar of 34 per cent. In sympathectomised animals, on the other hand, a similar duration of excitement resulted in no constant rise of the glycaemic level. As earlier observations had revealed, animals deprived of this regulatory arrangement are extremely sensitive to insulin.

Associated with other evidences of failure of the sympathetic system to operate there is a lack of the normal increase of red blood corpuscles that attends excitement. This absence of polycythæmia is due to non-cooperation of the spleen. All these features—the circulatory deficiencies and the abolition of the mechanisms for liberating blood-sugar and for discharging extra erythrocytes—doubtless work together to bring about the reduced efficacy of the sympathectomised animal when required to make a muscular effort. It must be admitted that many of the details of this picture need to be worked upon further before definite quantitative statements can be made, but its main features are, I believe, as I have stated them.

Not only are sympathectomised animals defective in the performance of muscular work, they are also defective when exposed to cold. The pilomotor muscles are not under control and the hairs are not erected. The smooth muscles of the blood-vessels are likewise no longer under nervous government. Cold has no local contractile effect on either of these structures. For these reasons there is no check on heat loss from the body. Furthermore, the organism has been deprived of the service of an increased

secretion of adrenalin to accelerate heat production when the body temperature tends to fall. The sympathectomised animal, therefore, when confronted by the problem of maintaining a normal temperature when it tends to fall, is physiologically inefficient. The behaviour of such an animal in cold weather is in accord with this inefficiency. It exhibits marked antipathy to cold air and to draughts. During the winter it lives almost continuously in the neighbourhood of sources of heat, leaving them only long enough to obtain food.

To test the physiological abilities of sympathectomised animals to control the body temperature we placed them in a cold room, ranging between 0.8° and 0.0° C., and made periodic observations on their rectal temperature and their shivering reactions. In some instances the tests were carried out on the same animals before and after the operation. In the normal state exposure to the cold caused no noteworthy change in the rectal temperature. After sympathectomy there was a rapid drop of the temperature when the animals were placed in the cold room. This was associated with a much greater frequency and prominence of shivering than in normal conditions, and the shivering in turn was associated with a check in the temperature drop. Since shivering was the only resource, except exercise, that was left to protect the animals from a grave hypothermia, the maintained low temperature probably indicates an equilibrium between the heat lost to the cold surroundings and the heat produced by the shivering process.

Sympathectomised animals have difficulty not only when exposed to cold but also when exposed to heat. In order to prove that an animal which takes the upright position may survive sympathectomy, we removed the sympathetic chains from monkeys. For the purpose of giving a group of these animals (among which was one on which we had operated) the benefit of sunlight and fresh air, we placed them in a cage in the yard near the laboratory last July. The normal monkeys were not at all disturbed by the heat. The monkey without the sympathetic chains, however, was found in a short time lying prostrated and gasping; it had a very high temperature and, indeed, succumbed from heat stroke.

In surveying the results of the observations on animals which survive the exclusion of sympathetic nerve impulses you may be more impressed by the slight effects of the operation than by the actual deficiency phenomena. A little thought, however, will show that the slight effects may be misleading. The sympathectomised animals, to be sure, continue to live, but they live within the protective confines of the laboratory, where there are no marked temperature changes throughout the year, no necessity of struggle for food, no requirement of escape from enemies, no danger of hæmorrhage—indeed, where there is a very special and limited sort of existence. Judging by behaviour under such conditions one might reasonably draw the inference that the sympathetic system is of minor importance for the proper functioning of the body. We believe, however, that the inference would be erroneous. If these animals were set free in the outer world and had to meet its requirements of struggle, there would be no delivery of sugar to the blood according to need, no polycythæmia, no splanchnic vaso-constriction with consequent rise of blood pressure and faster blood flow, no great acceleration of the heart, no shifting of the circulation to benefit the contracting muscles, no secretion of adrenalin to hasten coagulation and to abolish the effects of fatigue. The deficiencies of the sympathectomised animal are clearly revealed when it is exposed to cold or heat. If exigencies arise it is unable to preserve the constancy of its internal environment.

CONCLUSION.

The foregoing survey emphasises a distinction, which has long been recognised, between the "voluntary" and the "involuntary" or "vegetative"

functions of the nervous system. It is desirable to remove from physiology terms having psychological and botanical implications. The nervous system has two relations—toward the *external* and towards the *internal* environment. This fact naturally suggests that a distinction might be based on these oppositely directed functions. The “voluntary” system, which is elaborately provided with exteroceptors and with muscles which operate bony levers, is arranged for altering the external environment or the position of the organism in that environment, by labouring, running, or fighting. These activities may be appropriately regarded as exteroceptive functions, and the “voluntary” system may therefore be called the *exteroceptive system*. As we have seen, however, exteroceptive activities necessarily produce coincident, and possibly highly disturbing changes in the internal environment. Under these circumstances the “involuntary” nervous system plays its part by acting upon the heart, smooth muscles, and glands in such ways as to keep the internal environment constant and fit for continued exteroceptive action. This interoceptive action of the “involuntary” or “vegetative” nervous system justifies calling it the *interoceptive system*. Inactivity of the exteroceptive system establishes a basal state for the organism because minimal functioning of that system is accompanied by minimal functioning also of the interoceptive system. Exteroceptive action is mirrored in interoceptive action, which rises as the internal disturbance rises and subsides as the disturbance subsides.

The interoceptive system has just been referred to as if it were single, instead of consisting of the three divisions of which I have already reminded you. If we apply to these three divisions the idea that the function of the interoceptive system is to preserve *homeostasis*—that is, stability and constancy of the internal economy—we can, without great alteration of previous considerations, give a common interpretation to the services of all three divisions. The sacral division, as a group of reflexes for emptying hollow organs, preserves constancy by getting rid of waste and by discharging accumulations which disturb or check the free action of the individual. Identical thereto the race is assured continuance. The cranial division, as a group of reflexes protective and conservative in function, is more obviously concerned with the preservation of uniformity in the organism; in so far as its main services are involved, those of regulating digestion and absorption of energy-yielding material, it is of fundamental importance for the maintenance of steady states. The sacral and cranial divisions, however, operate only indirectly and somewhat remotely to assure constancy. It is the middle or thoraco-lumbar division of the interoceptive system which acts promptly and directly to prevent serious changes of the internal environment. By mobilising the bodily reserves and by altering the rate of continuous processes this division operates to keep uniform the fluid matrix of the organism and therefore may properly be regarded as the special and immediate agency of homeostasis.

In offering you this interpretation of the services of the autonomic system I am aware that in many respects it is quite deficient and inadequate. Repeatedly I have had to remark that we need more light before we can see clearly the nature of the functions which are performed by that system. Perhaps, however, the point of view which I have taken may not be the same as yours, and the somewhat different way of regarding familiar facts may lead to new ideas and new researches. If what I have said should have that effect I should be most gratified.

MEDICAL APPOINTMENTS FOR WOMEN.—The Central Public Health Committee of the London County Council has decided that appointments to the hospitals and district medical services which have passed into their control under the Local Government Act shall be open to women as well as to men doctors.

THE CAUSATION OF ECLAMPSIA.

OBSERVATIONS AND EXPERIMENTS.

By G. W. THEOBALD, M.D. CAMB., M.R.C.P. LOND.,
F.R.C.S. EDIN.,

LATE VISITING PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN
THE CHULALONGKORN UNIVERSITY, BANGKOK; SOMETIME
ASSISTANT MASTER OF THE ROTUNDA HOSPITAL, DUBLIN.

ECLAMPSIA is still the “disease of theories,” but it is generally attributed, at any rate in this country, to a toxin formed in the placenta. I do not think that this can be the correct explanation.

Eclampsia is, of course, a syndrome rather than a specific disease. It is usually associated with fits, coma, a high blood pressure, and albuminuria, and often with hematuria, and is commonly preceded for some days by malaise and albuminuria. But it may prove fatal without any fits being observed, and there may be no coma. I have seen two fatal cases in which the blood pressure was so low that it could not be recorded, and I have also seen one case in which the secretion of urine was free and no albumin could be detected in the urine until after the nineteenth fit, and two cases in which the symptoms came on suddenly in patients under observation in the antenatal ward.¹

Geographical Incidence of Eclampsia.

The features and circumstances of the disease vary greatly in different parts of the world. Oxley² has recently reported that among the last 10,000 consecutive confinements at the East End Maternity Hospital only one woman developed eclampsia.

He states, moreover, that the vast majority of pre-eclamptic patients may be so improved within 24 hours by rest in bed, purgation, and water diet that they are no longer in danger of developing eclampsia. During the last four years, he informs me, only two or three such patients failed to improve, so that induction of labour was imperative. This testimony can be endorsed by all those who have tried this treatment initiated and carried out with such conspicuous success at the Rotunda Hospital.

Cruikshank, Hewitt, and Couper³ report that 3.6 per cent. of all the admissions to the Glasgow Maternity Hospital are diagnosed as eclampsia. In other words, 360 patients out of the last 10,000 confinements at that hospital have had eclampsia. I am well aware that the institution serves a wide area and that a high percentage of the patients admitted are abnormal; but, nevertheless, the incidence of the disease is extraordinarily high in such places as Glasgow, Dundee, Kirkcaldy, and Kilmarnock. Comment on a ratio of 360 : 1 is clearly superfluous.

It is well known that the incidence of eclampsia in Germany declined very markedly during the war. H. v. Heuss⁴ and others have shown that its incidence in that country is closely related to certain meteorological conditions and that it is largely a disease of cities. I have recently pointed out⁵ that the incidence of eclampsia and all the toxæmias of pregnancy is extremely low in Siam, and relatively low in Southern China, in most areas of India, in the Persian Gulf, Iraq, Syria, Palestine, and Egypt. It is noteworthy that in the same areas, with their teeming millions, gastric ulcer, diseases of the gall-bladder, carcinoma of the intestines, and appendicitis are also but infrequently encountered.

Theories of Causation.

I submit that these facts by themselves disprove the placental toxin hypothesis. I cannot believe, either, that the Siamese placenta is less toxic than the Scottish placenta or that the anæmic women of Siam are more successful in providing themselves with an

antitoxin than the robust women of Scotland. It is, moreover, impossible to explain how a diffusible toxin formed in the placenta can poison or kill the mother and allow at least half the full-term children of such women to be born alive and thrive.

The only serious attempt to correlate pathological changes in the placenta with the disease has been made by Young,⁶ who holds that it is caused by the products of autolysis in a placental infarct which are absorbed only if the main body of the placenta remains attached to the uterine wall. I submit that his hypothesis is untenable for the following reasons:—

1. Infarcts of the placenta are exceedingly common and were found by Siddall and Hartman⁷ in 67.7 per cent. of the placentae they examined from 700 consecutive confinements.

2. The hypothesis cannot explain how patients may recover from ante-partum eclampsia and give birth some weeks later to healthy full-term children; neither can it explain the aetiology of post-partum eclampsia.

3. Placenta prævia is but seldom associated with toxæmic symptoms.

4. Young's experiments offer no conclusive evidence in support of his theory.

5. I shall show that it is disproved by experiments I have carried out.

Young injected products from human placenta into the subcutaneous tissues of guinea-pigs and so caused convulsions, focal necroses in the liver, and parenchymatous degeneration of the kidneys. He assumed these three effects to be the cardinal criteria of eclampsia. It is, however, well known that eclampsia may occur without convulsions or albuminuria; nor does it always cause specific necroses in the liver. In 1889 Wooldridge⁸ reported that he had caused intravascular clotting and hæmorrhagic necroses in the liver by injecting extracts of tissue fibrinogen into dogs. Schmorl⁹ repeated his experiments and satisfied himself that this substance when injected into dogs caused not only the typical hæmorrhagic necroses in the liver, but also the changes in the lungs, kidneys, and brain which he associated with eclampsia. In 1929 Dieckmann,¹⁰ apparently unaware of these experiments, injected tissue fibrinogen into dogs and obtained similar results. I have myself injected subcutaneously into a guinea-pig powdered ox lung prepared in the manner described by Dr. Young. The animal died in convulsions after two injections. The liver showed severe degenerative changes and small hæmorrhages, and the kidneys a cloudy swelling of the convoluted tubules.

I have recently had the opportunity of examining sections from the livers of 44 patients who died from eclampsia in different centres in the British Isles. No hæmorrhages were found in 14 out of the 43 cases, and the typical fibrino-hæmorrhagic necroses were present in only 24. Moreover, typical fibrino-hæmorrhagic necroses were found in the liver of a patient who died from post-partum hæmorrhage in whom no evidence of toxæmia was noted during several days in hospital. It is, therefore, clear that the so-called typical hepatic lesions occur in only about 30 per cent. of fatal cases of eclampsia, while they also occur in association with the other toxæmias of pregnancy. The one constant finding in all cases of eclampsia and in all the toxæmias of pregnancy were areas of necrosis in the liver, and I am convinced that the pathological evidence supports the contention that all the toxæmias of pregnancy are caused by the same factors.

I do not propose to enumerate all the hypotheses which have been advanced to explain eclampsia for they are well known, and the voluminous literature has lately been reviewed by Stander.¹¹

Albuminuria and Pregnancy.

Before developing my thesis, I should like to make a few observations on the kidneys, the main functions of which are to eliminate endogenous waste products and to assist in maintaining the normal pH of the blood.

Lever,¹² of Guy's Hospital, first pointed out the association of albuminuria with eclampsia in 1843. Because it is so easy to detect albumin in the urine and it is impossible to detect moderate damage of the liver, a great deal of attention has been paid to the kidneys by those investigating the toxæmias of pregnancy. It was even thought that eclampsia was synonymous with uræmia until it was shown that the blood-urea and non-protein nitrogen were not appreciably altered in the former disease.

If it can be proved—and it has been proved—that a patient can have eclampsia without having albuminuria, this evidence is of more value than that of 999 cases in which albuminuria does occur. Such a case offers conclusive evidence that neither albuminuria nor any functional defects of the kidneys are necessary concomitants of eclampsia. On the other hand, albuminuria may be found apart from disease.

Nicholson¹³ gave a good account of orthostatic albuminuria in schoolboys, and showed that a high protein diet caused not only albumin but granular casts to appear in the urine of certain boys. Collier¹⁴ and others have described albuminuria following severe exercise.

Fischl¹⁵ reviewed the literature dealing with experimental albuminuria and confirmed the statements that albuminuria could be caused in rabbits and dogs by tying them in various positions or by "palpating" a kidney for a minute. He showed that albumin and casts are passed in the urine of a dog or rabbit if it be tied on a table for 40 minutes with a cushion under its back to cause lordosis. If the animal be repeatedly tied in this position it will develop a fatal hæmorrhagic nephritis. He, moreover, showed that the tendency of such animals to pass albumin and the quantity passed could be influenced by the diet given on the days preceding the experiment.

I have succeeded in causing three out of seven volunteers to pass albumin in their urine by placing them in a modified Walcher's position for 30 to 40 minutes. Two passed urine containing a heavy deposit of albumin and the third a specimen which contained a definite cloud. One volunteer, a healthy athletic medical student, is extremely interesting. After the first experiment his urine contained a very heavy deposit of albumin (alb. +++). On the second occasion his urine, which was clear before the experiment, contained a heavy deposit of albumin after he had been in Walcher's position for 10 minutes. The urine again became clear within an hour of the experiment. His urine contains a cloud of urine after tennis or any sustained exercise, but otherwise it has always been clear on the many occasions on which it has been tested. I am convinced that he would suffer from a severe albuminuria were he but to become pregnant. All the specimens were centrifuged and examined microscopically, but neither casts nor abnormal cells were found on any occasion.

It is therefore certain that the position of lordosis maintained for 30 to 40 minutes can cause a healthy man or woman (two of the volunteers were women) to pass albumin in the urine, which disappears shortly after the experiment. The albuminuria is probably caused by traction on the left and possibly on both renal veins, and it is possible that the length of the veins may be one of the factors which decides the amount of lordosis necessary for its production. I have recently shown¹⁶ that rapidly growing benign ovarian tumours may cause albumin and casts to appear in the urine which disappear when the cysts are removed.

Dr. F. R. Winton authorises me to say that he intends to publish in a few weeks the results of some experiments he has been carrying out at University College which show that a reversible albuminuria may be caused by increasing the pressure in the renal vein of an isolated dog's kidney. Albuminuria cannot, however, be caused by increasing the pressure in the renal artery.

Taking these facts together, there is every reason to believe that albuminuria may be caused in a pregnant woman by pressure or traction on the renal vein especially during the latter weeks of pregnancy, when the tumour is big and the woman stands and

walks with her spine in the position of lordosis. It is also reasonable to assume that the albuminuria so often associated with labour may be due to the increased pressure in the renal veins associated with the pains. In any case, it is certain that the amount of albumin in the urine bears but little relation to the extent of the lesions in the kidneys. It is, however, probable that long-continued traction on the renal veins may cause damage to the kidneys. I suggest that pregnant women with albuminuria should lie flat on their faces on a wooden bed in which a hole is cut through which the abdomen may protrude and be supported with suitable straps.

Nephritis and Eclampsia.

The kidneys of women dying from eclampsia show a cloudy swelling, especially affecting the convoluted tubules, and in only a small percentage of cases is there any evidence of nephritis. The lesions in many cases are very slight. It is, therefore, abundantly clear that the kidneys are not concerned in the aetiology of eclampsia and that the lesions found in them are caused either by the toxin which caused the toxæmia or by mechanical factors—or possibly by a combination of both factors. It is, however, more than probable that a nephrosis, however caused, may sometimes develop into a nephritis.

Where pregnancy is associated with nephritis the history, response to treatment, and chemical findings are completely different from those of eclampsia.

A woman is known to suffer from nephritis. She becomes pregnant. The symptoms of the nephritis become more marked, and there is often a miscarriage or premature labour. It may be necessary to perform induction of labour in order to save the woman's life. The nephritis gradually improves after the pregnancy is terminated. She again becomes pregnant, and may first be seen by the physician when she is suffering from a fatal uræmia. Severe symptoms appear earlier with each succeeding pregnancy. She does not have eclampsia but uræmia—and that frequently before the twenty-eighth week of her pregnancy.

It is almost true to say that a woman with obvious nephritis never develops eclampsia. There is no reason, however, why a patient with a mild degree of chronic nephritis should not have eclampsia, and it is possible that the liver may be indirectly embarrassed by such a condition.

Source of Toxins in Eclampsia.

If eclampsia be caused by a toxin and that toxin does not originate either in the foetus or in the placenta—then it must be absorbed from the bowel. We must therefore explain why the disease should only occur in association with pregnancy.

Pregnancy affects the woman in the following ways:—

1. It causes metabolic changes, the most important of which are: (a) The blood volume is increased while its specific gravity is lowered. (b) There is a marked increase of fat, lecithin, cholesterol, and fibrinogen in the blood. (c) The blood calcium is lowered. (d) The proportion of urea nitrogen to non-protein nitrogen in the blood is lowered. (e) The alveolar CO_2 tension is lowered and the CO_2 combining power of the blood is decreased. (f) The basal metabolic rate is increased. (g) The cardiac output is increased. (h) The amount of glycogen in the liver and muscles is very much decreased at the end of pregnancy (in dogs).²⁷ (i) The partition of nitrogen in the urine is altered. (j) A marked storage of nitrogen occurs in the body.
2. The bulk of the uterus embarrasses the intestines and may cause albuminuria.
3. The mother has to undertake some of the metabolic functions of, and get rid of the waste products of metabolism for the child.
4. The growing foetus deprives the mother of considerable quantities of such important substances as calcium, iron, iodine, and sugar, and in increasing amounts. The foetus increases its weight by nearly a third during the last four weeks of gestation, and

probably uses in that time about 8 g. of calcium. The total amount of calcium in the maternal blood is about 0.5 g.

I suggest that the causation of eclampsia depends on two main factors—namely, the absorption of toxins from the bowel and a breakdown of the normal defensive mechanism.

Dietetic Deficiency and Pregnancy.

Absorption of toxins from the bowel will depend upon the food ingested and the time its residue remains in the intestines.

In spite of amazing discoveries on the effects of diet—stimulated by the discoveries of Hopkins less than three decades ago—but few physicians realise the significance of dietetics or the vast possibilities it offers in preventive and curative medicine. Deficiency of one or more vitamins in the diet is recognised to be the cause of pellagra, beri-beri, scurvy, Barlow's disease, Pink's disease, rickets, osteomalacia, keratomalacia, xerophthalmia, dental caries, and vesical calculus. Other diseases and morbid conditions, such as pernicious anaemia, sprue, rheumatism, atheroma, cyclical vomiting, gout, urticaria, and certain mental conditions are probably caused by or related to imperfect diets. Constipation—the thief of health, the ally of sepsis, the handmaid of toxæmias, the friend of insomnia, and the builder of piles—is in the vast majority of cases the penalty of an incorrect diet. If infants be included in our review there can be but little doubt that a very high percentage of the ill-health and disease in the world is directly or indirectly attributable to faulty diets.

Most animals, including man, can adapt themselves for long periods of time to incomplete diets, and that is one of the main reasons why their importance is so little appreciated. Moreover, the troubles caused by food deficiencies may take a long time to develop, so that it is difficult to relate cause and effect. The strain of pregnancy often lays bare such deficiencies, and that is why beri-beri is so often associated with pregnancy and osteomalacia, but rarely causes symptoms apart from it. It is possible that the severe neuritis which is sometimes associated with pregnancy in this country may be a form of beri-beri. A certain type of pernicious anaemia is peculiar to pregnancy and is associated with a high mortality. This disease is very prevalent in the Bombay Presidency. It may be invariably "cured"—providing the woman is not seen for the first time when moribund and in labour—by the exhibition of liver extract, and it is, therefore, almost certainly another example of a deficiency disease made evident by pregnancy.

Assimilation During Pregnancy.

It is obvious that a diet has not only to be complete but has to be assimilated. A woman when pregnant needs to provide herself with more calcium, iron, and iodine, and probably a greater amount of vitamins than an ordinary person.

The assimilation of her food may be interfered with by several factors, two of the most important of which are anxiety and the bulk of the uterus.

The influence of the nervous system on digestion has long been known to physiologists, but the implications of these facts have not been adequately realised by the clinician. During the war several observers found that men, afraid of being conscripted, developed a dilatation of the stomach associated with marked disorders of the digestion and with insomnia. The dilatation of the stomach disappeared as the probability of war service receded. Business worries, financial and family anxieties, over-study, nervous exhaustion, however produced, cancerphobia and other fears may, and often do, destroy the appetite, upset the digestion, and disturb the metabolism of the body.

Marriage calls for great adjustment in a woman's mental and physical life, and she often suffers at the very beginning of her married life from mental trauma which produce important, varied, and often ill-recognised sequelæ. Moreover, the fear of pregnancy and what it means, followed by the very natural dread of labour, add to her worries. If at this time she

lacks sympathy and understanding, these and other psychic traumata may upset the digestion and the metabolism of the body. It is evident that unmarried primiparae are more likely to suffer from these anxieties than those who are married, and this fact alone might account for the higher incidence of the toxæmias which is said to occur in such women.

The bulk of the pregnant uterus undoubtedly tends to cause intestinal stasis, and thus not only prevents food from being assimilated, but causes an increased absorption of toxins. Mills¹⁸ has shown that the complex protein tissue fibrinogen may be absorbed through the intact mucous membrane and be excreted unaltered through the kidneys of dogs and rabbits. It is, therefore, clear that it is not always necessary for proteins to be split into amino-acids before they are absorbed, and it is conceivable that a mucosa damaged by prolonged coprostasis might allow proteins to pass unaltered into the blood stream. Such proteins might be extremely toxic to the body. I have described¹⁶ the serious effects that may be caused by rapidly growing ovarian tumours, and there is no reason why the pregnant uterus should not cause similar symptoms.

Before concluding these remarks on diet I should like to refer to the significance of sunlight. Maxwell¹⁹ has conclusively proved that osteomalacia is caused by a deficiency of vitamin D in the diet, but I think that it is clear that deficiency of sunlight is the aetiological factor of most importance in causing the condition. It is also clear that the sun's rays save the vast majority of people in the East from one or other of the deficiency diseases which would otherwise inevitably result from their diet.

Sunlight, absence of worry, and a diet having a low protein content go hand in hand with a low incidence, both of the toxæmias of pregnancy and diseases of the intestinal canal.

It is well that "bottled sunlight" is available for the peoples of these islands, and it is to be hoped that one or other of the many excellent preparations now on the market will be more frequently prescribed for pregnant women; for it is important to remember that not only may certain diseases and complications of pregnancy be caused by an incomplete diet, but that the health and welfare of the unborn child is affected, probably more than is realised, by the food its mother takes.

Toxæmia and the Protective Action of Calcium.

Having briefly considered the subject of diet and the embarrassment caused to the intestines by the bulk of the pregnant uterus, we are now in a position to study the effects of intestinal stasis and note how the defensive forces of the body are upset by pregnancy.

The lower part of the small intestine and the colon are inhabited by countless billions of bacteria. These bacteria have the important function of causing fermentation and decomposition of those foodstuffs which resist the action of the digestive juices in the higher bowel, and thus allow certain products, otherwise lost, to be absorbed by the body. This decomposition, should it proceed too far, ends in putrefaction and the formation of such toxic substances as acetic and lactic acids, and the aromatic compounds indol, skatol, cresol, and phenol. Added to these toxic substances are the endotoxins, liberated by the dead bacteria. It has been estimated that an adult person passes some 480,000,000,000 bacteria in a normal stool, so that it may be assumed that the amount of these endotoxins absorbed is in some circumstances far from inconsiderable.

Indol and skatol are oxidised to form indoxyl and skatoxyl and are then conjugated in the liver capillaries with potassium sulphate to form potassium indoxyl and skatoxyl sulphate. It is believed that the other toxins are in some manner not yet understood rendered harmless to the body in the liver. I propose to offer evidence that calcium is the most important substance concerned in protecting the body against these and other toxins, although I do not wish to minimise the importance of the vitamins or the significance of such substances as iron or iodine.

Calcium is by far the most abundant metallic element in the body and is found in all of its cells and fluids. It is present in animal and vegetable foods partly in loose combination with albumins of an acid character, but to a much greater extent in the salts of phosphoric and carbonic acids. It is mainly excreted through the bowel, but the proportion excreted through the kidneys is raised if the urine be markedly acid. There are usually about 10.2 mg. of calcium in 100 c.cm. of blood-serum. Calcium is controlled in the body by the parathyroids but can only be properly utilised if a sufficient supply of vitamin D be assured.

King and Stewart²⁰ showed in 1909 that the bile-pigments and not the bile-salts caused the toxic symptoms of obstructive jaundice, and that calcium combined with these pigments and rendered them non-toxic. This work was confirmed by King, Bigelow, and Pearce²¹ in 1911. They found that calcium protects the organism against the toxicity of bile-pigments, but at the same time depletes the reserve of calcium in the tissues and causes its increased elimination. There may be an actual increase in the total calcium present in the blood, but much of it is combined with bilirubin so that the result is a decreased concentration of ionised calcium.

P. D. Lamson has for some years been directing research on the toxicity of carbon tetrachloride. He and his associates while working at Johns Hopkins University found it impossible to produce visible signs of intoxication in dogs by the oral administration of carbon tetrachloride, even when given in doses up to the capacity of the stomach (250 c.cm.). The usual dose given to an adult is 3 c.cm. In 1925 the work was transferred to the Vanderbilt University Medical School, and Minot²² states that "in striking contrast to the results obtained at Johns Hopkins University the dogs at Vanderbilt University died after a dose of 4 c.cm. of carbon tetrachloride per kilo of body-weight." These dogs lost their appetite and either became unconscious or developed muscle twitchings which ultimately involved the entire musculature in typical tetany. Death always occurred between 40 and 60 hours after the drug was administered.

On investigation it was discovered that the dogs at Nashville were fed on a lean meat diet and allowed but little bone. It was found that the simple addition of calcium salts to the meat diet for two weeks before the administration of carbon tetrachloride made the dogs at Nashville show the same tolerance for the drug as those at Baltimore. Furthermore, it was found that if calcium chloride were administered intravenously to dogs in the convulsive or unconscious stages of intoxication they were able to walk round the laboratory in a fairly normal condition 15 to 30 minutes after the injection. But although these dogs were saved and appeared to return to normal health their livers subsequently revealed severe lesions. The oral administration to dogs of carbon tetrachloride in doses of 2 c.cm. per kg., always caused lesions of the liver and kidneys but no demonstrable functional disturbances as estimated by the phenol-tetrachlorophthalein, and phenol-sulphone-phthalein tests.²³ The poison caused different lesions in the body according to its route of entry.²⁴

I will show that sodium and potassium oxalate given in sufficient dosage not only cause nephritis, but severe necrosis of the liver, the lesions being comparable to those seen in some cases of eclampsia. Dogs in convulsions and dying from these poisons may be saved by the intravenous injection of calcium chloride. I will also show that guanidine carbonate is much more toxic to dogs if their blood calcium be previously lowered by an intravenous injection of sodium oxalate. From this evidence it is clear that calcium defends the body against the toxic effects of bile-pigments, carbon tetrachloride, sodium oxalate, and guanidine carbonate. It is peculiarly interesting to note that dogs can draw on their store of calcium in their bodies to defend themselves against the toxic bile-pigments, but that the mobilisation of the calcium is not rapid enough to defend them against carbon tetrachloride. In both sets of dogs the blood calcium was normal or above normal levels, so that it is evident that estimations of the blood calcium by any known means are valueless in these cases. Calcium in the blood is locked up or bound in many ways. It is only the free or ionised calcium that is of service in defending the body against toxic substances, and

biochemists will render a great service to medicine if they can devise means of measuring such calcium in the blood.

If the liver function be upset by any toxin the proper metabolism of meat is prevented and an increase of guanidine appears in the blood. Guanidine, like insulin, lowers the blood-sugar and is antagonistic to calcium. A vicious circle is thus initiated; the calcium, which is insufficient to deal with intestinal toxins, is opposed by increasing quantities of guanidine which lowers the blood-sugar. The glycogen stores of the body are seriously depleted at the end of pregnancy, and the great demands for sugar on the part of the foetus must be met from "current" supplies and not from reserves.

The Genesis of Eclampsia.

I will now describe how I believe an attack of eclampsia to be initiated. For reasons I have already stated the pregnant woman absorbs more toxins than normal from the intestinal canal. These toxins should be detoxicated and conjugated in the liver, calcium being the most important chemical in the processes involved. The liver possibly carries on its functions with low reserve powers for several weeks; but the calcium intake is insufficient. The foetus, a true parasite, demands considerable and increasing supplies of those very substances—calcium, sugar, iodine, and iron—which the mother needs to save herself from impending disaster; and the mother, obeying biological laws, meets the demands. The liver, carrying out metabolic functions for both mother and foetus and overwhelmed by an excess of toxins, fails, and the stage is set for a catastrophe which may be precipitated by the ingestion of food, by the onset of labour, by some violent emotion, or by a sudden change in the meteorological conditions.

The fits are probably caused by a sudden drop in the level of the blood-sugar associated with a hypocalcemia, or by hæmorrhages into, or oedema of, the brain. Minot and Cutler²² state that the blood-sugar is lowered by carbon tetrachloride. It may be raised either by giving calcium or sugar. If sugar alone be given the nervous symptoms persist, but if calcium alone be given the blood-sugar is raised and the nervous symptoms disappear. They²³ state that the blood-sugar is low both in eclampsia and in pre-eclampsia and that in eclampsia the blood guanidine is definitely raised. Mann and Magarath²⁴ showed in 1921 that removal of the liver in dogs produces a condition which closely resembles eclampsia. It has also been shown that increasing doses of insulin given to dogs on a well-balanced diet cause similar symptoms leading to death, with changes in the liver comparable to those seen in those of patients who die from the toxæmias of pregnancy.²⁵

The results of investigation into the blood-sugar levels in eclampsia are conflicting. A few workers report a definite hypoglycemia, but the majority are unable to obtain results which do not fall within normal limits. The time at which the blood is taken for analysis is of paramount importance. There is evidence²⁶ to suggest that a sudden fall in the level of the blood-sugar occurs immediately before the fit, and that it may be higher than normal during and immediately after the convulsion. That is to say, a patient suffering from hypoglycæmic convulsions may actually have a higher blood-sugar than a man in possession of normal health. Similarly, a sudden drop in the blood calcium causes tetany, and I am informed that it has occurred with a blood calcium of 14 mg. per cent.²⁷

In eclampsia the damaged liver will be unable to elaborate antithrombin, and the unopposed fibrinogen in the blood, already greatly in excess of normal, might cause intravascular clotting as described by Woodriddle and hæmorrhages in the liver, brain, and lungs.

A primipara would be more liable to the condition for the three following reasons: (1) Her abdominal musculature is more taut and causes greater embarrassment to the intestines. (2) The head of

the foetus usually fixes in the pelvic brim four weeks before the onset of labour and increases the tendency to intestinal stasis. (3) She fears labour and her anxieties are usually increased by her friends.

Hydræmnios and multiple pregnancy obviously cause increased embarrassment of the intestines; and the latter condition causes an increased drain on the maternal supplies. The association of the disease with certain weather conditions may be explained by the fact that the sudden onset of cold weather demands an immediate rise in the blood-sugar which the woman might not be able to meet. It has been shown by Embden, Lüthje, and Liefmann²⁸ that metabolic rates are normally increased in cold weather and decreased in warm weather.

There is no known fact about eclampsia that cannot be explained on the hypothesis that it results from increased absorption of toxins and a breakdown in the mechanism which normally defends the body against them. There is no hard-and-fast line, clinical or pathological, to demarcate eclampsia from any other of the toxæmias occurring during the latter months of pregnancy, and the evidence suggests that they are all caused by the same factors, and are different expressions of a damaged liver.

Accidental Hæmorrhage.

Cases of accidental hæmorrhage may be divided into two groups. The larger group consists of those in which the placenta has a lower insertion than normal, but too high to be termed placenta prævia. Such cases are not usually associated with albuminuria. The other group of cases is associated with a true toxæmia. Failure to recognise these distinct groups has caused much confusion and has tended to obscure the ætiology of the toxæmic group.

Browne,²⁹ as the result of some interesting experiments with rabbits, has suggested that chronic nephritis is a predisposing factor in the causation of this condition. I submit that his conclusions are untenable for the following reasons:—

1. Toxæmic accidental hæmorrhage does not occur in Siam, the Persian Gulf, Iraq, Syria, although chronic nephritis is not uncommon in these countries.
2. A high percentage of cases offer no evidence of chronic nephritis when examined a fortnight after delivery.
3. Of the nine fatal cases whose kidneys I have examined not one showed evidence of a chronic nephritis.
4. I obtained sections of the liver from seven of these nine cases. They all showed areas of necrosis, and in three hæmorrhagic necroses were present.

It seems clear that toxæmic accidental hæmorrhage, like eclampsia, is associated with areas of necrosis in the liver, and its ætiology can be explained in a similar manner.

EXPERIMENTAL WORK ON THE NATURE OF ECLAMPSIA.†

I will now give a résumé of the experimental work I have done during the last three years at Bangkok. Dogs were used because their metabolism is similar to that of man and they have placenta which are partly deciduous.

They were kept in suitable cages in the open air under thatched roofs, and were exercised morning and evening. The urine was examined daily for albumin and at frequent intervals for casts and cells. Most domestic animals in Siam are fed on boiled rice with a few boiled vegetables, and this was the diet given to the dogs until they were given the all-meat diet mentioned in the experiments. The meat given was beef muscle and contained little fat. No bones were allowed. Such a diet contains all the vitamins.

It must be remembered that the duration of pregnancy in dogs is 63 days compared with 265 days in man. It is always difficult to procure pregnant bitches, and such animals when obtained are usually within three weeks of

† The expenses were met from a grant given by the Rockefeller Foundation for the use of the visiting professor at Banckok, to whom I have pleasure in expressing my gratitude. I also wish to thank my past assistants, Dr. Chumras and Dr. Plam, for looking after the dogs and assisting me with the operations, and my friend, Dr. Wilfred Shaw, for allowing me the hospitality of his laboratory at St. Bartholomew's Hospital since my return to England and for taking the microphotographs.

term. It is thus obvious that errors in diet have much more time to produce their effects in man than they have in dogs.

The experiments fall into four main divisions: 1. The injection of substances intravenously. 2. The operative separation of the placenta, and the injection of substances into the uterine vessels to cause local thrombosis. 3. The causing of an intestinal obstruction, usually by closing the anus. 4. The feeding of pregnant and non-pregnant dogs on a meat and water diet.

Intravenous Injections.

1. *Solution of fœces.*—Fœces from a pregnant bitch were placed in a tin and covered with water in which they were stirred. The tin was allowed to stay in the sun for three days. The fluid was then boiled and filtered. On Dec. 5th, 1927, 10 c.cm. of this solution together with 10 c.cm. of a 2 per cent. solution of sodium oxalate were injected into a vein of a large black bitch near term. Three pups were born within 24 hours of the injection. Two were stillborn and the third died the next day. The bitch had albumin + in her urine for two days, and a trace of albumin for a further six days.

2. *Eclamptic blood.*—On August 20th, 1928, 5 c.cm. of citrated blood from an eclamptic patient were injected intravenously into a small pregnant bitch. Next day 15 c.cm. of blood from the same patient (it had been kept in an ice-chest) were injected intravenously into the same bitch. Some of this blood missed the vein. The day following the bitch had albumin + in her urine. A trace of albumin was found on the 23rd, but none was subsequently discovered. The bitch remained well and was used for further experiments.

On Feb. 11th, 1929, 40 c.cm. of citrated blood from an eclamptic patient were injected intravenously into a pregnant bitch which had been for five days on a meat diet. The injection apparently had no effect on the animal, and albumin never appeared in the urine. She did, however, die on the 14th evening of the meat diet.

It is evident that relatively large doses of eclamptic blood are not very toxic to pregnant bitches.

3. *Potassium and sodium oxalate.*—(a) Bitch near term; 45 c.cm. of a 4 per cent. solution of potassium oxalate were injected intravenously in three doses of 10, 15, and 20 c.cm. between Jan. 7th and 10th, 1929. The anus was closed on the 9th and the bitch was put on a meat diet. On Jan. 11th the animal refused food; on the 12th it reeled around as if drunk, and on the 13th it went into convulsions. The back was extended, the eyes remained open, and there was a marked tremor of the limbs. The bitch died after the convulsions had lasted one hour and before the pups were born.

Non-pregnant bitch.—(b) 80 c.cm. of a 2 per cent. solution of sodium oxalate were injected intravenously in three doses of 20, 20, and 40 c.cm. between Jan. 16th and 19th, 1929. One hour after the last injection convulsions commenced. The dog crunched its teeth, bit its tongue, and died half an hour later.

A third dog developed convulsions after three doses of sodium oxalate but was saved by two injections of calcium chloride.

The livers of both the dogs who died showed severe degeneration with areas of necrosis. Many of the capillaries and veins were blocked by hyaline thrombi. The kidneys showed a severe parenchymatous degeneration. The convulsions were very similar to those seen in eclampsia, and it is noteworthy that animals with areas of necrosis in the liver and severe parenchymatous degeneration of the kidneys may be saved by the intravenous injection of calcium chloride.

4. *Guanidine carbonate.*—With the object of lowering the blood calcium two dogs—a bitch of 11.5 kg. and a dog of 12.3 kg.—were given three intravenous injections of 10 c.cm. of a 2 per cent. solution of sodium oxalate on June 29th, July 1st, and July 3rd. On July 7th 1.0 g. guanidine carbonate in 5 c.cm. of normal saline was injected intravenously. The symptoms in the two dogs were very similar: (1) The blood pressure rose by 40 mm. Hg within five minutes. The highest reading obtained was 170 mm. (60 mm. above the original reading). (2) A definite weakness of the legs, especially the hind legs, was apparent after a few minutes. (3) The dog stood or sat with half closed eyes and bowed head and sneezed frequently, knocking its head on the floor. I have seen the same symptoms in severe cases of distemper. (4) The dog vomited and passed frequent soft light-coloured stools. (5) Excessive salivation was very pronounced. (6) The pulse became

very irregular, with frequent extrasystoles. In one dog a definite coupling of the beats persisted for over an hour. (7) The blood pressure remained elevated for over six hours.

At 10 A.M. on July 8th a bitch of 10 kg., with a blood pressure of 110 mm. Hg, was given 20 c.cm. of a 2 per cent. solution of sodium oxalate intravenously. At 2.30 P.M. 1.0 g. guanidine carbonate in 5 c.cm. of saline was injected intravenously. The symptoms observed were similar to those already described. In this case, however, the dog vomited more frequently and the respiration-rate was amazingly affected. Half an hour after the injection the respiration-rate was 204. Later the following readings were made: 3.15 P.M.: blood pressure, 100; pulse, 126; resp., 188. 4.30 P.M.: B.P., 155; pulse, 103; resp., 30. The dog appeared to be quite well five hours after the injection.

Three dogs which had been fed on meat and water for four weeks were then used. On August 5th 1.0 g. guanidine carbonate in 5 c.cm. of saline was injected intravenously into all three dogs and did not appear to have any effect on the animals. It was thought that the drug which had been kept in solution in ampoules might have deteriorated. On the 8th 1.0 g. guanidine carbonate in a freshly prepared solution was injected intravenously into two of the dogs used on August 5th. One dog had mild symptoms with marked coupling of the pulse beats, but became quite normal in three and a half hours. The other dog had mild symptoms, but the blood pressure remained elevated for seven hours.

It is thus evident that the same dose of guanidine is made much more toxic to dogs if the blood calcium be previously lowered by an injection of sodium oxalate. It is possible that the continuous presence of an increased amount of guanidine in the blood might prove to be more serious than the sudden introduction of a large dose of the drug, for guanidine is antagonistic to calcium which obviously protects the body from its toxic effects.

The effect of separating the placenta was tested as follows:—

Separation of the Placenta.

On Dec. 14th, 1927, a bitch was anaesthetised with ether and the abdomen was opened. A small incision was made through the wall of the uterus superficial to a placenta. The placenta was then separated from the uterine wall with the little finger for an inch in all directions. The incision in the uterus was sutured with catgut and the abdomen was closed. The urine remained normal, and the dog took its food well and enjoyed excellent health.

An effort was then made to produce thrombosis in the vessels supplying the placenta by injecting drugs into the uterine vessels.

On Dec. 17th, 1927, I opened the abdomen of a medium-sized bitch and selected a large vein immediately superficial to a placenta. Into this vein 6 c.cm. of a 25 per cent. solution of sodium chloride were injected and the vein was then tied. Albumin + was detected in the urine for three days after the operation.

After this date the use of ether was discontinued and all operations were performed under morphine narcosis, morphine sulphate gr. 4 being injected half an hour before the operation commenced.

On Feb. 1st the abdomen of a large bitch was opened and 10 c.cm. of a 25 per cent. solution of sodium chloride were injected into the right uterine artery. The urine next day contained albumin ++; and two days later it contained 12.0 g. of albumin per litre. The albumin became less and less and finally disappeared 12 days after the operation. No pups were born.

On Feb. 16th the abdomen of a medium-sized bitch was opened and 10 c.cm. of a 25 per cent. solution of sodium chloride were injected into the right uterine artery. A trace of albumin was detected in the urine only on the day following the operation. On the 24th the wound was opened and two veins immediately superficial to a placenta in the left cornu were selected. Into one of these 10 c.cm. and into the other 8 c.cm. of a 25 per cent. solution of sodium chloride were injected. The veins were then tied. The faintest trace of albumin was detected in the urine on the two days following the operation. On March 8th the wound was reopened and an incision was made in the wall of the uterus in the immediate neighbourhood of the veins into which the injections had been made. The placenta was then separated for about a third of its area of attachment and the incision closed. Some old blood, probably the result of the injections, escaped during this manoeuvre. 10 c.cm.

of a 25 per cent. solution of sodium chloride were then injected between the placenta and the uterine wall. On the following day one dead pup was born in an excess of old blood. The urine contained a trace of albumin. Next day the urine contained no albumin. The other pups were not born.

On March 29th the abdomen of a medium-sized bitch was opened and 3 c.cm. of a 25 per cent. solution of sodium salicylate were injected into the right uterine artery. 2 c.cm. of the same solution were injected into the right uterine vein. Both vessels were tied. The urine contained no albumin. On April 3rd the wound burst open and the dog died. The pup in the right cornu was macerated. Many of the vessels in both horns of the uterus were thrombosed and were stiff like pipe-stems. All the placentae were still attached to the uterine walls.

It is thus evident that neither separation of a small

mangy. This was the only case of antepartum separation of the placentae.

Dog 5.—Medium-sized bitch. The abdomen was opened and the neck of the uterus, including the vessels on either side, together with the rectum were included in two strong chromicised catgut sutures. The dog had convulsions and died 41 hours after the operation.

Dog 6.—A large black bitch, not pregnant. The abdomen was opened and the rectum was occluded as low down as possible with two chromicised catgut ligatures. After six days the dog vomited and was unable to take any food, so it was killed with an injection of sodium cyanide. The urine contained many red blood corpuscles and epithelial cells.

The pathological findings in all these animals were remarkably similar. The kidneys showed a parenchymatous degeneration, especially affecting the

FIG. 1.

(Dog 10.) Section showing villi of jejunum which have lost their epithelial covering.

FIG. 2.

FIG. 3.

(Dog 30.) Section of liver showing fatty degeneration and loss of liver structure.

area of the placenta nor thrombosis of vessels in the uterus causes a toxæmia.

Intestinal Obstruction.

Several methods were tried to obtain a chronic intestinal obstruction in pregnant bitches. The method adopted was to close the anus in the following manner.

Two purse-string sutures of silk or chromicised catgut were passed through the anal mucous membrane about a quarter of an inch distal from the anus. These ligatures when tied closed the anal canal. The anus was then closed with silkworm gut. These ligatures were covered with adhesive plaster passed under the tail and round the body.

Six dogs were treated in this manner; they were given the ordinary rice diet, to which some meat was added. The sutures tended to cut out after about three days and further sutures had to be introduced.

Dog 1.—Experiment lasted five days. A faint trace of albumin was found in the urine before the dog was killed.

Dog 2.—Bitch was not pregnant. Experiment lasted 11 days. A trace of albumin was found in the urine before the dog was killed.

Dog 3.—Experiment lasted 10 days. Red blood corpuscles, pus cells, and epithelial cells were found in the urine.

Dog 4.—Experiment lasted 12 days. Red blood corpuscles, epithelial cells, and a trace of albumin were found in the urine before the dog was killed.

Dog 5.—Experiment lasted 11 days. On the sixth day the abdomen was opened and two small pieces of liver were excised. The urine towards the end of the experiment contained albumin +, and the uterus was found at the post-mortem examination to be septic.

Dog 7.—The dog died within 24 hours of the anus being closed. At the post-mortem examination it was found that all the placentae had been separated before death. As the uterus was incised a lot of old blood escaped. The urine contained albumin and pus cells. The dog was

convoluted tubules. The liver showed marked degenerative changes. The cells with their nuclei stained badly; many showed marked vacuolation. Small areas of necrosis were seen, but had no relation to any part of the lobule. Small collections of leucocytes were occasionally seen. Large numbers of leucocytes surrounded the portal vessels. Areas of hæmorrhage were seen in sections from dogs 2, 4, and 7.

In the intestines small hyperæmic areas were visible in many areas of the small intestine, the jejunum being especially affected. On microscopic examination these areas showed villi without any epithelium. Many of the villi were completely destroyed (Fig. 1).

These experiments produced very grave lesions in the liver and kidneys, but were open to the accusation that the results were due to sepsis rather than to an intestinal stasis.

Feeding Experiments.

Three dogs were then kept in cages and fed on fresh lean meat and water. They all became extremely constipated.

Dog 11.—A large pregnant bitch, and dog 12, a large bitch, not pregnant, were killed on the twelfth day of the experiment. Six pups were born to dog 11 on the seventh day of the experiment one being stillborn. Dog 13, a medium-sized pregnant bitch, died on the fourteenth day of the experiment. It is possible that the blood from an eclamptic patient injected on the sixth day of the experiment had some effect on this animal.

The urine of all the animals contained red blood corpuscles, pus, and epithelial cells before they died. The urine of dog 12 contained a slight trace of albumin. All the kidneys showed parenchymatous degeneration, especially affecting the convoluted tubules (Fig. 2). The changes were most marked in dog 13. The livers of dogs 11 and 12 contained an excess of fat and showed small areas of cellular necrosis. The liver of dog 13 showed severe degeneration and areas of

cellular necrosis. Many hyaline thrombi were seen in the sections from all these dogs. Sections taken through the hyperemic patches scattered through the small intestines and particularly in the jejunum, showed villi without their epithelial covering and in all stages of degeneration.

Two large bitches which had been frequently served between Feb. 10th and 15th, 1929, were placed in cages on Feb. 15th. They were both killed after they had been on a meat and water diet for 33 days.

Dog 30 was thought to be pregnant, for the abdomen became definitely enlarged. After about four weeks the abdomen became smaller, and towards the end of the experiment the dog became weak and ill although it was taking about one and a half pounds of meat daily. The dog was killed with ether on March 18th. The colon was very distended for its entire length with enormously hard black faeces. The small intestines were practically empty. There were small hyperemic patches in the intestines, especially in the jejunum. The uterus was enlarged and showed definite signs of a recent pregnancy. There were five distinct placental sites and a lot of sticky fluid in both horns. No pups were born. They must have died and been partly absorbed and partly discharged per vaginam. The urine remained normal. On microscopical examination of the liver the whole section stained badly. One portion of the section shows extreme fatty degeneration, looking like omentum. There are areas of cellular necrosis with loss of liver structure (Fig. 3). One large vein and many smaller vessels are occluded by hyaline thrombi. The kidneys showed parenchymatous degeneration especially affecting the convoluted tubules.

Dog 31 was never thought to be pregnant. On the 19th it was killed with chloroform. The post-mortem findings were similar to those seen in dog 30. The urine contained a trace of albumin and a few hyaline casts. The uterus was enlarged. Two placental sites were seen in the left cornu and one in the right. In the tip of the right cornu was a small foetus, the placenta of which was partly detached. There was some old blood in the sac and behind

FIG. 4.

(Dog 35.) Section of liver. The liver cells are merely indicated in order to show up the hemorrhage in the periphery of a lobule. Hem. = areas of hemorrhage. L.C. = liver cells. Th.V. = thrombosis of vein. Leuc. = collection of leucocytes.

the partially detached placenta. On microscopical examination of the liver the cells appeared to have undergone a granular degeneration, but there seemed to be no great excess of fat in the sections. There was a fair amount of congestion with early hemorrhages in one or two areas, and there were small areas of cellular necrosis.

One dog and two non-pregnant bitches (32-34) were confined in cages and placed on the meat diet. They were killed at the end of four weeks. The findings were similar to those of dogs 30 and 31. The kidneys showed parenchymatous degeneration. The liver showed marked fatty degeneration with many areas of cellular necrosis scattered through the sections, and affecting all portions of the lobules.

Dog 35 was a medium-sized bitch, not pregnant; the experiment began on March 12th and she was killed on April 16th

(34 days). For the first 23 days 1 lb. of meat was given daily. From that date until the end of the experiment, with the exception of two days when nothing but lung was given, 2½ to 3 lb. of meat were allowed. For the last three days lung was given with the meat. The animal became very constipated, going for three to four days without passing faeces. On three days in the week immediately preceding its death it passed large amounts of soft, light-coloured faeces (almost diarrhoea), and then again became constipated. The urine remained normal except for an occasional trace of albumin. No casts were found. The dog was killed by an intracardiac injection of potassium cyanide. The colon was found to be comfortably filled with dark, hard faeces. The small intestines were nearly empty. The liver was congested and showed areas of subcapsular hemorrhage. The kidneys appeared to be fairly normal. The capsules were adherent in one or two places.

On microscopical examination of the liver the whole section shows marked degenerative changes.

There are areas of cellular necrosis scattered through the sections and many areas showing hemorrhage in the periphery of the lobules (Fig. 4). There are also a considerable number of areas showing collections of leucocytes, usually in association with necrotic liver cells. Many of the capillaries and veins show thrombosis. The kidneys show a moderate degree of parenchymatous degeneration. The glomeruli appear to contain an excess of endothelial cells.

I am not yet in a position to say whether the hemorrhages in the liver of dog 35 were caused merely by giving two to three times the amount of meat allowed to the other dogs or whether the lung (containing as it does a rich supply of fibrinogen) added to the diet had this effect. I am disposed for the present to believe that the important factor was the increase in the amount of meat.

It is thus clear that simply by feeding dogs on a lean meat diet, we can produce a parenchymatous degeneration of the kidneys and severe degeneration of the liver with the following changes: (1) recent and hyaline thrombi in the veins and capillaries; (2) collections of leucocytes in the lobules; (3) fatty and other types of degeneration; (4) areas showing cellular necrosis; (5) areas of hemorrhage in the periphery of the lobules. Any poison may affect any or all portions of the lobule depending on its concentration in the blood and route of entry. In the toxæmias of pregnancy, eclampsia included, the centre and middle portions of the lobule are more often affected than the periphery, although the areas of hemorrhagic necrosis, when present, are more frequently encountered in the periphery of the lobule.

It will be observed that I have not been able to procure a pregnant bitch for experiment earlier than 14 days before its confinement.

Conclusions from the Experiments.

(1) Eclamptic blood is not markedly toxic to pregnant bitches.

(2) Sodium and potassium oxalate cause dogs to die with convulsions. These drugs cause severe degeneration of the liver and kidneys, but the animals may nevertheless be saved by the intravenous administration of calcium.

(3) Guanidine carbonate causes a rapid and prolonged rise in the systolic blood pressure in dogs. It has a very much more toxic effect if the blood calcium be previously lowered.

(4) Separation of a portion of the placenta causes no toxic symptoms in pregnant bitches.

FIG. 5.

(Dog 32.) Section of kidney showing parenchymatous degeneration especially affecting convoluted tubules.

(5) If intestinal stasis be caused by closing the anus the liver and kidneys become severely damaged. These changes occur whether the animal be pregnant or not, but are more marked and occur more quickly if the bitch be pregnant.

(6) A lean meat diet given to dogs for about 30 days causes the following effects: (a) A marked constipation associated in every case with patches of hyperemia in the small intestine, particularly the jejunum, which on microscopical examination show the villi to be denuded of their epithelial covering and undergoing degeneration. (b) A parenchymatous degeneration of the kidneys, especially affecting the convoluted tubules (Fig. 5). (c) Severe degeneration of the liver, with cellular necrosis and perivascular hemorrhage.

(7) A lean meat diet if given to bitches early in pregnancy causes death of the fetuses.

(8) A parenchymatous degeneration of the kidneys is not necessarily associated with albuminuria. A marked albuminuria did not occur in any of these dogs.

(9) The damage to the kidneys is slight compared with the severe damage to the liver.

SUMMARY.

1. Eclampsia is neither caused by a placental toxin, nor by any functional or organic lesions in the kidneys.

2. The defensive forces of the body are compromised by pregnancy in several ways: (a) the liver has to undertake duties both for the mother and the fetus; (b) anxieties associated with pregnancy and the bulk of the uterus may prevent the proper digestion and assimilation of food; (c) the fetus requires considerable quantities of sugar, about 8.0 g. of calcium and corresponding amounts of other important substances during the last four weeks of pregnancy.

3. Deficiencies in the diet are exposed by pregnancy.

4. Intestinal stasis, aggravated by the bulk of the uterus and by the fixing of the foetal head in the pelvis, causes an increased absorption of toxins.

5. A lean meat diet causes severe changes in the livers and kidneys of dogs. This diet contains all the vitamins but very little calcium.

6. This diet causes death of the fetus if given to bitches sufficiently early in pregnancy, and it is probable that human abortions, for the majority of which no adequate explanation can be offered, may be caused by deficiencies in the diet.

I submit that one is, therefore, justified in deducing from the known facts about eclampsia, together with the results of the experiments recorded, that the disease is caused by toxins absorbed from the intestinal canal, which, owing to a breakdown in the defences of the body, are not detoxicated. The success of the various expectant methods of treatment, which are all based on that in use in the Rotunda Hospital and first described by Tweedy in 1896, as well as the brilliant results obtained by antenatal care, testify to the truth of this.

I have attempted to elaborate my thesis by suggesting that a deficiency of ionised calcium in the blood is the cause of the breakdown of the defences of the body. Whether this suggestion be true or not in no way vitiates the truth of the main hypothesis.

The following are the main points of the elaboration:

(1) It is probable that calcium is the chemical most closely concerned in protecting the body from toxins, and that it can only exercise such functions when in an ionised form.

(2) The available maternal supply of calcium may be deficient for the following reasons: (a) deficient intake; (b) deficient absorption; (c) increased elimination associated with an acid urine; (d) a certain amount is used for making colostrum; (e) the fetus requires heavy supplies; (f) vitamin D is required for its proper use and may be deficient.

(3) A damaged liver cannot properly metabolise ment so that the amount of guanidine in the blood is increased. Guanidine is antagonistic to calcium and lowers the blood-sugar.

(4) A damaged liver is associated with a deranged metabolism which may express itself in a variety of ways. Its failure to produce antithrombin would allow the excess of fibrinogen in the blood to cause hemorrhages in various parts of the body.

(5) The fits may be caused by: (a) a sudden drop in the blood-sugar associated with a hypocalcemia; (b) by oedema

of, or hemorrhages into the brain; (c) by the toxins acting directly on the central nervous system.

A FATAL NEURO-PARALYTIC ACCIDENT OF ANTIRABIES TREATMENT.

By G. STUART, O.B.E., M.D. ABERD., D.P.H.,
AND

K. S. KRIKORIAN, M.D. BEIRUT.

(From the Central Laboratories, Department of Health,
Government of Palestine.)

THIS paper is written primarily to record a fatal case of acute ascending (Landry's) paralysis which recently followed on treatment at the Central Antirabies Institute, Jerusalem.

The patient was an unmarried agricultural labourer, aged 24 years, a Jew of Russian extraction, resident in Palestine eight years. The family history contained no affections of the nervous system and no evidence of mental disease, paralysis, or fits. There was nothing in the patient's occupation, mode of life, or environment likely to injure health or predispose to nervous instability. He had had benign tertian malaria for several months during 1928, but otherwise no acute illness or infectious disease. There was no abnormally in the circulatory system and no chronic renal disease.

On Dec. 27th, 1929, he was bitten in a rural district by a stray dog which had escaped after having, unprovoked, inflicted a single wound of moderate severity on the upper extremity through the clothing. The wound was not cauterised; there is no record of other persons or animals bitten at the same time. On Jan. 1st, 1930, antirabies treatment was begun at his request, and continued until Jan. 14th, when a full course of injections had been administered. During his period of attendance his conduct was exemplary; no local accidents or accidents with a local

point of departure occurred, and he showed no signs of nervousness and remained well throughout.

On Jan. 14th, in the afternoon, some six hours after receiving the last injection, while shaking hands with a friend, he experienced a feeling of weakness in the right arm; towards evening he was compelled to lie down on account of numbness in the legs. On Jan. 15th he could not pass urine or lift his arms, and was admitted to hospital.

He was strong and athletic looking; his temperature was 98° F., his pulse-rate 90-96, and the pulse regular but somewhat weak. His respiration-rate was 26. His tongue was coated but his tonsils and pharynx were normal. The pupils reacted promptly to light and to accommodation, and his mind was perfectly clear. He complained of nausea and of a slight pain between the shoulder-blades. There was total flaccid motor paralysis of both inferior extremities; limited movement of the arms was still possible. The patellar tendon reflex and abdominal reflex were abolished, but Babinski's sign was not elicited. There were no sensory disturbances in the extremities, and the tactile pain and temperature senses were unaffected. The heart and lungs were normal, there was no enlargement of the abdomen, no pain on pressure, and the spleen and liver were not palpable. The urinary bladder was distended, reaching to within 8 cm. of the umbilicus. There was retention of faeces and urine, necessitating the use of a catheter. The urine was free from albumin, sugar, bile-pigments, and other pathological constituents. After catheterisation the patient was given 0.05 g. luminal (phenobarbital). He slept badly, suffering from nausea and vomiting, and was only able to retain a little tea. On Jan. 16th his temperature was normal but his pulse very frequent and irregular, and he had complete motor paralysis of both arms.

After injections of strychnine, lobeline, and hexetone (a camphor preparation: methyl-isopropylcyclohexenon in solution with sodium salicylate) improvement in his general condition was noted; the pulse became more satisfactory and the nausea disappeared. Constipation was relieved by an enema. During the night direct transfusion was performed, 700 c.cm. of blood being taken from a donor who had lately received identical antirabies treatment; a slight feeling of chill but no temperature followed the operation.

During the forenoon of Jan. 17th the patient felt better, took nourishment with considerable appetite, and passed urine freely; the motor paralysis of both extremities remained unchanged. His temperature was 98.6° F. and his pulse 90, strong and regular. Late in the afternoon he complained of heaviness and pressure, feeling as if a large stone were resting on his chest. At 10 P.M. salivation became markedly increased, and he frothed at the mouth without cessation. He was fully conscious and complained of difficulty in breathing. At 4 A.M. on Jan. 18th respiration ceased, the pulse continuing to beat for a few seconds more.

This summary of the clinical course and therapeutic measures has been prepared largely from notes supplied by Dr. Ben-Shabetai, physician to the Shaare Zadek (Jewish) Hospital, Jerusalem.

A pathological condition presenting as its main features a rapidly advancing (flaccid) paralysis, without fever, without sensory changes, without loss of sphincter control, and terminating fatally within a short time from involvement of the bulb, is characteristic of a paralysis of the Landry type.

The vaccine employed was a 2 per cent. emulsion of fixed virus brain killed by the combined action over 24 hours of heat at 37° C., and of 1 per cent. phenol, and diluted to half with physiological saline solution prior to use. Treatment consisted of the daily administration, over 14 consecutive days, of 5 c.cm. of killed carbolised virus, and the paralysis, which occurred six hours after the fourteenth injection, followed on the introduction of 0.7 g. of nerve substance.

"The doctor should, above all, bear in mind the old adage, *primo non nocere*, and, as Roux was the first to advise, will avoid any active or progressive medication and will let the disease follow its natural course." (Remlinger, 1927.)

From this standard there was, in the present instance, obvious departure. The blood transfusion, surely without precedent in the treatment of such accidents, was carried out as a result of deliberation among the consulting staff of the hospital. Their recommendation appears to have been based on a belief that the condition was due to a lack of antibody to nervous substance in the patient's tissues; this want, it was argued, might be supplied by blood transfusion from a treated person who, remaining unaffected by the injections, presumably possessed such antibody.

After two preliminary failures to find a suitable donor—both sera hemolysed the patient's red cells—success was achieved in the person of a young volunteer who had completed antirabies treatment on Jan. 4th. According to Babes (1912), the serum of animals and of persons immunised against rabies may develop hemolytic properties; the hemolysis resulting from the admixture of the patient's corpuscles and the two original sera investigated might thus be explained.

Notes on Neuro-Paralytic Accidents in General.

(a) *Varieties*.—The clinical forms of paralysis encountered during and following antirabies treatment, and inseparably linked with its administration, present great diversity. Classification based on their degree of intensity, however, gives three main types: neuritic forms or simple localised paralyses from involvement of peripheral nerves (35 per cent.); dorso-lumbar myelitis (30 per cent.), and paralysis of the Landry type (35 per cent.). The percentages are those given by Avezzu (1923). They occur normally within 35 days of commencement of treatment. The greatest incidence falls within the first three weeks, and the earliest date of onset recorded is the fifth day (Brault, 1897). There is no connexion between the date of the bite and the appearance of symptoms. The most serious cases occur during the second week of treatment; in the milder forms the onset is commonly delayed to the end of treatment, or after. The mortality-rate in Landry's paralysis is 30 per cent., in dorso-lumbar myelitis 5 per cent., in neuritic forms nil.

(b) *Pathology*.—Those parts of the cord affected show obvious softening, and the distribution of lesions through white and grey matter alike renders differentiation between these components impossible, the whole cord surface presenting a homogeneous greyish-pink appearance. Microscopically the characteristic lesion is a perivascular demyelination, indistinguishable from that of a subacute disseminated sclerosis.

"The vessels are surrounded by a broad embryonic zone, around and attached to which is a network, formed in large part by a proliferation of neuroglia and connective tissue cells." (Babes and Mironesco, 1908.)

The complete histology has been described by Perdrau (1928).

(c) *Incidence*.—The frequency of occurrence per 1000 persons treated is variously estimated: thus, according to Babes it is 1.3, to Pelsler 0.77, to Simon 0.48, to Remlinger 0.37, to the findings of the 1927 Rabies Conference 0.28. This disparity is to be accounted for by the "inexactitude of the present statistical bases" (Lubinski and Prausnitz, 1926). The figures prove, however, that the condition is relatively rare, and the degree to which it complicates treatment with killed carbolised virus may be gauged from the fact that up to the present there are on record only seven cases, as follows: at Lemberg, one accident among 2213 patients treated—an incidence-rate of 0.218 per 1000; at Jerusalem two among 5409, or 0.37 per 1000; at Kasauli two among 7296 Europeans and one among 77,548 Indians, or 0.27 and 0.013 respectively per 1000 treated persons. The seventh case is from Aquila, one of the dispensaries supplied by Puntoni, and has been described in detail by Alessandrini (1928). Post-treatment paralysis is almost unknown among children and elderly patients and males and females are almost equally liable. Susceptibility is more marked among Europeans than among the natives of tropical countries, and educated people are more readily attacked than those engaged in manual labour. Cases occur, *ceteris paribus*, at any time during the year without apparent reference to month or climatic condition. While the occurrence of paralysis is unaffected by the nature of the biting animal, the method of treatment and individual predisposition undoubtedly play predominant parts in causation.

(d) *Ætiology*.—During the period 1925-28 we made investigation into the ætiological factors responsible for the production of post-treatment

paralysis. The results of animal experimentation strengthened the evidence gained from a study of the condition in human beings. The principal findings of the inquiry, published elsewhere (1928), may be summarised as follows:—

From Results of Experiments on Rabbits and White Rats.

1. Though nervous substance may induce anaphylactic shock, paralytic symptoms are not anaphylactic phenomena.
2. Fixed virus and rabies "toxin" are not concerned in the production of paralysis.
3. Accidents follow the exhibition of brain substance, whether normal or rabid.
4. Homologous and heterologous nerve substance alike induce the condition.
5. The *causa causans* is to be found in the protective inoculations themselves, presumably in some constituent of normal nerve substance unavoidably introduced during immunisation.
6. The deleterious, paralysis-provoking substance present in normal (and equally in rabid) nerve tissue can definitely be rendered innocuous to rabbits and rats by appropriate treatment with 1 per cent. phenol.
7. There appears to exist, within limits, no relationship between the occurrence of accident and the total mass of nerve substance injected. The actual quantity of nerve substance introduced, therefore, is not *per se* a determining factor; further, absence of such relationship argues strongly in favour of individual hypersensitiveness to the inocula being a principal cause.

The cause, therefore, lies in some constituent of brain substance which is rendered innocuous by the action of phenol. The actual occurrence of accident is governed by predisposition or idiosyncrasy.

From an Examination of the Several Theories of Causation.

1. An explanation of the occurrence of post-treatment paralysis does not need to be sought in subjective phenomena, psychic or hysterical, in street virus rabies attenuated by treatment, street virus, fixed virus, rabies "toxin," enzyme or ferment action, anaphylaxis, accidental bacterial infection, neurotropic virus, or the *genus epidemicus* of Kraus.
2. The cause of paralytic accident lies in the antirabies injections themselves, and more specifically in some component of nerve substance necessarily introduced during the process of immunisation, perhaps in a cytotoxin.
3. Incidence has been reduced to a negligible percentage at institutes where use is made of fixed virus and its—for practical purposes—insuperable vehicle, nerve substance, which has been reduced in concentration or exposed to certain chemical or physical agents. Thus, safety can be achieved by the administration either of emulsions of unaltered nerve substance in high dilution or of emulsions of nerve substance previously subjected to the action of phenol, ether, glycerin, phenol + heat or desiccation—all of which modifications of the original Pasteurian method permit the exhibition of relatively large dosage of vaccine.
4. While the occurrence of paralytic accidents is determined not by the quantity but by the quality of the nerve substance introduced, the vital importance of individual predisposition must be recognised.

Conclusions.

Paralytic accidents can be produced experimentally in a small percentage of cases by the repeated inoculation of nerve substance, whether normal or rabid, homologous or heterologous. In rabbits and white rats it can be prevented by exposure of brain suspensions to the combined action of phenol (1 per cent.) and heat (37° C.) over 24 hours. Apparently in the basic nerve substance of all antirabies vaccines there exists some deleterious component which, although adversely affected by several physical and chemical agencies, is still capable in peculiarly susceptible human beings of exciting symptoms of those nervous disorders classified as the paralytic accidents of anti-rabies treatment. It is as yet impossible to say whether the whole or only part of the nerve substance is to be incriminated. To ascribe causation to fat, lipid, or a similar component, ether-destructible or ether-soluble, is untenable, as cases of paralysis have followed treatment by Alivantis's (ether) method. Again, while it is the belief of the majority that a solution will ultimately be found in the action of the protein constituent, actual proof is still wanting, for, no matter what modifications of Pasteurian treatment have been

employed, no matter to what degree protein must by such means have been altered or denatured, accidents have surely, if rarely, supervened. Although, therefore, the nerve substance of the inoculations is without doubt primarily responsible, its paralysis-provoking toxic constituent has not yet been determined with certainty. Actual occurrence, however, is governed by individual idiosyncrasy—i.e., relative intolerance to foreign inocula.

Clinical and Laboratory Notes.

A CASE OF

CONCURRENT HERPES ZOSTER AND VARICELLA.

BY JOHN N. CUMINGS, M.B., M.R.C.P. LOND.,
 LATE HOUSE PHYSICIAN TO KING'S COLLEGE HOSPITAL.

A GIRL, aged 19, was admitted to hospital on August 28th, 1929, suffering from a badly lacerated right arm.

On Oct. 1st her temperature began to rise (see chart). On the 2nd it was 100.2° F. at 6 P.M., but there was no apparent cause. On the morning of the 3rd she complained of stiffness and neuralgic pains on the right side of her neck, together with some earache. By the afternoon of that day a slightly swollen and reddened area about 1½ in. x 1 in. was present on the lower jaw on the right side, just anterior to the angle. There was a single enlarged and tender right submaxillary gland. That evening the temperature was 101.2° F. with a pulse-rate of 96.

On the 4th pain was still present, although diminished in intensity; the submaxillary gland was less tender, and

there were a few palpable cervical glands on the right side. Over the reddened area, which had been noticed on the 3rd, could now be seen a number of typical vesicles of herpes zoster. There were also a few on the helix of her right ear and one or two on the scalp just above the ear. There was a stinging sensation over the affected area. A number of small vesicles were found scattered on the trunk, particularly on the right side, over the shoulder, the back, and the abdomen. These all resembled the vesicles of varicella, although they were a little smaller than usual. There was no stinging sensation over the trunk but itching around the area of each vesicle was present.

On each of the three succeeding days a fresh crop of vesicles appeared on the body. On the first of these three days a few more appeared on the back and the abdomen; on the second day a smaller number on the upper part of the neck and lower part of the scalp, and a few on the legs; whilst on the third day one appeared on the right ring finger. All these were smaller than usual, resembling in size those that were present on the 4th. They were more

numerous on the right side of the body than on the left side, although both sides were affected. The vesicles became pustular, finally forming scabs and healing. On the 14th the lesions on the face were completely healed, but the spots on the body did not disappear until the 21st.

The temperature chart shows the accompanying general disturbance.

It is of interest to note that another patient in a bed on the opposite side of the ward, admitted on Sept. 9th, developed on Sept. 25th herpes over the area supplied by the left seventh thoracic nerve. She was discharged on Sept. 29th. Whether this has any connexion with the case recorded it is extremely difficult to say, for as far as is known these two patients never came near each other or had anything in common, but there are records of varicella infection from contact with herpes zoster.

I have to thank Dr. C. F. T. East and Mr. Harold Edwards for their permission to publish this case.

A NOTE ON CHANGES IN THE BLOOD-PLATELETS AFTER OPERATIONS AND INJURIES.

BY B. WILLINSKY, M.D. TORONTO.

(From University College Hospital Medical School.)

Dawbarn Earlam and Howel Evans¹ showed that surgical operations of any but the most trivial kind are generally followed by an increase in the number of platelets in the circulating blood; the same thing happens in most cases of normal childbirth and is very marked after Caesarean section. They showed also that the rise in the platelet count is associated with a diminution in the clotting time of the blood and they suggest that it has a good deal to do with the occurrence of post-operative thrombosis. The platelets usually reach their maximum at about the tenth day, the time at which thrombosis is most likely to occur. There is no change in the count after anaesthesia, simple haemorrhage, or stopping in bed, and the common feature which excites the reaction seems to be tissue injury. Their observations seemed so important in relation to the troublesome question of post-operative thrombosis and embolism as to be worth confirmation, and with the kind help of Prof. C. C. Choyce and Mr. Julian Taylor I have examined a number of cases from this point of view.

After trying a number of methods I came to the conclusion that Howel Evans's technique was the most reliable and practical. Using paraffined surfaces the blood is diluted with 2 per cent. sodium citrate in 0.29 per cent. sodium chloride stained with cresyl blue, and the ratio between platelets and number of cells determined in a haemocytometer chamber. It is necessary to use the utmost care to have everything clean and free from particles, and the blood must not be diluted too much or contact haemolysis² may occur. The normal range is, by my counts, from about 200,000 to 600,000 with an average of rather less than 400,000 per c.mm. in the adult male and around 350,000 in the adult female.

In the majority of cases a rise of some degree occurred. Fig. 1 shows a response to the radical cure of a femoral hernia. An extensive comminuted fracture of the femur, without an external wound or any operative interference, gave the interesting result shown in Fig. 2, in which case there is no obvious cause for the platelet increase except tissue injury. In Fig. 3 a moderate rise followed the first stage of a colostomy and the trivial disturbance of opening the bowel led to a count of more than one and a quarter millions. Fig. 4 illustrates the unexplained ups and downs which may be found (fractured tibia).

Additional examples of the post-operative increase are:—

Salpingectomy: 470,000 to 720,000 on third day.
Inguinal hernia: 315,000 to 600,000 on fifth day.
Colostomy: (1) 500,000 to 1 million on second day; (2) 440,000 to 1 million on second day.
Prostatectomy, first stage: 250,000 to 650,000 on sixth day.
Adenoma of breast: 290,000 to 610,000 on sixth day.
Carcinoma of breast: 215,000 to 640,000 on thirteenth day.
Haemorrhoidectomy: 350,000 to 800,000 on seventh day.
Fractured humerus: 180,000 to 600,000 on thirteenth day.
Compound fracture of tibia and fibula: 290,000 to 850,000 on eleventh day.
Compound fracture of femur: 375,000 to 620,000 on fourteenth day.

Platelet counts in four typical cases mentioned in the text.

A fractured femur, an adenoma of the breast, a gastro-enterostomy, an umbilical hernia, a prostatectomy (second stage), and an injection for varicose veins showed no change. In five instances there was a fall; their preoperative level was high:—

Femoral hernia: 590,000 to 160,000 on eighth day, to 370,000 on tenth day.

Prostatectomy (second stage): 470,000; gradual fall to 310,000 on twenty-fourth day.

Ischio-rectal abscess: 550,000 to 220,000 on eleventh day.

Gastro-enterostomy: 510,000 to 180,000 on fourth day, to 520,000 on sixteenth day.

Appendectomy: 450,000 to 110,000 on fifth day, to 565,000 on thirteenth day.

Several cases showed a slight fall on the first day after operation which does not seem to have been previously noticed. The bone cases showed a rise after manipulation and, taken together, entirely support the view that the increase of platelets is caused by tissue injury, presumably by the absorption of the products of autolysis into the circulation.

¹ Earlam, D., and Evans, H.: Jour. Path. and Bact., 1928, xxxi., 833.

² Price-Jones, C.: Ibid., 1924, xxvii., 111.

No post-operative thrombosis occurred in any of these cases.

For observation of amoeboid movement of platelets all vessels and slides must be carefully cleaned. Acids must be avoided in cleaning glassware, which should be washed in distilled water for many hours and dried with pure filter paper before use. There must be no trace of acid or alkali on coverslip or slides, or the counts will be inaccurate. The diluting fluid must not come into contact with rubber or cork, and in mixing the diluted blood bubbles must be avoided or the counts will be valueless. It seems probable that the destruction of platelets is chiefly due to loss of carbon dioxide with alkalinity in the reaction of the blood. Change in reaction of blood is sufficient alone to produce destruction. The diluted blood may remain in the wax cup for half an hour without any noticeable change in the platelet count, but disintegration of platelets follows rapidly when they are allowed to come into contact with water-wettable surfaces. Therefore, the counting should be started within ten minutes after the diluted blood is introduced into the hæmocytometer. If reasonable care is used the counting of blood-platelets is no more difficult than an ordinary red blood-cell count, and the universal adoption of platelet counting will undoubtedly help to solve many of the hitherto unexplainable changes in the blood following operations and injuries.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

A MEETING of this Section was held on May 16th, with Dr. A. E. GILES in the chair.

Causation of the Toxæmias of Pregnancy.

Dr. G. W. THEOBALD read parts of the communication which we publish on p. 1115.

Mr. L. C. RIVETT did not think he had ever listened to a more interesting paper. The thesis advanced in it was very important, and every investigation possible should be made to test it.

Mr. EARDLEY HOLLAND said he had been for some time interested in the work of Minot on hyperglycæmia and calcium deficiency in the toxæmias of pregnancy. For a year, at London Hospital, cases of eclampsia and "acute yellow atrophy" had received glucose and calcium intravenously. Though he had not been much impressed by the results in pure eclampsia there had been two remarkable successes in bringing back to life two patients with acute yellow atrophy who were almost moribund. For twenty years the same theory had been accepted by the profession, but he had long felt that a suitable diet was one of the most important factors in the prophylaxis against these toxæmias.

The PRESIDENT also congratulated Dr. Theobald and expressed his appreciation of the thought and labour put into his research. The absence of real discussion he attributed to the need for a quiet assimilation of the contentions advanced.

Results of Hysterectomy.

Dr. MACDONALD reported that as a result of recent comments on hysterectomy figures he had looked up the records from 1920-29 inclusive. These were under three headings: (a) hysterectomy done alone for retroversion; (b) hysterectomy for polypus; (c) the operation performed incidentally for other purposes. 209 hysterectomies for retroversion were followed by no deaths. Under (b) there were 426 cases, with seven deaths; under (c) 236, with two deaths. In the course of 20 years there were 555 cases of hysterectomy alone with no reported deaths. Four of the seven deaths under (b) were due to

pulmonary embolism, two to heart failure, and both were over 60 years of age. The other death was from ileus. Under (c) one death was from pulmonary embolism, the other from acute phthisis.

The PRESIDENT said his own figures in the same connexion were: hysterectomy for retroversion, four deaths in his first 214 cases; in his last 620 cases, no deaths; in hysterectomy for prolapse, 342 cases, no deaths; for procidentia, two deaths in his first 89 cases; and in the last 45 cases two deaths. Altogether there were 1443 cases, and the last death was in April, 1920, the patient being a woman aged 73.

Mr. T. G. STEVENS expressed his admiration of the figures which had been quoted, but contended that the story at cottage hospitals would be a different one. Hysterectomy was a cottage hospital operation, rather than colporrhaphy.

A Case of Endometrioma.

Dr. F. J. HECTOR described the case of an unmarried woman, aged 26, who was admitted into hospital for the first time in September, 1921, her complaint being of severe dysmenorrhœa.

There was a fixed retroversion and a slightly enlarged uterus. On laparotomy the uterus was found to be held down by dense adhesions, and the left tube and ovary were adherent to the pelvic floor. The adhesions were separated, and the left tube and ovary were removed. There were numerous follicular and retention cysts, and in the tube were chronic inflammatory changes. Nine months later there was a persistence of dysmenorrhœa, with considerable pain in the left iliac fossa, accompanied by vomiting and a feeling of incapacity. A second abdominal section was therefore carried out, and numerous masses were found, resembling fibroids. Subtotal hysterectomy was performed. There was a very hard mass at the base of the left broad ligament, involving a portion of the left ureter, which was knicked and was found to have been occluded. Resection followed, and an end-to-end anastomosis was done. The uterus contained a soft interstitial fibroid, and the endometrium was thickened and showed some polypoid growths. The report was "benign adenomatous polypus of the endometrium." The patient was free from symptoms for four years. Then in 1926 she had an offensive brown vaginal discharge, which became bright red at monthly intervals. An almond-sized polypus was removed, which seemed to be undergoing cystic degeneration. Eighteen months later the discharge recurred, and three friable polypi were removed. They consisted of endometrial tissue embedded in a fine stroma, with some muscular tissue. Three applications of radium were given. Bleeding was now less, and the indurated plaque was smaller.

If radium treatment could be carried out for endometrioma it would be all to the good, said Dr. Hector, for it would save embarking upon a mutilating operation which, in a young woman, was a serious matter.

Dr. J. P. HEDLEY agreed that it might be difficult to deal effectively with an endometrioma, but in using radium one had to consider the secondary effect on the ovaries of a young woman. Hence the policy of applying radium so as to avoid a serious operation was a questionable one. With a woman near the menopause the application of radium might be preferable to a dangerous operation.

Dr. JAMES WYATT asked whether in this case the radium had a direct action on the growth in the vagina.—Dr. HECTOR replied that at present little was known of the effect of radium on the growth. No change was observed in this growth after radium was applied, but the plaque was reduced.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

At a meeting of this Society recently held at Liverpool, with Dr. J. W. BURNS, the President, in the chair, Dr. H. H. GLEAVE (Liverpool) read a note on

Endometrial Autotransplants in the Rabbit.

He quoted the results of observations on 45 rabbits in which shavings of endometrium were tied into

an incision in the liver. These developed into enormous cysts, which, however, reached a maximum of growth in two months and were no bigger a year later. The papilliferous condition of the uterus seen in rabbits in pregnancy or pseudo-pregnancy was exactly reduplicated, he said, in the endometrium of the cyst from the influence of the corpus luteum hormone. Similarly, during oestrus the rabbit showed cysts with thickened endometrium like the blunt folds of the uterus. After oöphorectomy both uterus and cyst atrophied, but the injection of 25 rat units of oestrin daily for a week restored the endometrium to the oestral type. Injections of pulped endometrium into the ear vein gave negative results. Vascularity of the site of implantation favoured the taking-root of the implant, and he considered the muscle of the implantation cyst arose from the graft itself and not by metaplasia of the local tissue. These experiments, he considered, offered support to Sampson's theory of the origin of endometriomata.

Dr. J. W. A. HUNTER (Manchester) considered there were two main factors in the growth of human endometrioma—namely, implantation and devitalisation at the site of implant.

Prof. W. BLAIR BELL disagreed that the papilliferous condition of the rabbit endometrium was always due to pseudo-pregnancy, and said it could occur as a result of long-continued oestrus.

Prof. J. H. DIBLE (Liverpool) thought the experiments mainly demonstrated that the endometrium of the cysts and uterus was in the same condition at any one time.

Prof. D. DOUGAL (Manchester) described a case of endometrioma of the abdominal wall occurring in a married nullipara aged 44 years.—Prof. BLAIR BELL reported a case of acute puerperal inversion of the uterus, and Dr. M. M. DATNOW showed a specimen of primary ovarian pregnancy in which Spiegelberg's criteria had been fulfilled. He also showed a calcified dermoid which had caused no symptoms.

CHELSEA CLINICAL SOCIETY.

THE annual general meeting of this Society was held at the Rembrandt Hotel on May 20th, with Mr. L. A. HARWOOD, the President, in the chair. A discussion on

SLEEP

was opened by Dr. S. A. KINNIER WILSON who said that the curious paradox of sleep was that its disorders were familiar, while its mechanism was little understood. Sleep disorders were becoming more common, a large number of cases being associated with encephalitis lethargica, whose appearance in 1919 reawakened interest in the whole subject. Hypersomnia used to be very rare, but was now often seen in encephalitis, being sometimes the only early symptom. Invasion of the sleep rhythm was another novel disorder, an organic affection revealing itself in a disturbance of function. It was incorrect to speak of a "sleep centre." Sleep was a process in time and could not be localised by static or anatomical rules, any more than the tune in a musical box could be localised. On the other hand, there was evidence that sleep was disturbed in encephalitis and brain tumours, especially when the lesion was at the floor of the brain in the third ventricle, by the stalk of the pituitary. Over-sleeping must be a positive symptom—the overworking of the sleep mechanism. The tumour could not be destroying the sleep mechanism; it must be causing it to overact. Pavlov had shown that after a certain number of repeated stimuli, the reflex arcs ceased to respond and the animal fell asleep. Sleep, according to this great authority, was merely inhibition. When it descended to the lower centres, the organism fell asleep; when it was spread over the

cortex, the symptom of catalepsy or trance was produced.

In recent years another disorder of sleep had appeared—narcolepsy. Sir William Gowers had referred to it in 1907, but Dr. Wilson said that he had never seen a case until 1920, since when he had seen over a score. The reason was unknown. The patient suffered a fit of sleep, and at once reawoke; the phenomenon was a kind of epileptic attack of sleep, not connected with Fröhlich's syndrome or pituitary tumour. It was related to catalepsy, in which the limbs gave way on hearty laughter or apprehension. This phenomenon was an extreme form of the familiar slackening of motor control due to emotion. Dr. Wilson hinted at an association between this syndrome and encephalitis lethargica. A large number of patients put on weight, sometimes two and a half stone in a year. In catalepsy the deep reflexes were completely abolished, to return immediately the attack was over. During the attack the patient was an organic case. The value of reflex tests, said Dr. Wilson, was thereby rendered very doubtful, and the evanescence of these signs, which he had always considered constant and immutable, in these cases had completely altered his attitude to them. They could only be dynamic and physiological changes occurring in mechanisms. We should not, he said, talk so much of diseases, but more of reactions to stimuli. Symptoms, even that of sleep, were signs that the mechanism producing them was active and healthy; this view of nervous symptoms was more interesting and threw a truer light on nervous diseases than the present concept.

Sleep in General Practice.

Dr. P. SEYMOUR-PRICE said that the chief difficulty of the clinician investigating sleep disorders lay in obtaining a reliable account of them. No one really knew exactly when he went to sleep, and it was common to wake up refreshed after two hours' sleep. The evidence supplied by a patient was still less trustworthy. Sleep was a relative term, and it was easy to acquire the habit of doing with very little. Voluntary insomnia for several nights had been shown to produce no symptoms beyond a certain lack of concentration, which a good night's sleep would restore. Insomnia was often, like diet, a fad, a phobia, and a fetish, and became itself the cause of sleep disorder. There seemed to be a newspaper conspiracy to suggest insomnia to the public. The reason for the high incidence of sleep disorders was a general increase in worry, excitement, or anxiety; the times imposed hurry and forbade leisure. The ordinary type of insomnia was associated with slight nerve exhaustion, fatigability, and indigestion. It was no use trying to go to sleep or counting sheep; the patient should let himself glide to sleep.

Insomnia was a habit, and any simple sedative plus suggestion would often work a cure. His formula was a cachet containing grs. 5 each of aspirin and sodium bicarbonate, but the aspirin should be given its chemical name.

Dr. Seymour-Price had never known any ordinary sedative form a habit. Nevertheless, prescriptions should be for a limited amount and be marked *ne rep.*, as they were otherwise usually handed on. The tolerance some patients acquired to hypnotics was extraordinary. He had known a patient drink, without harm, half a pint of bromidia, which could be obtained in this quantity without a doctor's certificate. Few patients really needed a prescription; most of them wanted advice, not drugs. A hyperpætic could be bludgeoned into sleep with a powerful narcotic, but unless the condition was treated this practice was unsound. Many patients took grs. 10 of medinal night after night for months, but a drug which would produce artificial sleep in this way must produce moral, mental, or physical degeneration, or all three. Such patients were in a chronic state of intoxication, slept very poorly, and were inert and apathetic. Even bromide, given for long enough—except for definite conditions, such as epilepsy—did irretrievable harm.

Much spade-work of suggestion was needed from the profession. Fear of insanity, fear of the dark, fear of sleep because it imitated death, fear of drugs as habit-forming, were all very common obstacles to treatment. They could not be dealt with by articles in the lay press; what was needed was the treatment of each case on its merits—the *argumentum ad hominem*. The public were on the whole utterly ignorant of the laws governing the important functions of diet and sleep, and it was the business of the profession to educate them.

Discussion.

Mr. RALPH THOMPSON asked if the limbs of a sleeping man became atonic, how it had occurred that in the retreat on Corunna a large number of soldiers had marched asleep. There was great difference between the tone of sleep and of paraplegia. He asked for explanation of the fact that ten minutes' sleep was as refreshing as ten hours'. He had once been deprived of sleep for three weeks by a painful affection of the knee, no drug being of any use, but had not suffered any particular harm. He recommended in difficulty the imagination of a black target in a black landscape. He did not believe that drugs such as aspirin formed a habit in a person of common sense. He asked whether the knee-elbow position of some healthy children in sleep was a phylogenetic reminiscence of arboreal life.

Dr. G. MURRAY LEVICK remarked that it was as well not to place too much credence in the report of the night-nurse. A patient lying still and awake was often reported asleep. The patient was the more trustworthy witness, unless the night-nurse made a very careful examination. Patients nursed in bed had no fatigue products, which played a large part in producing sleep.

Dr. G. T. CREGAN asked if it was harmful to become accustomed to sleeping in a noisy thoroughfare.

Dr. GORDON LANE said that no one who retained normal sensory faculties lost hearing in sleep. No one from birth to death ever lost all connexion of the soma with the environment. The auditory faculty was the sentinel of the organism. The subconscious mind discriminated between important and unimportant noises, and the unimportant did not affect the sleeper.

If the salt used in mental hospitals were cut down, fewer hypnotics would be needed. The sodium-ion content in the blood was the conducting medium of psychical reflexes; if toxic products poisoned that reflex arc, sleep was lost. No particular drug dealt with sleeplessness. If the sodium content were sufficiently reduced, bromides were effective; otherwise they were not. Pavlov had said that bromide was not a sedative but an excitant to the centre which cut out exhausting stimuli.

Replies.

Dr. WILSON, in reply, said that narcoleptic patients went to sleep standing; they did not suffer from atony, for they were not in deep sleep. There were all degrees and kinds of sleep. The question of depth of sleep was important; ten minutes' sleep was not always refreshing and, even if it were, it did not make up for length of sleep. The knee-elbow position of the infant was not, he thought, a reversion to an arboreal type; it probably had something to do with flow of blood to the head, pressure of viscera on venous channels, and getting away from light. To know when a stimulus changed its action on an arc from awakening to narcotising would be a clue to the mystery of sleep. He did not agree that a self-preservative mechanism was necessary in sleep, nor that the brain could reject unimportant sounds as a matter of course. If we could cut out auditory stimuli, especially on busy thoroughfares, our sleep would be much deeper.

Dr. SEYMOUR-PRICE, also in reply, recommended a contrary suggestion, that of keeping awake. Noise

was entirely a question of habit; men had often slept through heavy shell-fire. Silence might be more disturbing than accustomed noise.

New Inventions.

A NEW CAPSULE FORCEPS.

ONE is apt to fail in doing a satisfactory capsulectomy from the teeth of the forceps refusing to bite into the capsule, this being specially the case in hypermaturity from toughness of the capsule or fluidity of the cortex. A more vertical inclination of the teeth to the capsule than is possible with the

usual pattern of forceps, thus giving a better grip, is obtained by setting the teeth on short primary arms, which in turn are opened and closed by long secondary arms. The latter, as shown in the illustration, are given a ring grip, and provided with a screw stop to limit the distance to which the teeth can separate to a distance not exceeding 3 mm. The heels of the short arms are not only separated to the extent of 1 mm., but are raised 1 mm. above the level of the teeth, so that they cannot possibly grasp the iris.

The makers are Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E.

G. F. ALEXANDER, M.B., O.M. Edin.

A MODIFIED FORM OF FARABEUF'S RASPATORY.

THE illustration shows a modified form of Farabeuf's raspatory. The standard form of rugine designed by Farabeuf, of Paris, for use on the long

bones was found to bring the hand somewhat inconveniently near the work, while the longer rugines designed by Pierpoint and Mitchell are rather heavy for fine work round the orbit, and it is thought that the rugine here referred to will be found convenient for delicate and precise work which falls to the lot of an ophthalmic surgeon. Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E., are the makers.

J. N. DUGGAN, F.C.P.S. Bombay, L.M.S., D.O. Oxf.

WEEKLY PAYMENTS FOR MEDICAL SERVICE.—An association has been formed at Stockton-on-Tees, and has already begun work, which provides for the attendance of a family doctor in return for payments ranging from 6d. per week for one adult to 9d. per week for one adult and three or more dependents. The organisation embraces the boroughs of Stockton and Thornaby, and the neighbouring districts of Billingham, Haverton Hill, Port Clarence, Eaglescliffe and Yarm, and up to the present 22 medical men have joined it. The object of the service is to coordinate the provision on a contract basis of medical attendance and treatment for uninsured persons and the dependents of insured ones.

Reviews and Notices of Books.

THORACIC PUNCTURE FLUIDS.

The Clinical Pathology of Thoracic Puncture Fluids.
By S. ROODHOUSE GLOYNE, M.D., D.P.H.,
Pathologist, City of London Hospital for Diseases
of the Heart and Lung. London: John Bale,
Sons and Danielsson, Ltd. 1930. Pp. 83. 10s. 6d.

THERE has long been a demand for a book of this type, and Dr. Gloyne has succeeded in presenting one small in size, clearly written, and containing just the information that the average practitioner requires. The chapters dealing with the anatomy, physiology, and pathology of the pleura are of considerable importance. The lymphatic system is a closed one and a layer of endothelium intervenes between the capillary blood-vessels and the lymph vessels, so that organisms from an infected pleura cannot pass readily through the lymphatics to the mediastinal glands. It is for this reason that suppurative mediastinitis is a rare condition. The method of making an exploratory puncture is explained in detail. The syringe should be sterilised by boiling, and no antiseptics should be used if a bacteriological examination is required. Clotting of the exudate should be prevented by sodium citrate. The importance of a cytological examination is discussed, and the reader is warned that an excess of lymphocytes, although usually indicating a tuberculous infection, does not necessarily do so. The author suggests the term "small round cell" for general use instead of lymphocyte, since the origin of these cells is uncertain. A very full account is given of the means by which tubercle bacilli can be found in some of these effusions. Their detection is largely a matter of careful search; the longer the search the higher the percentage of cases in which the bacilli are found.

In the effusion which follows spontaneous pneumothorax a considerable number of polymorphonuclear cells are generally combined with tubercle bacilli, and this is of importance in diagnosis. A full account of the bacteriology of pleural fluids is given, and the methods of staining are carefully described. An interesting chapter deals with rare types of effusion such as cholesterol, chylous, and fluids found in hydatid disease. The last chapter deals with auto-serotherapy. Dr. Gloyne points out that whilst this is always of very doubtful benefit, it may even be dangerous; and the reader is warned against injecting fluid containing tubercle bacilli. The book concludes with a good bibliography and index.

The work is excellently constructed and quite up to date. It should appeal to the busy practitioner who will find in it useful information and clear instructions how to conduct some of the more simple examinations.

PREPUBESCENT SYPHILIS.

By PHILIP C. JEANS, A.B., M.D., Professor of Pediatrics, Iowa University School of Medicine; and JEAN V. COOKE, A.B., M.D., Associate Professor of Pediatrics, Washington University School of Medicine; Supervising Editor, ROYAL STORRS HAYNES, Ph.B., M.D., Clinical Professor of Diseases of Children, College of Physicians and Surgeons, New York City. London: D. Appleton and Co. 1930. Pp. 295.

THIS book is one of a series of volumes issued under the general title of Clinical Pediatrics, of which Prof. Royal Storrs Haynes, of Columbia University, is supervising editor. The analytical record here supplied of the authors' experience of more than 1500 cases of syphilis in children observed during a period of 16 years will be widely appreciated. This is a considerably larger group of cases of inherited syphilis than any yet reported, and it is noteworthy, though this was to be expected, that the incidence is at least two

and a half times as great amongst coloured as amongst white infants. The book opens with an interesting chapter, containing excellent portraits of outstanding syphilologists, on the history of syphilis—particularly of hereditary syphilis. The brilliant investigations of Ehrlich and Hata in the domain of chemotherapy hardly receive adequate recognition in the statement that "after many fruitless trials Ehrlich at last hit upon what we now know as arsphenamin." Chapters on the aetiology and pathology of syphilis, with special reference to the laboratory examination of the blood and cerebro-spinal fluid, give sufficient information without going too deeply into technicalities. The upper limit of the normal cell content of the fluid is given at ten per c.mm. This is at least double the figure usually accepted in this country, though admittedly one may occasionally come across a cerebro-spinal fluid with a cell count of ten per c.mm., and with no other abnormal feature. The chapters on the transmission of syphilis by inheritance and the familial effects of syphilis, with the social aspects, are full of interest, and that dealing with the social aspects stresses the damage done to families by syphilis and its great cost to the State. The clinical description of the early and late manifestations of the disease are well given, and the large amount of material upon which the authors base their analyses gives weight to their percentage occurrence of symptoms. It is curious that they had only two cases of paroxysmal hæmoglobinuria amongst their series of over one thousand cases of congenital syphilis. We find no references in this book to the eczema oris described by Leonard Findlay, to the syndrome of Hennebert (nystagmus and giddiness on applying pressure to the external auditory meatus), or the possible effects of congenital syphilis upon the endocrine glands. The chapter on neurosyphilis is particularly valuable; the high incidence of congenital neurosyphilis is not sufficiently appreciated. Table XXVIII. is difficult to follow. The chapters on diagnosis, prognosis, and treatment are very good, but it would have been a convenience to British practitioners if the European equivalents of the "arsphenamin" products had been added in the text or a footnote. The bismuth preparations bistovol, bismuth-oxychloride, are also omitted, and even the names (salvarsan and neo-salvarsan) originally given by Ehrlich to the preparations "606" and "914" are nowhere to be found in the volume. The book is well printed and produced and fully illustrated, though some of the illustrations of the skin lesions are not very informative. A few coloured illustrations would have still further enhanced the value of the book, which is a most useful addition to the literature of inherited syphilis.

DISEASES OF THE EAR.

Fourth edition. By PHILIP D. KERRISON, M.D., Consulting Aural Surgeon to the Manhattan Eye and Ear Hospital. London: J. B. Lippincott Company. 1930. Pp. 627. 35s.

THE fourth edition of this admirable text-book contains few additions or alterations, compared with the third edition which appeared seven years ago. New matter includes a description of Sir Charles Ballance's work on the treatment of facial paralysis by anastomosis of the facial and glosso-pharyngeal nerves. Dr. Kerrison also now provides a fuller account of the various surgical measures which have been proposed for the treatment of otitic purulent meningitis. These methods include repeated lumbar puncture, dural puncture, through-and-through cerebro-spinal lavage, and drainage of the cisternal magna. Dr. Kerrison believes that none of these methods increases the patient's chances of recovery, and that most of them add to the danger of spreading the infection; he prefers free exposure of middle and posterior fossæ from the mastoid area, with incision of the dura if under tension, and, if labyrinthitis is present, drainage by simple removal of the

promontory. We would suggest, for a future edition, a more systematic description of the characteristics of the normal cerebro-spinal fluid, and of its modifications in various forms of meningitis and in other diseases. A new chapter has been added which deals in a sympathetic manner with the training of the totally deaf child; it is not stated at what age systematic education should be begun.

As we noted when reviewing the third edition, this book is a model of what a text-book should be, for it contains a careful and thorough description of examination methods, providing elementary knowledge which the student should and the practitioner must possess, and gives details about the more obscure conditions which the specialist requires.

SURGICAL TREATMENT IN TUBERCULOSIS.

Traitément médico-chirurgical des pleurésies puritentes tuberculeuses. By F. DUMAREST, M. GUILLEMINET, and P. ROUY. Paris: G. Doin et Cie. 1930. Pp. 42. Fr.16.

UNTIL recently surgical intervention was almost the only thing not to advise in a case of tuberculous empyema. It is now recognised, however, that the best results are obtained by collaboration between the surgeon and the physician. In this book the authors make the following annotated classification: 1. Cold abscess of pleural cavity with or without pneumothorax. In this condition the general health of the patient remains good and the treatment consists in occasional aspirations. 2. Tuberculous empyema associated with pyrexia and malaise. Here the essential treatment is pleural lavage. 3. Septic tuberculous effusion. In this type secondary infection has occurred, and there is often a pulmonary or parietal fistula. Intercostal drainage is often the best treatment, and a subsequent thoracoplasty may be necessary. The technique of the various operations mentioned are briefly described and the X ray plates are well produced.

The book gives a concise account of the modern treatment of tuberculous empyema and forms a useful addition to the literature on the subject.

INTERNAL DISEASES.

The George Blumer Edition of Billings-Forchheimer's Therapeutics of Internal Diseases. Supplement. Edited by GEORGE BLUMER, M.A. Yale, M.D., David P. Smith Clinical Professor of Medicine, Yale University School of Medicine. London: D. Appleton and Company. 1929. Pp. 760. 30s.

Dr. Blumer has in this volume brought up to date his edition of the Billings-Forchheimer's Therapeutics which was first published in 1924. The contributors have now added such supplementary material and corroborative data as the progress of the past few years has made necessary. The result is a striking commentary on recent advances in therapeutics, even though the authors as a whole have not found much occasion to modify their articles of 1924. For the most part the chapters in this book are self-contained and the reader will find no call to refer back to the original text of 1924; a few, however, are essentially supplementary. The subject matter of the articles here collected range from such matters as the surgical treatment of angina pectoris and of diseases of the heart and pericardium to the problems of serum therapy and vaccination. George Minot contributes an authoritative paper on the treatment of pernicious anaemia, in which he urges that the best results will be obtained when large doses of the liver substance are prescribed rather than small doses "sufficient to create pronounced improvement and permit a continued fairly satisfactory sense of well-being," and that additional amounts should be given in the presence of associated infections. In other types of anaemia

he suggests trial for a period of weeks of a régime of liver and iron with a proper supply of other foods. A valuable list of references is included in this contribution. D. Marine contributes a concise account of the views of American workers upon the use of iodine in the treatment of thyroid diseases; for exophthalmic goitre he suggests that small doses may be continued "for one or three months," whilst large doses should only be used in those cases which are to be operated upon within two weeks after its administration is begun; no comment is made upon the prolonged usage of large doses which has recently been advocated. Other chapters of interest to the general physician are those dealing with quinine, novarsol in cardiac oedema (a note on its dangers in renal cases is included), protein shock therapy, malarial treatment of general paralysis, and the treatment of heart disease. There is little new to be found in the articles on the treatment of nephritis or of cirrhosis of the liver. Insulin therapy is adequately dealt with, but little mention is made of its applications in non-diabetic conditions. The plan of treatment of obesity described in some detail by Burgess Gordon is one that has as yet hardly received sufficient confirmation; its main feature lies in the reduction of potatoes and all foods derived from grains and the administration between meals of divided doses of dextrose. Collapse therapy in pulmonary tuberculosis is discussed in considerable detail (W. B. Soper), as are the various branches of serum therapy, particularly the specific treatment of lobar pneumonia.

On the whole the attitude of the authors has been a properly critical one, and all who wish for a concise summary of recent advances in the main branches of internal medicine would be well advised to read this volume. The illustrations are numerous and excellent and the lists of references at the end of each chapter are valuable.

NURSING AND DISEASES OF SICK CHILDREN.

By Various Authors. Edited by ALAN MONCRIEFF, M.D., M.R.C.P., Medical Registrar and Pathologist, Hospital for Sick Children, Great Ormond-street. London: H. K. Lewis and Co., Ltd. 1930. Pp. 580. 15s.

Diseases of Children for Nurses. Sixth edition. By ROBERT S. MCCORMIS, M.D., Children's Hospital of Philadelphia. London: W. B. Saunders Co., Ltd. Pp. 594. 12s. 6d.

THE additions which have been made to the nurse's curriculum during recent years have been a matter of general, if not always of favourable, comment. But even those medical men who regard detailed knowledge of medicine and surgery as unnecessary for nurses will welcome books, such as these, which will facilitate the acquisition of knowledge now required by statute. No more eloquent testimony to the high professional level at which nurses are expected to aim on both sides of the Atlantic could be found than the issue of these books.

The first of them is new, and has been compiled by Dr. Alan Moncrieff with due regard for the syllabus of the examination for the Supplementary Part of the Register for Sick Children's Nurses. Following this syllabus, the work includes sections on nursing, and on both medical and surgical diseases of children. The subject matter has been admirably handled, and has yielded a volume which is well representative of the great paediatric training centre from which it comes. The principal collaborators are Miss M. A. Fussell, Sister Tutor of the hospital, Mr. Twistington Higgins, Mr. Eric Lloyd, Dr. B. E. Schlesinger, and the Editor: Mr. P. G. Doyno has contributed a chapter on diseases of the eye. A useful feature is an appendix containing essential facts about drugs in common use. This book will be valuable to candidates for the General Nursing Council examination, and may be recommended to members of the nursing

profession engaged in private practice who have had no special training in diseases of children. There are few omissions of any importance, but in a future edition the nursing of infections of the frontal and ethmoid sinuses should be discussed.

Dr. McCombs's text-book has reached its present level by a process of successful evolution, having passed through six editions since its original publication in 1907. The new edition has been enlarged and brought thoroughly up to date. This book is devoted exclusively to medical diseases, the account of the nursing of each disorder following the clinical descriptions. The style of the text is simple and lucid, and the information accurate. Among the best features of the book are the illustrations, which include a number of colour plates.

LONDON HOSPITAL PAPERS.

Researches Published from the Wards and Laboratories of the London Hospital during 1929. London: H. K. Lewis and Co., Ltd. 7s. 6d.

This volume contains 48 original papers selected from the published communications of London Hospital authors during the year 1929. A great variety of subjects are treated. Mr. Hugh Cairns has two papers on the subjects of intracranial tumours and head injuries. Dr. Donald Hunter writes on hyperparathyroidism and Dr. O. Leyton on the administration of insulin in suspension. In addition to the articles of surgical, medical, neurological, and histological interest, the volume contains a series of four papers on the filtrable viruses by Dr. S. P. Bedson and Dr. J. O. W. Bland, two on the tetanus bacillus by Dr. Paul Fildes, and a large number of important biochemical papers by Dr. John Marrack, Mr. F. L. Hewitt, Mr. H. D. Kay, Dr. Campbell Smith, and others. The consistently high standard of the contributions here collected, together with the wide and important field of medical subjects concerned, makes the collected work of interest not only to members of the London Hospital but also to all students and teachers who are occupied in promoting the advance of medicine. The book is, moreover, a tribute to the scientific vigour of the medical school from which it comes.

RECENT ADVANCES IN PLANT PHYSIOLOGY.

By E. C. BARTON-WRIGHT, M.Sc. Lond., Lecturer in Botany in the University of London, King's College. London: J. and A. Churchill. 1930. Pp. 352. 12s. 6d.

THE compiler of a volume dealing with recent advances in any branch of science is confronted with the difficulty of selection; Mr. Barton-Wright admits that he has been guided entirely by his own predilections in deciding what is important work, and on the whole we do not cavil at his choice. He has divided his subject matter into six chapters, dealing respectively with the soil and water relations of the plant, transpiration, translocation and root pressure, carbon assimilation, nitrogen metabolism, respiration, and the physiology of growth. In the first chapter he gives a somewhat brief review of the much debated question of soil acidity and also of the base exchange, while the investigations of Weaver in America on the ecological and physiological characters of different root systems receive fairly extensive consideration. In the second chapter will be found a useful account of the question of the mechanism of the ascent of cell sap with a criticism of Bose's vital theory of pulsatory activity which should help to clarify ideas about Bose's rather sensational deductions. The same chapter also contains an account of the subject of translocation, including the work of Mason and Maskell in Trinidad on the cotton plant. The chapter on carbon assimilation is perhaps the least satisfactory of the six, containing on the whole little information that cannot equally well be found in most of the more recent text-books. In the chapter

dealing with respiration the student should be grateful to the author for an account of the researches of Blackman and Parija which in the original are rather difficult to disentangle. The last chapter covers a large field, and includes a consideration of much recent and widely scattered literature which has not yet entered the text-books. Though his enthusiasm has at times led Mr. Barton-Wright to criticise the work of others in a manner which does not seem justified, he has produced a useful book obviously founded on extensive reading.

THE BRIDLE OF PEGASUS.

By WARREN R. DAWSON, F.R.S.E. London: Methuen and Co., Ltd. 1930. Pp. 203. 7s. 6d.

THIS book, dedicated to the learned author of "The Golden Bough," is addressed equally to the medical profession and to the public. The studies of magic, mythology, and folk lore are well selected in subject and well set down, while a profuse bibliography shows the author to be widely read. As a result he has been able to bring together some interesting tales illustrating popular beliefs whose history reaches back to primitive times, and whose precepts are even yet rooted in the minds of the more uneducated and simple of all populations. The volume is made up of eight separate and independent studies, but the different essays have this in common, that they reveal certain efforts of primitive man to control the forces of nature by magical aid. A word of praise should be added for the scrupulously careful way in which the full references are given.

NOTABLE BRITISH TRIALS.

Trial of George Chapman. Edited by HARGRAVE L. ADAM. London: W. J. Hodge and Co. 1930. Pp. 223. 10s. 6d.

George Chapman, alias Severin Klosowski, hanged in 1903 for the murder of Maud Marsh, forms the subject of the fiftieth volume in Messrs. Hodge's Notable British Trials Series. Dr. Thomas Stevenson, the Home Office expert, was called to prove that Maud Marsh died of antimony poisoning. His evidence of the similar deaths of Mrs. Spink in 1897, and Bessie Taylor in 1901 (with each of whom Chapman had lived), was admitted for the purpose of negating any suggestion of accident in the Marsh case. Up to a point Chapman was fortunate in his victims' medical attendants; Mrs. Spink's death was attributed to phthisis, and Bessie Taylor's to "exhaustion from vomiting and diarrhoea" with no suspicion of foul play. The uninquisitive attitude of the doctors was criticised by Mr. Justice Grantham, whose characteristic summing-up (delivered in days before the Court of Criminal Appeal was established) almost took the guilt of the accused for granted. Mr. Hargrave Adam's adequate, if sometimes diffuse, introduction mentions the possibility that Chapman was identical with Jack the Ripper. The main ground for their suggestion is Chapman's presence in London, and indeed in Whitechapel, during the period of the Ripper murders; similar murders are said to have occurred subsequently in Jersey City at a time when Chapman was in that part of America, and to have ceased when Chapman returned to England. This argument from opportunity will probably not convince those who hesitate to identify an antimony poisoner with the madman who had mutilated a number of unfortunate women ten years earlier. If the letter and card received by the police in 1888 were the authentic writing of the Ripper, could the writer have been Chapman, who in 1903, was unmistakably illiterate? Officials like Sir Melville Macnaghten have, as Mr. Adam says, claimed to have penetrated the Ripper mystery. But they leave us no wiser. A constable had a chance to catch the murderer red-handed on one occasion, but turned violently sick at the ghastly sight of the corpse and so the Ripper got away.

THE LANCET.

LONDON: SATURDAY, MAY 24, 1930.

REGIONAL HOSPITAL ORGANISATION.

THE Merseyside Hospitals Council, which organised and administers the contributory fund for the Liverpool hospitals, has issued a memorandum upon a subject which cannot fail at an early date to engage the serious attention of every person concerned with hospital policy. It deals with the organisation of hospital services in south-west Lancashire, Cheshire, and North Wales, and has been called forth by the heavy demands now made upon the Liverpool hospitals, and especially the teaching hospitals, from districts outside the scope of the fund. Patients from those districts, which include the Isle of Man, last year cost the Liverpool medical institutions a net sum exceeding £16,000, after allowing for contributions by them or on their behalf and subscriptions known to have been received from their areas. That is to say, the Merseyside contributors are paying part of the cost of hospital treatment and maintenance of "foreigners" in much the same economic condition as themselves. This, in itself, is a serious situation, but the financial is really less grave than the medical aspect of the matter. The swamping of beds results in the creation of waiting-lists which would otherwise be of comparatively small proportions. The Liverpool beds would be inadequate in any event, but this pressure from areas distant more than ten miles from Liverpool town hall intensifies congestion without bringing compensation. The unfairness of the burden is obvious; the difficulty is how best to remove it. It is essential to bear in mind that the object of the Liverpool penny-in-the-pound fund, like all other contributory schemes, is not merely to improve finance, but to increase the medical efficiency of the hospitals. To ban the "outsider" is clearly unthinkable. The smaller centres cannot possibly provide the resources either of personnel or equipment of a large town which is the seat of a medical school; the avenues of access to these advantages must therefore be kept open to the whole of the region which looks to a particular hospital centre.

In the opinion of the Merseyside hospital council the only way out of the difficulty is the establishment of contributory schemes similar to its own in suitable centres of the outer zone. This need not be a very elaborate process, since four such schemes ought to suffice—West Lancashire, centring on St. Helens, Widnes, or Runcorn; Deccide, centring on Chester; north-east and north-west Wales, centring the one upon Wrexham and the other upon Bangor. These regional councils might be federated, or affiliated, with the Merseyside council, and in dealing with their finances they would necessarily take into account not only the cost of maintaining the patients they sent to Liverpool, but the overhead costs of the teaching hospitals. This, however, is to solve only a part of a problem which will rapidly grow more insistent. How can the best use be made of the hospital services, of varying importance, which already exist in these outside areas? If the Liverpool hospitals can do what even the larger local ones cannot do, the smaller ones, in their turn, are depen-

dent for special services upon the more central institutions of the district. Those institutions would form the natural core of a regional system which would always have a head-centre to which it could turn when the highest skill or special equipment was necessary. To work successfully such a system would need a measure of elasticity which there is no need to suppose would be lacking. The existing haphazard and unsystematic state of things is always wasteful and sometimes dangerous. Either the costly equipment of a local metropolitan hospital is used for cases which do not require it, or its employment may be perilously delayed in cases in which it is essential.

Results of practical importance to national hospital policy may be expected to follow the issue of this memorandum, which is intended to form the basis of discussion at a series of conferences to be convened by the Merseyside Hospitals Council. The difficulties which are being so keenly felt at Liverpool are likely to be, if they are not already being, felt in other great centres. It would seem that the contributory scheme bids fair to be the financial basis of the voluntary hospital service for a long time to come, in the absence of revolutionary changes of which there is at present no sign. Wherever these schemes have been established they have not only succeeded, but succeeded in a measure and with a rapidity that has been startling. Sheffield and Birmingham, Leeds and Liverpool, to mention only some outstanding instances, to which the Hospital Saving Association in London may be added, are raising much of their hospital revenue from the pence of the artisan. But the benefits of these pence are everywhere being claimed—and enjoyed—by those who do not subscribe them, and there are large areas, even in the industrial north and midlands, where there are no contributory schemes. Sometimes, too, there are large, but not teaching, general hospitals just outside the area of a scheme which are yet not infrequently beholden to it. Sometimes, moreover, it has been complained that a contributory scheme has invaded territory which believes that, with its own excellent hospital, it is sufficient to itself. Regional coördination of contributory schemes will rapidly become imperative if they are not to be left suspended in mid-air. The delimitation of boundaries will not only be for the advantage of existing schemes but will be likely to encourage the formation of others. This step is, indeed, a necessary part of that systematising of the voluntary hospital service which has been imposed upon it by recent events. The existence of a highly organised municipal service side by side with a casual and unsystematised voluntary service would involve perils which grow in gravity the more closely they are looked at.

THE FUNCTION OF THE AUTONOMIC SYSTEM.

THE function and arrangement of the autonomic system used to be one of those branches of knowledge which the medical student was at liberty to forget as soon as he had passed his preclinical examinations. The system was known to play an important part in the internal economy of the body, but disorders of the autonomic nerves seemed so rare or the symptoms of them were so obscure that little interest was taken in them even by neurologists. The position has certainly altered to-day. It is true that it needs a bold man to diagnose vagotonia, that the surgery of the sympathetic is still in the experimental stage, and that the hypothalamus is still regarded as a region

of the brain best left alone; but there is no doubt that disorders of the autonomic system do exist and that they may become amenable to treatment.

Prof. CANNON's Linacre lecture at Cambridge gives an account of the autonomic system which differs strikingly from much that has been written on the subject. It is an authoritative statement based on experimental work in which a high standard of accuracy has been required, and it gives a clear picture of the work which is normally carried out by the autonomic nerves and of the results which follow from their removal. In his discussion of the double nerve-supply of the viscera, Prof. CANNON draws an interesting contrast between the cranial and sacral, or parasympathetic, systems and the opposing sympathetic. He points out that the cranial and sacral nerves are arranged to produce a number of distinct and independent reactions—e.g., constriction of the pupil, salivary flow, slowing of the heart—whereas the sympathetic, with its overlapping connexions, gives a general diffuse activity in the opposite sense over a very wide area. By the simultaneous action of the two systems any special viscus can be separately affected in either direction, but the diffuse action of the sympathetic ensures a widespread discharge when the stability of the organism is threatened. This function of preserving the "homeostasis" of the body—i.e., of preserving a constant internal environment in spite of the activities of the animal and of its surroundings—is the main concern of the sympathetic system, aided by the discharge of adrenalin which accompanies sympathetic activity. By regulating the peripheral vessels and the sweat glands, the system helps to preserve a constant internal temperature, it causes a discharge of sugar from the liver and of red blood corpuscles from the spleen, if either are needed to increase the capacity for muscular exertion, and in face of injury it checks the bleeding and prevents any reduction in the flow of blood through the heart and brain. There are, of course, many other systems concerned in maintaining the internal environment, but a nervous mechanism occupies a peculiar position in that it is linked to the brain and so can be brought into play when danger threatens, but before the actual moment for combat or flight has arrived.

The total removal of the sympathetic system naturally reduces the efficiency of the animal, but the remarkable fact brought out by Prof. CANNON's experiments is that the reduction becomes a serious matter only when extreme conditions have to be faced. When animals are totally sympathetomised they become exhausted more rapidly by severe muscular work, because the vascular system is no longer adjusted to meet the increased demand. Sugar is no longer liberated from the liver during emotional excitement and the spleen fails to contribute its reserve of erythrocytes. But with all this the animals are able to live comfortably in the sheltered conditions of a laboratory. There is a negligible change in the basal metabolism and unilateral sympathetomy produces no change in the rate of growth, in the muscular tone, or in the resistance to fatigue on the affected side of the body. No doubt some of these negative results will not go unchallenged, but the fact remains that the sympathetic seems to play a relatively unimportant part as long as the animal lives under conditions "where there are no marked temperature changes throughout the year, no necessity of struggle for food, no requirement of escape from enemies, and no danger of hæmorrhage." As Prof. CANNON points out, this is a very special and limited sort of existence for an

animal, and it would be a mistake to belittle the importance of the sympathetic for the proper functioning of the body. But man has so much control of his external environment that his life is more like that of a laboratory animal than of one set free to look after itself in the open. We regulate our body temperature by clothing ourselves and heating our rooms; many of us have no need to undertake exhausting muscular work, and the struggle for food is a mental rather than a physical struggle. The sympathetic system is clearly not as essential to our well-being as it would be to that of a wild beast. Parts of it have now been removed in man for the relief of various disorders ranging from spasticity of the muscles to angina pectoris. The theoretical basis for many of these operations has been extremely uncertain and the results are difficult to assess, but at least it seems to be true that very little harm has come from the excision of sympathetic ganglia except in some of the operations for angina. Intractable pains have undoubtedly been relieved, and a more exact knowledge of the nervous pathways may increase the percentage of successes, though it may reduce the number of cases in which an operation seems advisable. In any event, the possibility of surgical interference with the sympathetic system has opened up a new line of attack on various disorders of blood-vessels and viscera, and if an animal can lead a comfortable though restricted life after the loss of its entire sympathetic we need not be horrified at the thought of its partial removal in man.

SANATORIUM AND AFTER.

TUBERCULOSIS illustrates, as nothing else in medicine, the operation of social circumstances. There are at the present time some 15,200 beds provided in England and Wales for the sanatorium treatment of pulmonary tubercle, the value of which in improving the general health is now beyond dispute, although many of the patients on leaving the sanatorium are still unfit to go back to work at their old occupations. This must account for the tendency, particularly noticeable last year,¹ to increase the duration of residence beyond the usual period of six months. In America at least one half of ex-sanatorium patients are reabsorbed at once into ordinary industry, but the proportion is certainly not so large in this country and is probably nearer 40 than 50 per cent. It depends largely on the operation of social circumstances. In times of industrial depression it is well-nigh impossible to find openings for ex-consumptives, but the qualms about taking them on again are subdued in times of industrial prosperity. Re-entry of such a worker into the industrial market postulates a high degree of intellectual capacity at some particular job, for he no longer possesses the essential requirement of an unskilled labourer which is a high standard of physical fitness. The position challenges all who are concerned with after-care to raise by every means the percentage of those whose skill entitles them to be reabsorbed into industry. The scheme for technical education of suitable youths between the ages of 14 and 19 undertaken by the National Association for the Prevention of Tuberculosis under the supervision of the Surrey Education Committee is one useful step in this direction. Taken by and large there is, however, little hope economically for the consumptive unless he is able to resume his previous occupation.

¹ See Ministry of Health Memorandum, 131 B/T.

But what of the remainder? There are, as the Employment Committee of the Joint Tuberculosis Council indicates,¹ three other channels into which the consumptive may be steered in attempting to land him on economic ground. He may be employed under an authority, State-aided or voluntary, in some sheltered position; he may be allowed to work at an urban or municipal workshop; or he may be admitted to one or other of the village settlements specially designed to meet his requirements, medical and economical. Some local authorities, such as those in Hull, Liverpool, London, and Walsall, have turned their attention to the employment of ex-sanatorium patients on the staff and if, as we may now hope, the problem of after-care is vested as a rule in a definite committee, more steady progress may be hoped for in this direction. But the employment of ex-patients on the staff of sanatoriums is a practical proposition already proved; its scope is large, for the total value of staff services rendered in such institutions must amount to at least £550,000 a year. The majority of medical superintendents are in favour of the employment of ex-patients except in the preparation of food, and there are probably over 450 now occupied as nurses, domestics, porters, gardeners, and the like. Few practical difficulties have arisen, and a margin of 10 per cent. of staff is suggested as sufficient to meet the expected breakdowns. The subsidy, whether in labour or money, does not seem to be greater for patients working on the sanatorium staff than for those in workshops attached to settlements. Employment is given only on the distinct understanding that its object is to restore the patient to health and working capacity, and if these posts are reserved for those actually suffering from tuberculosis, and not simply for those who have been diagnosed as such or who have had tuberculosis at some previous period in their history, a wide channel is opened for rehabilitation. After finding so large a use made of so small an industry it is somewhat of a shock to learn that the total number of tuberculous employees engaged in urban workshops in this country probably does not exceed 90 at the present time. Medical results have been satisfactory enough at the Leeds factory-in-the-fields and at the Spero workshops in London, although naturally none of the workshops has been self-supporting. At Leeds it has cost the corporation about £1 a week for every man so employed—care committees have often spent on individual cases much more than this sum without any real economic advantage—but the experience has been too small to decide what subsidy is necessary for workers in such schemes.

Employment in village settlements, the remaining channel to consider, has, in the Committee's opinion, passed from the experimental stage and may be discussed in the light of its contribution to the problem of tuberculosis. The criticism of needlessly high expense comes badly from any local authority which has been relieved by the existence of the settlement from statutory responsibility for an infective individual, and which actually gains by having the house of the sufferer free for a healthy member of the community. Although at Preston Hall the capital expenditure per settler to date is over £500, this is regarded as an outside figure; in any case, money should be forthcoming from rates and taxes for this

as for any other branch of the tuberculosis scheme. More cogent is the criticism that the settlement caters only for the few. During the first ten years at Papworth fewer than 7 per cent. of the cases treated were admitted to the settlement, and at Preston Hall during 1925-28 the proportion was a bare 14 per cent. The total number of ex-patients employed in village settlement industries in this country is now only about 340, whereas, if the settlement scheme is to meet all needs, for every sanatorium of 150 beds there should be an absorption rate of 9 patients per month (which would mean at the moment a total of 900) into settlement conditions, a result, the committee remarks, beyond the wildest dreams of the most optimistic. The success of a settlement depends on factors met with but rarely in the realm of medicine and economics. Settlements run on Papworth lines must depend for prosperity on a turnover which is secured in spite of giving to a number of sub-standard individuals the security of tenure denied to healthy workmen in prosperous concerns outside. In view of fluctuating markets, Preston Hall would hesitate to take the risk of indefinite enlargement, and it is probably true that large settlements on similar lines could not be repeated in more industrialised counties, were patients to be drawn solely from surrounding areas with a particular type of technical ability. If the settlement idea is to extend, as it should, each separate unit must grow from a small nucleus, the centre of which will be a scheme for occupational therapy. Places should be reserved for the type of case who would not ordinarily be absorbed into industry in the outside world; the settlement must not come to be a refuge for substandard labour but remain part of the mechanism for continued treatment. Key-men might be allowed to remain on after they could safely find for themselves outside, but it is strictly as a community for restoration to health and working capacity that the village settlement approaches to the perfect solution of the medical and economical problems of the consumptive. Further development might well be in the direction of forming a national association of village settlements as set out on p. 1143 by Dr. VARRIER-JONES of whose pioneer work at Bourne, Cambridgeshire, the modern conception of these settlements is the outcome. Preston Hall and Papworth represent the end-results of that unique experiment, for Dr. VARRIER-JONES took charge of Preston Hall when the British Legion assumed responsibilities there in 1925 and was succeeded in 1927 by Dr. McDougall to whom the report owes its present form.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Demonstrations will be given at the Miller General Hospital, Greenwich, at 2 P.M. on Monday, May 20th, by Dr. E. G. Warner (selected cases, children), and on Friday, the 30th, by Mr. Arthur Gray (gynaecological operations). Lectures suitable for M.R.C.P. candidates will be given by Dr. B. T. Parsons-Smith, at 11, Glandos-street, W., at 8.30 P.M. on Tuesday, May 27th (Coronary Thrombosis), and on Friday, the 30th (Cardiac Failure). Two courses will be held from May 26th to June 7th—a morning course on Diseases of Children at the Hospital for Sick Children, Great Ormond-street; and an all-day course in Medicine, Surgery, and the Specialties, with special reference to tuberculosis, at the Queen Mary's Hospital, Stratford. Courses in June will be as follows: Gynaecology, at Chelsea Hospital for Women (June 18th to 28th); Dermatology, at the Blackfriars Skin Hospital (10th to 28th, afterwards); Medicine and Surgery, at the Prince of Wales's Hospital (10th to 28th, all day); Proctology, at St. Mark's Hospital (June 30th to July 6th, all day). Copies of all syllabuses and particulars of post-graduate work are obtainable from the Secretary of the Fellowship at 1, Wimpole-street, London, W.1.

¹ Report of the Employment Committee of the Joint Tuberculosis Council on Care and After-care Schemes in Tuberculosis. Signed by Dr. Jane Walker, Dr. D. P. Sutherland, Dr. H. Vallow, Dr. G. Jessel, Dr. P. W. Edwards, Dr. C. O. Hawthorne, and Dr. J. H. McDougall, the last-named being convener of the Committee. May, 1930. 1s. 6d., post free, from the Secretary, Preston Hall, Aylestone, Kent.

Annotations.

"Ne quid nimis."

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

THE Royal College of Physicians of Edinburgh was founded in 1681, and it has been decided to celebrate the 250th anniversary of its foundation on St. Andrew's Day, Nov. 30th, 1931. An attempt to incorporate the practitioners of medicine in Scotland for the purpose of raising the standard "both of the character and acquirements of physicians" originated in 1617, when application was made to King James I. of England and VI. of Scotland for that purpose. The King issued an order to Parliament for the establishment of a college to fulfil the design indicated, but political and religious dissensions prevented the scheme from being carried out. A further attempt was made in 1630, when King Charles I. referred the matter to the Privy Council, but the unsettled state of the country again delayed the project. With Cromwell in power accomplishment took a stride further, for the Protector took up the matter warmly, and a patent was made out in 1656 instituting a College of Physicians of Edinburgh. The patent, however, gave powers to the proposed college, which did not meet with general acceptance among doctors, and Cromwell's death put a stop for a time to the proposals. Eventually a charter of incorporation was obtained, chiefly through the exertions of Sir Robert Sibbald and the Earl of Perth, and the Great Seal was appended to the Charter on St. Andrew's Day, 1681, when King Charles II. was on the throne. The first president of the College was Archibald Stevensone. Owing to the destruction of the early minutes of the College the exact scene of the original meetings of the corporation is in doubt, though it may have been the house of Sir Robert Sibbald, the virtual founder of the College and its President in 1684. In 1698 the College resolved to purchase a house, but the members continued to meet in apartments rented for the purpose until 1704. In this year a property was bought in Fountain Close, and seven years later some adjacent land was added, by which time, we learn from contemporary writing, "the grounds and the shrubbery were the envy of the neighbouring Peers, to several of whom the privilege at their request was granted to walk in them as a favour." The buildings erected, however, were not worthy of their environment, and plans for their improvement did not find favour, so that a request was made by the College to the Royal Infirmary for permission to hold meetings at the institution, as well as shelter for the books which were suffering injury. For 15 years the College enjoyed the hospitality of the Infirmary with whose origins it was closely concerned, and the premises in Fountain Court were sold in 1770 for £800. A College Hall was commenced in George Street in 1775, when the foundation-stone was laid by the famous William Cullen, the President. The present hall, designed by Thomas Hamilton, dates from 1844, the adjoining premises having been added at different times. The story of the College, especially in its various connexions with the Royal Infirmary, illustrates the progress of academic and clinical medicine in Edinburgh from the union of the two kingdoms, and there is no need to point to the fact that the science of the senior partner has been repeatedly reinforced from Scotland.

THE SILICOSIS BILL.

THE object of the Workmen's Compensation (Silicosis) Bill, which has now been read a third time in the House of Lords, are first to bring cases of asbestosis within the scope of Section 47 of the Workmen's Compensation Act, 1925, and secondly to give

powers to the Secretary of State to make a general scheme for all the industries to which compensation schemes apply, in order that the medical arrangements may be orderly and efficient. At present such cases are reported by certifying surgeons with medical referees to fall back on in case of disagreement; examination by a medical board, devoting itself entirely to this type of case, will no doubt replace this system. Amendments brought forward by Viscount Brentford at the committee stage of the Bill to each of these proposals were rejected. In the first place, it was suggested that the amount and severity of asbestosis did not warrant its inclusion in the schedule, and that if included there would be an increasing number of claims, many of them without justification. In reply, Earl Russell showed that although the number of workers in asbestos was not large, yet the incidence of disease in them was considerable; more careful and skilled examination of the workers would, he suggested, unmask the presence of asbestosis which had previously been mistaken for some other pulmonary disease. Lord Brentford also expressed anxiety lest the scheme for co-ordinating medical arrangements should involve a large staff and expenses, of which the major part would fall on the employers who already made their contribution through the national health insurance system. Earl Russell was able to assure him that the Treasury would make an annual contribution to medical expenses, while the national Exchequer would be relieved of the present expense of appeals from the certifying surgeon. Furthermore, existing medical boards for the various silicosis industries would be the basis of the new medical service, and would no doubt be able to cope with the extra work with the addition of one or two new centres. The amendment was not pressed on the understanding that the scheme should be prepared in consultation with the employers' federation.

CERVICITIS AND BACKACHE.

OF the disabilities that cause a person to seek medical aid, backache is one of the most common. The symptoms vary from a heavy dragging sensation which makes life burdensome to an acute stabbing, crippling pain which makes any form of work impossible. The causes of backache are legion; Prof. J. P. Maxwell,¹ of Peking, has recently added to the long list by suggesting that a mild form of osteomalacia might be responsible for some of the cases in this country. The treatment of the condition is usually empirical, and ranges from a mustard plaster or some liniment through belts, extraction of teeth, dietetics and diathermy, and manipulation to a severe surgical operation. All these procedures are praised by their several exponents, but none has received general favour. Dr. James Young² has recently restated and emphasised the view that chronic cervicitis is responsible not only for leucorrhœa, but also for abdominal and pelvic pain, bladder and menstrual troubles, and marked and varied disturbances of the general health. Indeed, he goes so far as to say that, with the possible exception of prolapsus uteri, chronic cervicitis is the commonest gynecological cause of abdominal and pelvic pain, and advises dilatation of the cervix and the cauterisation in its treatment. Dr. Harold Baker,³ writing on the same subject in America a few weeks later, while guardedly stating that these symptoms had been attributed to cervicitis, claims that the leucorrhœa may be cured by cauterisation without dilating the cervix and without any anæsthetic, "since patients experience very little discomfort or pain." That gonorrhœal cervicitis should be promptly and energetically treated, and that gonorrhœal arthritis may be rapidly relieved by treating the cervix, nobody will deny, but that the symptoms suggested by Dr. Young are actually

¹ Proc. Roy. Soc. Med., March, 1930, p. 639.

² See THE LANCET, March 15th, p. 575.

³ Amer. Jour. Obst. and Gyn., April, 1930, p. 548.

caused by, not merely associated with, cervicitis is difficult to believe. The cervix is practically insensitive, and large numbers of women suffering from leucorrhœa complain neither of abdominal nor of pelvic pain. All authorities are agreed that the condition is more common in women who have borne children, and that it is associated with constipation, anemia, and general ill-health. It is equally well known that women who are run down from any cause, social or industrial, suffer from menstrual disorders and leucorrhœa, and that these symptoms disappear when the general health improves. Many authorities hold that a loaded colon is the commonest cause of the symptoms attributed by Dr. Young to cervicitis. At one gynaecological clinic which has a large out-patient department no woman is examined per vaginam until she has taken a mixture containing iron and magnesium sulphate for at least a week. The result of this routine is that 70 per cent. of women are cured without further treatment. The very varied opinions on the subject are not a credit to gynecology.

THE CARNEGIE TRUST AT HOME.

THE programme of the Carnegie United Kingdom Trust during the years 1931 to 1935 is to include an increase of children's play centres, development of a better service of public libraries and public baths, and a more comprehensive policy in the field of adult education.

The sixteenth annual report gives an interesting survey of the success of the playing-field movement as a result of the propaganda begun in 1927. The grants made have been comparatively small, varying from one-tenth to one-sixth of the total cost in each case, but in spite of this local authorities have proved anxious to undertake and carry through schemes for the provision of playing-fields in their areas; only two or three grants have been refused out of a total of 260 offered during the years 1928 and 1929. In the distressed mining areas special grants have been made towards playing-fields, with a twofold purpose: to provide the unemployed miners and their children with opportunities for enjoying fresh air and exercise, and to offer employment to some of the men in the construction of the fields. In many places where fields have been provided under the scheme there is evidence that the demand is in excess of the accommodation, and the authorities are considering extension of their present areas. One of the dangers experienced during the last few years has been deterioration owing to lack of adequate maintenance and supervision. Turf, fencing, and equipment suffer quickly from neglect, and if the playing-fields are to fulfil their function constant care and restoration are necessary. In Scotland a committee has been formed to supervise the spread of the movement, which has hitherto been slower than in England. The demand for play centres for young children has been considerably stimulated by the playing-field movement, and grants are made for equipment, such as swings and see-saws, and for sanitary accommodation and shelters. The value of such play centres in crowded districts can hardly be over-estimated; the danger of death or disablement from accident increases yearly where children have no playground but the streets. Another of the activities of the Trust has been to provide shower bath installations in a small number of selected villages in Lincolnshire. These have been much appreciated, and it is hoped that they will shortly begin to pay their way. The Lindsay Education Authority are making a grant to enable school-children to attend without charge. The model child welfare centres established in various towns during past years are now all recognised as essential parts of the municipal health services. The work is steadily developing. The Rhondda Centre, built in 1927 but not opened for financial reasons, has at last been equipped, and was to begin work in April, 1930.

The new social survey of London, to which the Trust has promised a grant of £1000 when other contributions shall have reached £14,000, has now £12,200 available and will presumably secure the remainder shortly. The survey is to cover poverty, housing, industry, and special subjects. Poverty has been the subject of conferences between school attendance officers, employment exchanges, boards of guardians, police, house and estate agents, and the Charity Organisation Society. Information on housing is being supplied by the various boroughs, and the industrial survey is in the hands of appropriate experts. Special subjects will include, among others, the influx and efflux of population, the social influence of trade-unions, dwellers in neighbouring garden cities, and habits of leisure in the city of Westminster.

THE TRAGEDY WITH BCG VACCINE AT LÜBECK.

OUR Berlin correspondent tells us of the disastrous sequel to the use of BCG vaccine which has been reported from the Hanseatic city of Lübeck. It appears that the Calmette method of protecting infants against tuberculosis has lately been brought to the notice of the Berlin Medical Society and the German Central Tuberculosis Committee, and Prof. His had invited Dr. Weill-Hallé, of Paris, to initiate a discussion at the Charité Hospital in Berlin. In Düsseldorf Prof. Schlossmann had already reported favourably, and experience at the Children's Hospital at Berlin was similar. At Lübeck, however, it has been otherwise. There the vaccine was employed on the official recommendation of the local health authority and 246 infants were treated on the lines indicated by Calmette. Of these 50 became severely ill with swelling of the inguinal and abdominal glands and other symptoms of acute tuberculosis. Fourteen deaths have been reported and others are expected to follow. Prof. Lange has been sent by the German Health Office to inquire into the cause of the disaster, which has not yet been ascertained. It seems clear that the original culture was purchased in Paris, further subcultures being made in Lübeck by Dr. Deycke, an experienced immunologist, who is confident that no mistake can have been made either in the preparation or in the distribution of the remedy at Lübeck. Local criticism is directed to the fact that the method was applied outside the hospitals and dispensaries and that midwives were instructed to give the vaccine to newly born infants (their parents being agreeable) not under immediate medical control. Prof. Guérin, of the Pasteur Institute in Paris, has however, declared that the vaccine of which a quantity was sent to Lübeck in the autumn of last year was in good condition and that a mistake must have been committed in its application. It was as usual sent in bulk for subculture on the spot, as the ampoules do not travel. BCG, it may be recalled, is a bovine strain of tubercle bacillus, first isolated in 1906, and repeatedly subcultured for 13 years on a special medium of glycerinated ox-bile until its virulence was reduced to a point regarded as safe for inoculation work with living cultures. But although Calmette and his collaborators claim absolute proof of safety on an experience of 400,000 injections, laboratory workers have not all felt happy about the avirulence of the material. Two years ago at the Trudeau sanatorium S. A. Petroff and Arnold Branch found that the vaccine was not constantly innocuous to small laboratory animals. In two instances generalised tuberculosis followed direct inoculation into guinea-pigs and in a further instance tuberculosis was established after the second animal passage. When the vaccine was cultured in a fluid medium the appearance of two types of colonies made the Trudeau workers suspicious of the existence of variants similar to those observed in the reproduction of other acid-fast organisms; and after plating they were able to differentiate two distinct types of

colonies, one of which produced tuberculosis which in time healed, while the other produced progressive disease terminating in the death of the guinea-pig. Petroff's work was confirmed last year in the New York public health laboratories by M. J. King and W. H. Park, although the Pasteur Institute, using his technique, failed to obtain virulent bacilli either by culture or passage. Whatever may be the truth about the immunising value of BCG vaccine—Dr. Stanley Griffith is engaged on investigating it at the Cambridge field laboratories—the Lübeck incident brings to mind the all too obvious fact that the use of live vaccines has its dangers and limitations. It was long believed that the use of living but attenuated virus was essential to the production of a good prophylactic immunity, but as Prof. J. McIntosh pointed out in a presidential address four years ago¹ this belief broke down after the experience of Haffkine with his plague vaccine and Wright with his typhoid vaccine; since then the general trend of medical progress has been to drop the use of living virus for the dead virus or for some of its products. The injection of virus capable of multiplication in the injected body is far from ideal, for when multiplication occurs there is no possibility of estimating the dose to which the patient has been subjected, and in susceptible individuals this may lead to unforeseen results. The reintroduction of the use of an attenuated living virus in tuberculosis was described by Prof. McIntosh as a retrograde step. Who knows, he said, for how long an attenuated bacillus can lie dormant and then assume its former virulence?

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

At the annual general meeting of this Society, held on Wednesday, with the President, Mr. V. Warren Low, occupying the chair, the report for 1929 was presented. Five members have died, six resigned, and six new members were elected during the past year, making a total membership of 284, made up of one honorary, 162 life, and 121 ordinary members. At the end of the year there were 49 widows and 12 orphans in receipt of grants; during the year four widows and seven orphans came on the funds and four widows died. The benefits offered by membership are well illustrated by the grants received by these four widows.

One came on the funds in 1904, her husband paid in subscriptions £31 10s. and his widow received in grants £2200. Another who came on the funds in 1918 received in grants £750, her husband having paid £52 10s. Another came on the funds in 1915 and received £1050, her husband having paid £35 14s., and the last widow who came on the funds in 1925 received £300, her husband having paid £31 10s.

The invested funds of the Society amount to £140,700. The income received from investments was £4244, income-tax returned £764, interest on deposit account £51; £255 was received from subscriptions, and donations amounted to £108. One legacy was received of £140. £5252 10s. was distributed in grants, and working expenses were £330.

The smallness of the membership is a matter of concern to the directors, and they desire to bring to the notice of the newly qualified and also the newly married members of the medical profession the advantages that may be gained by joining the Society, which is both provident and benevolent. Should a member die and leave his widow with an income not exceeding £125 per annum, she would, on the present scale, receive from the Society a yearly grant of between £75 and £90, and any children under the age of 16 would receive a yearly grant of £60 each. Over the age of 16 special grants may be made to orphans to enable them to continue their education or start in some profession.

These grants in many cases amount to £52 10s. a year to each orphan. The amount of the annual subscription is small compared with the benefits that may be derived by unprovided dependents of a deceased member. For a member who at the time of his election is under 40 years of age it is two guineas; there are special terms for life membership. Relief is granted to the necessitous widows and orphans of deceased members of three years' standing, and of life members. Membership is open to any registered medical practitioner who at the time of his election is resident within a 20-mile radius of Charing Cross. Particulars may be obtained from the secretary of the Society at 11, Chandos-street, London, W.1.

RESEARCH FELLOWSHIPS IN TUBERCULOSIS.

FELLOWSHIPS for research in tuberculosis are being provided from a fund established in memory of Dorothy Temple Cross, and the first award will be made by the Medical Research Council in July for the academic year beginning on Oct. 1st. The object of the Fellowships, as defined in the trust deed, is to give special opportunities for study and research to persons "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." Candidates must be British subjects and must hold suitable medical, veterinary, or scientific qualifications. They must also be able to produce evidence of their ability to make good use of the opportunities offered. The Fellowships will preferably be awarded to candidates who wish to conduct their studies or inquiries outside Great Britain. They will, as a rule, be awarded for one year, but in special cases may be renewed. Their value will depend upon the standing and qualifications of the candidate, but will not be less than £300 per annum, with travelling expenses in addition. It is also hoped to award one senior Fellowship of considerably greater value, and with good prospect of renewal for a further period, to a well-qualified candidate wishing to undertake intensive investigation into some special problem of tuberculosis whether under a temperate or a tropical climate. Application must be made not later than June 30th, and further particulars are obtainable from the Secretary of the Medical Research Council, 38, Old Queen-street, London, S.W.1.

A SCHOOLBOY'S SUICIDE.

Two letters have recently appeared in the press the relation between which is not obvious at first sight. In the one Sir Farquhar Buzzard pleaded for the treatment of the sufferer from "nerves," a minor mental disorder for which treatment is not readily available. In the other the father of a boy who had committed suicide repudiated the suggestion that the lad was a coward. The need for this plea arose from an assumption that the cause of suicide was fear of fagging at school, and the headmaster of the school was likewise compelled to defend himself from the emotional storm aroused by the publicity given to that assumption. The storm was connected with an old controversy about fagging at public schools that need not concern us here; the belief that any boy could have a direct and rational fear of the discipline of present-day fagging so great as to lead to suicide is closely related to the neglect of minor mental disorders which prompted the letter of Sir Farquhar Buzzard. Doubtful points concerning physical disease are in little danger of neglect at inquests; expert assistance is promptly called for, especially if responsibility, direct or indirect, is likely to be fixed upon anyone. But in the much more difficult problems of behaviour the psychologist is seldom asked for an opinion.

In its characteristics this case does not stand alone. Suicides that are apparently inexplicable are common, and sometimes the victim's friends describe his over-conscientiousness, his devotion to work and duty, his

¹ THE LANCET, 1926, II., 889.

earnest and scrupulous regard for others—qualities estimable in their proper place, but in these cases recognisable as indications of one type of "nervous" disorder and suggesting to the psychopathologist other and deeper emotional stresses. This boy was described as capable, hard-working, and brave, the only evidence of emotional stress being a casual observation that he was subject to notable phases of silence. It is possible that the matter of fagging served as a point of fixation of troubles dependent upon deeper emotional difficulties, just as in the other cases we hear that the victim persistently worried over matters that others regarded as trivial or non-existent. It is the essence of some disorders that the patient suffers from anxiety of unconscious origin; this anxiety must be transferred to something in the world outside, and it may then appear as irrational and absurd. Perhaps the day will come when we shall be able to recognise temperamental difficulties in young people and give timely aid, just as we have already learnt to watch over the physical well-being of the child without waiting for the development of disease.

INFECTION IN ST. KILDA.

ST. KILDA lies 40 miles west of Northern Uist, and is the most isolated of the British Isles. This spring the relief ship sent out by the Scottish Health Department only effected a landing with difficulty at the second attempt, and in former times the island was regarded as almost inaccessible during eight months of the year. These circumstances have long deserved the attention of epidemiologists, and the name of St. Kilda has, in fact, become familiar to the profession in more than one connexion. It is well known, for instance, that formerly more than half the children born on the island died of tetanus neonatorum—a state of affairs which lasted as late as 1890, when Nurse Chisnell began her ministrations. This peculiar mortality had been variously explained before its cause was discovered, and there have been at least as many explanations of the strange way in which the St. Kildians take cold on the arrival of the first boat of the season. In his "Life of Johnson," Boswell relates that when Macaulay wrote his account of the island, "he was advised to leave out of his book the wonderful story that upon the approach of a stranger all the inhabitants catch cold." To which Johnson replied, "Sir, to leave things out of a book, merely because people tell you they will not be believed, is meanness." Dr. John Campbell, it appears, took a great deal of pains to ascertain the facts, and attempted to account for them "on physical principles, from the effect of effluvia from human bodies." But a lady of Norfolk wrote to Boswell to say that the "explication of this seeming mystery" was so very obvious as to have escaped attention.

"Reading the book," she said, "with my ingenious friend, the late Reverend Mr. Christian of Docking—after remaining a little. The cause, (says he), is a natural one. The situation of St. Kilda renders a north-east wind indispensably necessary before a stranger can land; the wind, not the stranger, occasions an epidemic cold."

As in the time of Mr. Christian, the need of epidemiology to-day is for accurate data, and St. Kilda might still provide some. A few years ago almost every inhabitant took whooping-cough, but unfortunately this incidence of infection on the virgin soil of an adult population could not be studied as it deserved. The opportunity for medical research on the island still exists, but it is rapidly passing. The native population—109 in 1852—is now only 38, to whom should be added the missionary and his family, and the nurse provided by the Highlands and Islands Medical Service. Attempts have often been made to get the inhabitants to leave their home, for it has not fully supported them within living memory. Soon, moreover, there may not be enough men to take boats across to the neighbouring islands where they keep sheep. The captain of the relief trawler says that all save two

old men would now be willing to leave, but our Scottish correspondent thinks this is "too good to be true." It does not allow, he says, for the nostalgia of the islander, and he doubts whether the maintenance of the remnant would be any less expensive on the mainland. Meanwhile we learn that a geologist lately spent a long period in verifying the structure of the island, and it seems likely that a medical research student of suitable gifts could make something equally important out of its unusual human material.

INSULIN BY NOSE AND MOUTH.

MANY attempts have been made to devise means of administering insulin which will be free from the inconvenience of daily hypodermic injections. Recently H. Wassermeyer and A. Schäfer¹ have recorded observations on absorption of the hormone from the nasal mucous membrane, when applied either on tampons or in the form of snuff. They find definite evidence that some degree of absorption occurs, the blood-sugar—both in the diabetic and in the normal subject—falling appreciably during three hours following the application. Unfortunately, the fall in the blood-sugar is not proportional to the dose of insulin employed. 100 units have no greater effect than 20 units, and it is apparently impossible to reduce the blood-sugar sufficiently to evoke hypoglycæmic symptoms.

Since the successful management of diabetes entails a nice adaptation of the dose of insulin to the varying tolerance of the patient, and since any chance catarrhal inflammation of the absorbing surface must adversely influence absorption, it is evident that the scope of intranasal insulin therapy is severely limited. Another and more ambitious attempt to solve the same problem has been even less successful. It has been claimed that insulin, when mixed with desoxycholin, is rendered immune to the destructive action of the digestive ferments and can thus be administered by the mouth. D. Kwilecki and K. Silberstein,² however, have failed to find any evidence that this preparation (Cholosulin) is of value in diabetes, and they observed dyspeptic symptoms in several patients to whom it was given. Cholosulin, even in such heroic doses as 200 units, does not depress the fasting blood-sugar. If it is given several hours before a meal it certainly tends to lessen the subsequent rise in blood-sugar, but this may well be due to the nausea which it undoubtedly provokes.

The hypodermic syringe remains indispensable to the diabetic requiring insulin.

A CONGRESS OF PUBLIC HEALTH.

Major-General J. E. B. Seely, as Lord Lieutenant of Hampshire, will preside over the annual congress of the Royal Institute of Public Health which meets at Portsmouth at Whitsuntide. After an inaugural session on the morning of Wednesday, June 4th, at which he will give an address on Health and Courage, the congress will adjourn until the following day, when the sectional meetings begin at the Guildhall. The two principal discussions in the Section of State Medicine will be on National Health and the Local Government Act, and on the Slum Problem. Prof. H. R. Kenwood's presidential address will be on the Reduction of Preventable Disease, and among the papers contributed will be one by Dr. C. O. Stallybrass on Variations in Virulence during the Course of Epidemics. Prof. René Cruchet, of Bordeaux, will address the Services Section on Post-encephalitic Parkinsonism and Military Pensions, and Dr. J. B. Christopherson will speak on the Role of Dress in the Tropics in Relation to Health and Disease. The chief subjects before the Section of Industrial Hygiene—as is suitable for a Portsmouth meeting—are Health in Seafaring Occupations and the Health of Dockyard Workers; while the section

¹ Med. Klin., March 28th, p. 474.

² Ibid., April 4th, p. 513.

concerned with women and children will have discussions on the Slum Child, and on the Prevention of Sickness and Death in Motherhood. Before this section Dr. Doris Odum will speak on Home and the Adolescent, Mr. W. Clarke Hall on the Problem of the Delinquent Child, and Lieut.-Colonel R. Kuper White on Post-puerperal Disabilities in Women. Sir Henry Gauvain's presidential address to the Section of Tuberculosis will deal with Sun Treatment in England, and Mr. H. Morriston Davies will open a discussion on the Present Position of Surgical Treatment of Pulmonary Tuberculosis.

Each of the sections has arranged visits to centres of interest in the locality, and there are, as usual, various excursions and functions for the congress as a whole. Application for membership may be made to the hon. secretaries of the Institute, 37, Russell-square, London, W.C.1.

MENTAL HYGIENE IN PUBLIC HEALTH.

A NEW conception of preventive medicine and public health work was outlined by Prof. Haven Emerson in his address to the First International Congress on Mental Hygiene held in Washington early this month. He spoke of mental hygiene as a public health problem and gave convincing arguments in support of his thesis that the public health service in its present form is inadequate to the needs of the community. The control of communicable diseases, the protection of maternity and infancy, the detection of physical defects or even of feeble-mindedness in children, and so forth, can no longer be considered the whole duty of the health officer. In the future he may be called upon to account to his constituency for the incidence of suicides, showing correlations perhaps with unemployment, the prevalence of divorce, heredity, sex, and occupation. The fact that the diabetes death-rate in America has risen in the last 70 years from approximately 5 to 20 per hundred thousand is important enough but is of less real moment to the community than that the suicide-rate has risen in the same proportion. It is questionable, he continued, whether investigation of the reasons for a rising death-rate from appendicitis is any more necessary than the analysis, with a view to prevention, of the conditions which have brought about a rise in the divorce-rate from 26 to 68 per hundred thousand in less than 50 years. He did not minimise the importance of diphtheria swabs and typhoid inoculations, but urged that the psychological welfare of the community should also receive attention. According to experienced child-guidance workers, in any unselected group of children of four years of age, considered by their parents to be normal, more than one-third are found on investigation to have characteristic behaviour problems which are likely to develop into personal or family embarrassments. It is not a matter of intelligence, to be dismissed as a problem that the proper ascertainment of defectives would solve. These ill-adjusted children are found among the dull, the average, and the precocious. Evidence of deviation from good mental health may include extreme shyness, severe speech defects, and the more precise phenomena of tantrums, interference with appetite for and use of food, and enuresis. The problem of public health, according to Prof. Emerson, is to include in the plan of service to parents such personnel as can be trusted to notice aberrations of conduct in the home, to advise parents to seek professional guidance when necessary, and to deal with early and mild disturbances in this field in the same way as health visitors deal with physiological errors in the field of growth, nutrition, and infection. The community should see that the psychiatrist gets to the mean lazy ne'er-do-well before the policeman does, and that the bully, the fearful child, and the miserable man meets a wise social worker before he is forced into an institution.

This stimulating address was a fitting introduction to the deliberations of a congress so important that

53 countries were represented and so interesting to the American people that an audience of over 3000 persons attended the inaugural session. Some of the scientific communications made to the congress were reported in THE LANCET of last week, and another group will be found on p. 1148. The history of the mental hygiene movement, from its inception in 1908, has been one of almost miraculously rapid development. The source of the movement, as Dr. William White pointed out in his presidential address, was the vision and zeal of one man. When he was a student at Yale, Mr. Clifford Beers had a mental breakdown from which he completely recovered. He returned to the community inspired with the purpose of saving others from the sufferings which he himself had undergone and the first committee on mental hygiene was formed in Connecticut with the single object of improving the conditions in mental hospitals. The growth of the organisation was speedy, accelerated by the strong public opinion created by Mr. Beers' book "A Mind that Found Itself," and the concept of definite curative treatment of the insane and of the prevention of insanity began to take shape. It was soon felt that this aim, valuable as it was, constituted only one aspect of mental hygiene, what might be termed the negative aspect. The positive aspect—the guidance of children, adolescents, and employees, which involves the education of parents, teachers, and employers to the knowledge that abnormalities of behaviour at all ages are influenced less by reason than by emotional undercurrents, is even more important. The communications to the congress show how much progress has already been made by Americans and how generous has been their endeavour to stimulate action in other countries. Partly through the good offices of the Commonwealth Fund, London is now equipped with at least three child-guidance clinics and more will come. The spirit of a few enthusiasts has flamed so brightly that it has compelled the attention of the whole world.

RETIREMENT OF MR. HAYWARD PINCH.

THE retirement of Mr. A. E. Hayward Pinch, F.R.C.S., after 21 years' work as medical superintendent and director of the Radium Institute, is announced to take place in June next. The reorganisation of the work of the institute, consequent on its affiliation with the Mount Vernon Hospital, and the setting up of the new Post-Graduate School of Radiotherapy, is in progress, and Mr. Pinch's state of health prevents him from undertaking new and more onerous duties. The committee of the Radium Institute, in announcing Mr. Pinch's impending retirement, put on record their appreciation of the service he has given during his long tenure of office, and have elected him a member of the honorary consulting staff.

THE sixth annual meeting of the National Institute for the Deaf will be held at Church House, Westminster, on Friday next, May 30th, at 3 P.M. Lord Charnwood, the President of the Institute, will preside, and Mr. Stanley Baldwin will address the meeting.

ROYAL INSTITUTION.—The Rockefeller Foundation has offered £20,000 for endowment of research in the Davy-Paraday Laboratory on condition that £50,000 is raised from other sources. This offer has been accepted.

JUVENILE BLINDNESS IN SCOTLAND.—Mr. William Adamson, the Secretary for Scotland, recently opened large extensions of the workshops of the Aberdeen Asylum for the Blind, which have cost close upon £5000. Mr. Adamson pointed out that the statistics warranted the hope that the newly born blind would shortly entirely disappear in Scotland. They have already done so in the north-east of Scotland, there no longer being a single blind child under 5 years of age in the county or city of Aberdeen, or in the counties of Banff and Kincardine.

The Clinical Interpretation of Aids to Diagnosis.

A-Series of Special Articles Contributed by Invitation.

LXXXIII.

THE SIGNIFICANCE OF IDIOPATHIC SKIN REACTIONS.

PART I.*

SKIN reactions in cases of inherited or idiopathic sensitisations have had too much medicinal virtue ascribed to them; in their clinical use they have almost developed into one of the pathological rituals designed towards magical healing. On the other hand, when sensitisation acquired through infection is in question—e.g., the von Pirquet or the Dick test—they are used too capriciously, no doubt because some coördinating pathological principle is lacking. The two types of reaction are quite distinct.

We have on the one hand the skin reactions which fall into line with the histamine reactions described by Sir Thomas Lewis—reactions taking 7 minutes to begin and about 20 minutes to finish. Typical of these is the effect of grass pollen on the skin of the hay-fever subject. On the other hand, we have a rather heterogeneous collection of reactions coming up in different times, sometimes showing best after three hours, sometimes best after 24 and lasting for an indefinite period; these group themselves round the old tuberculin reaction and may perhaps be typified by the von Pirquet. The first group are hereditary or idiopathic (the toxic idiopathies), the second are the result of some change in our circulating blood and fixed cells due to infection. It is true that these differences may be only apparent, since the tendency to tuberculosis, for example, is itself hereditary and presumably idiopathic, and no one knows how the hereditary tendency towards hay-fever develops into the actual disease.

In current parlance, "skin reactions" usually betoken tests in the first or idiopathic group, and it is with these that I propose to deal in this article, starting by describing as typical the hay-fever reaction. What is here said of hay-fever is applicable to all the others—horse asthma, egg sickness, bacterial sensitisation, and the rest.

Hay-fever Reaction.

In this asthma group of diseases there is a tiresome muddle in nomenclature. Some are named by the protein irritant which produces them, e.g., hay-fever, horse-asthma; others are named by the most prominent symptoms these irritants produce, e.g., asthma, urticaria; others again are named from the neural mechanism involved, e.g., vasomotor rhinitis, "reflex" asthma, and so forth. In each case the sponsor gave the name according to the part of the pathological mechanism which most impressed him; and the terms, therefore, are not mutually exclusive and it is necessary to emphasise that the term "hay-fever" is not a popular synonym for rhino-orhœa, vasomotor rhinitis, conjunctivitis, or laryngitis, though it frequently gives rise to these symptoms. Hay-fever is the reaction which takes place when grass pollen comes in contact with people with an idiopathic sensitiveness to it. In bringing a minimal quantity of grass pollen into contact with a selected area of such an individual we are producing a miniature attack of hay-fever; if the selected area is visible we can see the attack and can thus make it diagnostic of the spontaneously occurring disease. This in practice confines our experimental area to the surface of the body, but it is important to keep clearly in

mind that grass pollen works out of sight also. If sniffed up the nostrils of hay-fever patients it provokes a rhino-orhœa (Blackley); if injected up the rectum it provokes pruritus and tenesmus (Dunbar); if swallowed it provokes nausea, vomiting, and even diarrhœa; and if it gains access to the blood stream it may provoke any of the symptoms of the toxic idiopathies—asthma, rhino-orhœa, urticaria of any intensity up to angioneurotic œdema, eczema, migraine, epilepsy, functional albuminuria, &c. As has been said above, the grass pollen reactions are typical of what may be done by any of the other protein irritants; therefore any skin test showing a protein sensitisation may throw diagnostic light on any of the above-mentioned disorders.

A diagnostic reaction with grass pollen may be carried out by bringing it, or an extract of it, into contact with the living tissues of the sensitive person on some area of the body where we can observe the result. In practice four different methods can be used.

Injection into Conjunctival Sac.

Pollen (or preferably, a very dilute extract of pollen) may be dropped into the conjunctival sac of the eyeball; this area is perhaps the most sensitive in reacting. In a positive reaction the patient notices a tickling in the eye, and he may perhaps sneeze owing to an overflow of the extract down the lacrimal duct and so into the nasal cavity. In about seven minutes from the instillation of the pollen, the eye will be seen to be more watery than its fellow of the opposite side, the blood-vessels will become more noticeable, especially towards the inner canthus, and the caruncle will become slightly pinker. In a minimal reaction such as this the effects should be lessening in 15 minutes, and should have disappeared in from 20 to 25 minutes. With stronger extracts more definite changes are observed and they last longer; the whole eyeball gets bloodshot, the irritation becomes really distressing, and the effect may last for hours; presumably, if sufficient pollen substance were added to a sensitive enough case the conjunctiva would blister, and flake off as may happen in severe cases of the naturally occurring disease. It is therefore expedient in a new case to begin with a very weak dilution indeed, and gradually to increase the strength until a minimal reaction is obtained. The strongest extract will give no reaction on the normal man, but in the hay-fever subject the intensity of the reaction will depend on the extent of the pollen sensitiveness of the individual. In other words, the more sensitive the individual the weaker must be the extract which gives just a minimal reaction. It is thus possible not only to make a sure diagnosis of pollen sensitiveness but to gauge the intensity of the sensitisation by noting what strength of pollen extract will cause a minimal reaction. The most sensitive case I have ever tested reacted with one drop of 1:330,000 extract of *Phleum pratense* pollen, which would represent perhaps the extract from a sixth of a millionth of a gramme of the pollen. At the other end of the scale, if patients do not react to a drop of the 1:200 extract they will not react at all—i.e., they are not subject to hay-fever. This quantitative interpretation is not, of course, absolutely true, but it is true enough for therapeutic purposes with certain reservations. For example, the intensity of the reaction depends to some extent on the emotional state of the patient. A combative self-reliant person may, if sufficiently keyed up, diminish quite considerably the customary reaction, while an anxious emotional person may increase it (this may be a question of adrenalin in the circulation); but no emotion can produce a reaction in a non-hay-fever subject or can abolish it if a sufficiently strong extract is employed with the true hay-fever subject.

This eye method is a very delicate—perhaps the most delicate—test of sensitisation, but it suffers from two inherent defects: (1) that there is only

* Part II. will appear in our next issue.

one eye to test, since the other has to be kept as control; (2) it is not justifiable to take any risk with the eye either by instilling a normally noxious substance or by using too strong a reagent. Pollen causes such a strong reaction that very dilute extracts have to be used; but when a bland innocuous substance like cow's milk is suspected it is convenient sometimes to put a drop into the conjunctival sac for diagnosis.

Application to the Lips.

If grass pollen is applied to the lips of a hay-fever subject a feeling of burning or pepperiness will be experienced in a few minutes, and the lips will swell, become inflamed, and show blisters—the subjective and objective intensity of these phenomena varying with the sensitiveness of the person tested, and with the strength of pollen extract employed. In practice, this is not a very convenient method of testing; it is mentioned here only because it may be accidentally applied by nurse or mother to the newly-weaned child, when they try to force on it some new food to which it is sensitive. To quote a mother's story: "The baby fought and screamed for half an hour while we tried to get some egg into his mouth; then we noticed that his lips were all inflamed and swollen and covered with blisters; we stopped, supposing that he was fighting because his lips were sore. A week later, having first noted that his lips were all right, we saw them swell up after contact with the egg spoon."

Intradermal Injections.

If pollen or pollen extract is brought into contact with the unbroken skin of a hay-fever subject usually no reaction occurs, though some very thin skinned women and children may get a little itching and inflammation. The reacting substance must penetrate the dead superficial layers of the skin to the living cells beneath, to the cutis vera, in fact, before the reaction can be produced. It may be rubbed in (thoroughly unsatisfactory); it may be put into an abrasion, scratch, or prick (the method in general clinical use); or it may be injected intradermally (the method mostly used for experimental work in the laboratory).

Whatever method may be employed to reach the cutis vera, when the protein irritant reaches sensitive living cells, in about seven minutes an itching will be experienced and the tested area will show a red patch; a little later this red patch will become an oedematous raised white weal. Simultaneously an erythematous blush will develop round the weal to a distance of from a quarter of an inch to an inch or two according to the intensity of the reaction. Meanwhile the weal may become more pronounced, with possibly a little drop of serous fluid exuding through the scratch, and if the reaction is at all intense the white raised area will spread laterally over an inch or more, often in curious pseudopodial projections as the oedema fluid tracks through the thickness of the skin along the lines of least resistance.

These phenomena reach their height in 10 or 15 minutes, and are usually noticeably fading away in 20 minutes. Such an intense reaction as this, with a dead white weal of irregular margin which could not be covered by half a crown, surrounded with an erythematous blush which could barely be covered by the hand, is a striking and unmistakable reaction which could be read at a distance of ten yards; but in practice many smaller or even minimal reactions occur, and the decision what is and what is not a reaction becomes important. It is necessary in fact to make a control test with an equal amount of scratching or rubbing-in, on a neighbouring site, using in place of the pollen (or whatever it may be) a neutral substance such as normal saline. No reaction can be accepted as positive unless there is an unmistakable difference between it and that on the control site. These precautions are the more necessary because dermatographia tends to "run" in the family of sensitives.

In fact, it may itself be classed as one of the toxic idiopathies.¹

Testing by Proxy.

Lastly, the action of grass pollen on hay-fever subjects may be tested by proxy. If some blood is drawn from the vein of a hay-fever subject (1 or 2 c.cm. are ample) and allowed to clot, the serum can be injected into the thickness of the skin of a non-hay-fever man (e.g., the investigator); if this is skilfully done the skin can be well "mattressed" with the hay-fever serum over an area equal in size to a shilling or sixpence without any noticeable scarring, and the "mattressing" will quickly subside till in a day or two nothing is noticeable at the injected site (which therefore had better be outlined with indelible ink). If grass pollen is subsequently brought to this site, either by any of the methods described above or by injection into the vein of the investigator, then the site sensitised by the hay-fever serum, and only this site, will swell, giving the characteristic reaction; but if the pollen reaches the sensitised site diluted, via the blood, and not concentrated in a prick or scratch, it will give an oedematous reaction more approximating to angio-neurotic oedema, incidentally supplying a useful indication of how that condition may arise. Thus, a diagnosis can be made on serum sent through the post. A well-marked food sensitisation can sometimes be tested for in this way with striking results; all that the proxy has to do is to eat the suspected food.

WEST LONDON HOSPITAL.—Last year 3745 in-patients were received; there were 2232 major, and 4396 minor, operations, and 12,720 X ray plates were used.

ST. GEORGE'S HOSPITAL.—Presiding last week at the annual court of governors of St. George's Hospital, Prince George stated that unless an additional income of at least £20,000 could be assured the time would come when its activities would have to be curtailed. He added that last year some 5000 in-patients and 39,000 new out-patients were treated, and that 250 infants were born in the hospital.

HOSPITALS AND MOTOR ACCIDENTS.—Glasgow Royal Infirmary is publishing weekly figures of the number of motor accident cases treated. In the three weeks ended on May 10th the infirmary treated 76 such cases, 37 of which were admitted. During March the three Glasgow voluntary hospitals treated 222 motor accident patients, 31 of whom entered the wards.—Last year Leeds Infirmary dealt with 1135 motor cases, which cost £4307, and the amount paid was £167.—Blackpool Victoria Hospital treated 148 accident in-patients and 26 out-patients at a cost of £1062; £176 was recovered.

Special Articles.

SOME OBSERVATIONS ON THE AFTER-CARE OF TUBERCULOUS PERSONS.

By P. C. VARRIER-JONES, M.A. CAMB.,
M.R.C.P. LOND.,

MEDICAL DIRECTOR, PAPWORTH VILLAGE SETTLEMENT, AND
HON. MEDICAL DIRECTOR, ENHAM VILLAGE CENTRE;
LECTURER ON TUBERCULOSIS, STATE MEDICINE
SYNDICATE, UNIVERSITY OF
CAMBRIDGE.

THE Minister of Health (Mr. Greenwood), in his speech in the House of Commons on April 20th, has again focused attention on the important problem of the after-care of the tuberculous person. He said: "With regard to tuberculosis, the experience of village settlements and the principles on which their successful working depended had been brought to the notice of certain local authorities where the conditions seemed favourable to the establishment and maintenance of similar settlements. Even if settlements were provided for all tuberculous patients for whom they would be appropriate there would still be a number of people for whom after-care would be required. He hoped that local authorities, as the next move in the campaign against tuberculosis, would consider and experiment in methods of after-care." Again, in opening the new sanatorium recently built by the Essex County Council, he used the following words: "Sanatoriums could not provide assistance of a permanent nature, as patients, on leaving them, returned to unfavourable conditions. It seemed a little short-sighted for money to be devoted to the building and maintenance of sanatoriums when next to nothing was done to provide proper after-care treatment. He hoped that attention would be given to this problem."

While these official pronouncements are sufficiently important to warrant attention, they are by no means new to those of us who are daily working at the problem. Indeed, the problem is forced upon the attention of all those who in any way are in touch with the tuberculous population, whether at the dispensary or the sanatorium. The private practitioner has to face the difficulties of the situation in his daily work and especially the most serious aspect of the problem. Thus, when he has diagnosed pulmonary tuberculosis and succeeded in having the patient recommended for sanatorium treatment, the position is for a time relieved, but later, although the good results of this treatment are obvious, the patient returns home—to a house as unsuitable as it can be for any form of treatment, and the practitioner feels grave anxiety about the future, in spite of the assistance of the local tuberculosis officer and the palliative measures then put into force. Visits to the dispensary take place at regular intervals, reports are written at stated times—but the patient goes downhill, and the conditions at home go from bad to worse. Can the patient be readmitted to a sanatorium? Sometimes this question is answered in the affirmative—sometimes not. If he is readmitted there is a spell of comparative ease—the great burden on the family is for the moment relieved, but when the patient returns home once more the whole dismal story is repeated. The position of both the patient and the family becomes acute.

Further, a powerful deterrent in preventing the early case from accepting treatment is the fact that, if it were known that he had had treatment in such and such a sanatorium his economic future would be in jeopardy. If the patient could feel certain that his job would be waiting for him on his return from a sanatorium, if he were sure that when he was asked

what he was doing during this absence his answer would not mean that all doors of employment were closed to him, he could cheerfully accept treatment. To secure the treatment of early cases their freedom from economic chaos must be guaranteed. The public health service working under the county councils has prepared schemes embracing the medical aspect, but has only slightly, if at all, touched the economic aspect, while the boards of guardians have in some measure tackled the economic side of the question, but very imperfectly. The recent union of these two services combined under one local authority provides a great opportunity for dealing with tuberculosis on the broad lines which logically should be adopted. To divorce medical treatment of the disease from the economic treatment found necessary has been responsible for the lack of efficient after-care in the past. To amalgamate forces for the combined medical and economic treatment is not only obvious but will, in the immediate future as well as in the long run, save the country a great sum of money. But it is not possible to persuade employers to take back the employee. They will not do it, and it is no good shifting the burden of unemployment of the tuberculous on firms and employers who are already paying the State to do the very thing. It is as if we said "We cannot solve the problem, so let us shift it on to manufacturers and other employers to solve for us." All who have worked in the tuberculosis field know that a solution cannot be obtained in this direction, and that the difficulty of persuading employers of labour to act as philanthropists on a large scale should have been foreseen. It is economically impossible for them to do so, and it is therefore essential to find some other method of solving the problem of the employment of the tuberculous.

The alteration in the administration of local authorities which came into force on April 1st of this year makes it possible to take a new view of the after-care of tuberculous persons. For the first time one authority, and one authority alone, is responsible for the three aspects of the tuberculosis problem, the medical, the social, and the economic. Before this time these three corner-stones were in three different buildings, as it were, each supporting structures which should have been amalgamated into one concrete whole. We are now placed in what should be a favourable position to keep these three essentials as one. The medical aspect can be securely dovetailed with the housing question; both can be anchored to the key of the situation—namely, the economic. Progress on broad sound lines should now be possible. Local authorities are already manifesting great interest in the question, and naturally the finance of the scheme interests them not a little. It is not necessary, however, for any local authority to find all the capital involved so long as it will bear its fair share of the expenses of each patient and his family.

VILLAGE SETTLEMENTS: SUGGESTIONS AS TO NATIONAL DEVELOPMENT.

I recently submitted a memorandum to the Ministry of Health indicating the difficulties now standing in the way of an increase in the number of village settlements, and suggesting means by which they can be overcome.

There is, the Memorandum ran, no doubt that further village settlements would be established around and adjoining existing sanatoria if the primary obstacles of finance and of personnel could be surmounted.

(A) FINANCE.

The capital cost of a village settlement of the size of Papworth, excluding the hospital and sanatorium section, should not exceed £100,000. Such a settlement could house and support some 500 persons, including 100 married and 80 single tuberculous breadwinners who would be unemployable in any but village settlement conditions.

The cost of maintaining these 500 persons at a village settlement should certainly not exceed £1000 per annum. At Papworth the community only incurred a trading loss of some £160 in 1928, so that £1000 should be an adequate figure to meet almost any contingency.

The cost of maintaining these same 500 people outside a village settlement, however, would be far greater. With the breadwinners precluded from winning bread they could not avoid becoming a public charge. The tuberculous breadwinners would in many cases spread infection amongst their families and, through a breakdown, be compelled to be readmitted to sanatoria. Estimating the cost of normal maintenance (from the unemployment fund, friendly societies, the guardians, and other sources) at a minimum of 10s. per person per week, an annual charge of £13,000 is produced. The cost of readmitting a proportion of these tuberculous persons to sanatoria, and admitting new cases infected by them, would almost certainly represent a minimum additional annual charge of £1000. On quite a conservative basis, therefore, it is evident that the cost of maintaining these 500 persons outside a village settlement amounts to at least £14,000 per annum. Charges at this rate are in fact now being borne by the various public and private bodies who are responsible for the care of tuberculous workers and their dependents.

The admission of these 500 persons (men, women, and children) to a village settlement would therefore save these bodies not less than £13,000 per annum. £13,000 per annum is sufficient to provide for the service of a 5 per cent. loan of £130,000, amortising the whole sum in 15 years. Therefore, if the public and private bodies above referred to were to be given the statutory power to divert their relief expenditure in such cases to the service of village settlement loans, they could borrow the whole of the necessary capital in the ordinary way, and repay it within 15 years. At the end of this period the settlements financed by this means could accept and provide for normally unemployable persons and their families at practically no cost.

Formation of a National Association.

This proposal could be carried into effect in one or other of two ways:—

(1) By the formation of a Village Settlements Department at the Ministry of Health; or

(2) By the formation of a National Association of Village Settlements on which the Ministry would be responsibly represented.

In the former case the Ministry, on receiving an application from a local authority for the provision of a village settlement within its area, would investigate the circumstances in relation to already existing settlements, local requirements, &c. If satisfied, the Ministry would provide the capital sum required and the local authority would agree to contribute 10s. per week per person settled for a period of fifteen years, and 1s. per week per person settled thereafter. These contributions would repay the capital sum advanced, with interest, and provide adequately for any revenue losses incurred. No cost whatever would fall upon the national exchequer.

In the latter case an association not for profit would be registered under Section 20 of the Companies Acts, and managed by an expert body approved by the Ministry of Health. This association could affiliate to itself such approved existing settlements as might wish to join; and any local authority desiring to establish its own settlement would be advised to apply to the association. The association would then carry out the investigation indicated in the preceding paragraph, and in the event of approval would undertake to establish a settlement for the reception of suitable cases nominated by the authority on exactly the same terms. The contract with the authority would form the basis for an issue of 5 per cent. debentures by the association. Such an issue, secured upon a contract with a municipality, would rank with corporation issues; and if, in addition, a Government guarantee as to capital and interest were provided, the issue would rank as a trustee security. Practically no risk would be incurred by the exchequer under such a guarantee, and its grant might enable the issue to be made at a lower rate than 5 per cent., while the whole business of the association would, of course, be subject to the close scrutiny, if not the absolute control, of the Ministry of Health.

Of these two methods I am inclined to advise against the adoption of the first, since each settlement would have its own industries, and the fact that these were directly controlled by the Ministry and local authorities might create opposition to the whole scheme in certain quarters. Under the second scheme, this objection could not be maintained, while the Ministry would have almost as great a measure of control as it would under the first scheme.

Three Practical Points.

Attention is directed to three points:—

(1) That the figures employed are not intended to indicate the "ideal size" of a village settlement. They are simply used as an illustration. The size of a village settlement is only limited by its own inertia.

(2) That the whole of this scheme can be carried out without adding one penny to present expenditure upon social and health services. On the contrary, there would be a considerable ultimate economy depending entirely upon the extent to which the scheme was developed, for after the repayment of the original capital sums, the weekly contribution per person settled could be reduced to 1s.

(3) That the only action which need be taken by the Government is that required to secure the passing of an Act enabling local authorities to participate in the scheme in the manner proposed.

(B) PERSONNEL.

Past experience has shown that village settlements may cost so much to maintain as to render them impracticable, however desirable they may seem on medical and humanitarian grounds. So far from contesting this, I admit that village settlements may prove highly expensive; indeed, I would go so far as to say that they are bound to be disastrously expensive unless the personnel, both medical and industrial, is most carefully selected. This care in selection extends not only to those holding executive positions, but to those selected for settlement also, and local authorities should bear in mind that not only will a certain proportion of medically suitable cases decline to enter a village settlement, but that a percentage of those who are medically suitable and willing may be temperamentally unsuitable. It is for the residue that village settlements are needed, and that residue will increase in numbers as the scheme develops and its advantages become more apparent; so that while the number of suitable persons desiring settlement may not now be large, it will tend to increase more and more rapidly as time goes on.

Provided that the right principles are adopted there is no reason for any village settlement to fail. At Papworth certain principles have been evolved by the process of experiment, and their adoption at Preston Hall has met with success. It is not too much to suggest, therefore, that if the principles of village settlement work are fully understood and rigidly adhered to success will result.

It would, in my view, be a great mistake to sanction the establishment of large numbers of village settlements before trained personnel is available to guide them. And since theoretical training alone is useless, I suggest that the Ministry should sanction the training of medical personnel at Papworth and Preston Hall, though I have no authority to speak for Preston Hall.

While there is at the present time a dearth of medical and industrial personnel with village settlement experience, there is no reason to believe that this condition is chronic. As the scheme develops so will personnel become available, since village settlements provide considerable scope for enterprise both in medicine and in other branches of endeavour, and the association of reasonable remuneration with scope for initiative represents a combination which has never yet failed to attract the best elements in the population.

Let us clear our minds for a moment as to what we are attempting to do. It is nothing less than to stamp out tuberculosis. Everyone agrees that to do this the early cases must be treated and cured. But, as already pointed out, early cases are not available for treatment, on account of the fear of thus ruining their future economically. Suppose, however, that this fear of economic disaster can be removed, and that a man knew in the event of his becoming tuberculous that he would receive immediate treatment, that his family would be supported while he was receiving treatment, and that if he proved to be suffering extensive and permanent damage he would be able to live and work permanently in a village settlement with his family, the whole tuberculosis problem would be altered. Let us remove the fear of poverty after treatment by making it known that village settlements exist to protect the tuberculous worker from the economic consequences of his disease and manifestly there will be many more early notifications. Even so, many cases would not be discovered until too late, until, that is, extensive damage had been done, but the ratio of early to moderately advanced and advanced cases would slowly but surely increase. Instead of 40 per cent. sanatorium discharges requiring permanent settlement, the proportion would diminish to nearer 20 per cent., and the remainder—i.e., 80 per cent.—having received treatment early, would be fitted to resume work as economic units in the outside world.

TRAINING OF YOUNG CHILDREN.

PROF. BLATZ'S LECTURE.

ON May 13th, at University College, a lecture entitled *Modern Theories of Habit Training of the Pre-school Child* was given by Dr. W. E. BLATZ, assistant professor of psychology in the University of Toronto. Prof. C. E. SPEARMAN, F.R.S., in introducing the speaker, said that the movement in favour of child guidance was spreading rapidly. Experience showed that adult criminals and undesirable had nearly all been difficult or undesirable children. England had been tardy in adopting the movement, in which the United States of America had led the way. The United States were fortunate in many ways; for example, the different States were independent, and those which were progressive enjoyed great opportunities in consequence; besides this, wealthy members of the community would contribute freely to institutions both in their own country and abroad; they were even ready to subsidise the trial of new methods. They had established a child guidance clinic in this country and had invited a number of persons to visit similar institutions in America, and he had himself accepted such an invitation. But he could say that he had found the best work in this field at Toronto under the inspiration of Prof. Blatz. In a pre-school nursery there he had seen 17 children playing with an entire disregard of the students who lined the walls, and made systematic observations. Prof. Blatz had a more substantial backing of evidence than was usual with speakers on this subject.

Prof. BLATZ began his lecture by saying that he had never been satisfied with the analysis of motives found in text-books. Either this subject was crowded into a few paragraphs at the end of a chapter or a whole book was written about it, with recurrent use of the word "instinct." He proposed to speak entirely of children under five years of age, and to avoid the words "instinct" and "purpose."

Any factor which influenced human behaviour could be called a motive; he made no attempt to distinguish between motives arising outside the organism and those from within, because the individual was never separated from his environment. He must also deny that he was a "behaviourist," since it was impossible to maintain a strictly behaviourist psychology in dealing with living persons.

The Primary Motive.

To interest the psychologist the child must be born alive, and must express life in terms of the function of the whole. The primary motive was life. Children in all circumstances did something, performed some action, and at some stage they attempted to answer the question: "Why am I alive?" The foundation of all religions was an attempt to answer this question, but so far none had answered it in a way which was unassailable. Before the age of four the child was little interested in the answer; from four onwards he began to ask questions having a bearing on it, but up to that time he was not affected by the primary motive of life. Secondary motives must therefore be considered. Why did a child do the things he did? Why did he eat his food on one occasion and fling it at his nurse on another? The case of the mother who had been advised by the paediatrician to give her child spinach might be considered. She stood over the child with anxiety on her countenance, offering spinach; the child, realising the anxiety, felt that this was the moment to assert himself and throw the spinach on the floor.

The Attitudes.

Adults were described as having differing tastes, and taste was sometimes called feeling tone. There

was no such thing *per se*; all tastes developed from a form of behaviour present at birth. If a new-born child were allowed to suck a finger dipped in a solution of sugar he would behave in such a way as to express satisfaction, while if the finger had been dipped in a quinine solution the response would be one of resentment. There was therefore a twofold result to all sensory impressions—acceptance and rejection. They were antitheses and could not appear simultaneously. From these the child developed a series of reactions to all sensations, and a classification was gradually built up. But an error crept in which made him ascribe the quality to the object, not to himself. Pleasantness or unpleasantness was not really resident in the object but in a concept which he had to develop. This was proved by the fact that tastes were divergent; one object was not the same to all persons, nor did it necessarily remain the same to any given person.

To take an example, if a hungry boy was offered a slice of jam roll he would eat it with enthusiasm, but if helpings were continued indefinitely he would at last reject it, and might even perform the final act of rejection by vomiting. The rejection of children was similar to the disgust of adults, and the taste of adults depended on training, not on inherent qualities in the object. This meant that we held the taste of our children in our hands; we could decide whether they should have a preference for jazz or classical music. In Austria small children were being encouraged to paint, and showed tastes usually ascribed to adults. By analysing his past history it was possible to decide whether or not a child would eat spinach, and by training it was possible to get him to eat anything he was offered. At the Toronto clinic children took cod-liver oil readily, and asked for it if they were accidentally passed over, simply because they were taught to regard it as a food. If it were treated as medicine and the child was forced to take it the atmosphere would demand resistance on his part.

The Appetites.

The appetites, of which hunger, thirst, rest, elimination, and sex were examples, were connected with physiological functions of the body, and waxed and waned in intensity. Five to eight hours after birth a child became restless and cried; it was then fed and fell asleep. After a few hours the same cycle would be repeated, and the waxing and waning of hunger would continue throughout life. Nobody knew when we ought to be fed, how much, or why. The paediatrician asserted that it should be every four hours during infancy, without night feeds, and after a fortnight of this routine a child would be hungry at the correct times. This appetite, then, had a physiological background; it was cyclic, had a sensory component, hunger, and could be brought under individual and social control. Training arranged that the behaviour called forth by hunger should be socially acceptable. Later training would enable the child to use the socially accepted implements to feed himself.

Sex was a similar phenomenon to hunger. Like hunger it was potential at birth, and did not depend on puberty for its development; masturbation quite commonly occurred at six months. The cycles were longer than in hunger, but it could also be subjected to a definite control, both individual and social. The social control in this case was enormous, with laws to enforce it, though no one would think of taking legal measures against a man who ate with his knife. Sex was no more important than hunger, and possibly somewhat less so; but no time was spent on sex education and not more than 5 per cent. of persons received considered instruction before marriage. Children were left ignorant on the subject, and this was the reason for the many cases of sex delinquency. They should be instructed in this subject as carefully as they were taught to eat.

Elimination was wrongly regarded by many persons as a function directed by Providence.

Bed-wetting, for example, should never occur after 2½ years of age. Of the cases that persisted beyond this age 2 per cent. were pathological, but 98 per cent. were amenable to habit training and could be cured in six months. It was impossible to exaggerate the effects on a child of this condition. He was exposed either to punishment or ridicule, and his sense of inferiority made it impossible for him to adjust himself to his surroundings.

Sleep was the response which the child acquired as a satisfaction of the appetite of rest. A child should be taught when and how to sleep. The text-books said that during the first month of life a child slept 22 hours out of the 24; by actual observation he had never found the hours of sleep to exceed 18. No one knew how long we ought to sleep, and it was entirely a matter of habit and convenience.

The Emotions.

Watson had made the first really valuable experiments on emotions in children. He found that infants were potentially emotional, but showed only two types of emotional response; the first was fear, which was produced by a sudden change in environment, such as the occurrence of a loud noise, and it was expressed by a movement of flexion and a sudden inspiration. Anger, the second emotion, was produced by preventing the child from fulfilling some desire. If the wrist were taken between the observer's finger and thumb so that the child could not withdraw the hand, it would first make vigorous attempts to free itself; when it failed it would express its resentment by a movement of extension and an expiratory cry. The infant had no other emotions, and adult emotions were complexities of these. It was impossible to stamp out fear or anger, but we should train the child to fear those things which it was socially acceptable that he should fear, and be angry when it was socially accepted that anger was desirable.

A child should never be given what it wanted when it showed anger as otherwise it would count on gaining its ends in this way. But it must not be concluded that every child who showed anger was spoiled. Anger was a normal quality at 2 years of age; it increased up to 3, and then gradually diminished up to 5.

The psychiatrists talked of psychotic children, but Prof. Blatz did not recognise such cases. In all the examples he had observed the fault had lain in the training. He had seen a 6-year-old boy, described as psychotic, in a children's court, who had refused to answer the questions of a Binet test. At last his mother had been sent out of the room and he had been told she would not return until he consented to do the test. For 18 minutes he had given an exhibition of mania, flinging objects on the floor, and shouting and screaming. No one had touched or interfered with him. At the end of that time he had stopped and seated himself, the mother had come in, and he had performed the tests. The mother, however, had been less educable. She had seized him, exclaiming: "Wait till I get you home!" But when that boy was placed in a proper environment, as he would be, he would find this behaviour would not get him what he wanted, and would become normal. His intelligence quotient was high.

Self-assertion reached fruition at the age of 2, and remained one of the most potent motives throughout life.

Prof. Blatz referred to the curious anomaly whereby nursery schools in England and Canada tended to be the monopoly of the children of the under-privileged classes. In Canada children were expected to attend school from 8 to 16 years, so that all their important years of early childhood were unsupervised. He hoped to see a revision of the law, requiring children to begin school at 2 years and to leave when they had completed the curriculum adapted to their intellectual level.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT).

Insurance Data for Medical Research.

I AM glad to see, from the First Annual Report, that the Department of Health for Scotland are "considering a method whereby the particulars recorded on medical certificates may be made available to them shortly after issue. This would give complete and trustworthy data from which may be compiled statistical records showing, inter alia, the illnesses to which incapacity is ascribed and the loss of working time in each area arising therefrom. It is hoped, incidentally, to adapt this procedure to supply information on certification which is necessary for administrative purposes." The Department are to be congratulated on this effort to make some use of the hundreds of thousands of medical cards now in their possession. Some years ago the Ministry of Health Medical Department issued an admirable study on rheumatism and the data were taken from the records of the insurance practitioners. Why these data have not been studied on a much larger scale is difficult to explain either for England or for Scotland. The insurance practitioners are required to make returns and fined if they do not. It is regrettable that this gold mine of medical facts has received so little attention during these 18 years.

Insurance Domiciliary Service and the New Local Government Act.

The Department are also giving careful consideration to the problem of securing to the insured person the institutional advantages of the new Act. "With the passing of the Local Government (Scotland) Act, it is to be expected that local authorities in Scotland, in co-operation with the great voluntary institutions which have served the insured and non-insured population in the past, will develop a service which will be of great value to all. The Department realise that to secure the fullest value from the organised medical services of the country a definite relationship must be established between the insurance practitioner and these institutions, and consideration is being given to the best method of securing full consultation and co-operation between all the parties concerned." This great flaw in the insurance system will now be rectified. It is gratifying to find that this immense clinical problem is brought by the Department into the front place. This new departure in "treatment" policy, as well as in the handling of the medical returns, will be welcomed by all interested in developing the efficiency of the national insurance system.

Edinburgh Royal Infirmary Appeal.

The appeal for £500,000 for Edinburgh Royal Infirmary is now being launched, and at a meeting, convened by Lord Provost Whitson, officers were appointed to take charge of the procedure. Colonel J. M. B. Scott was appointed Appeal Director, and Mr. J. D. Imrie, City Chamberlain, will act as honorary secretary and treasurer. The case for extension of the infirmary is overwhelming. From time to time facts about the waiting-lists have been published, and however they may be interpreted, they are always disturbing. But there is now a general consensus of lay and official opinion that the time has come for a large expansion. The Town Council, under the new Local Government Act, is proceeding with the correlation of all its medical institutions; but this will not in any way interfere with the great appeal of the Royal Infirmary. To judge by the other Scottish hospital appeals, Edinburgh is likely to have a handsome response. It is not without significance that the 250th anniversary of the Royal College of Physicians comes next year, and, as the College was really the originator of the infirmary, the interest created by the anniversary will help the principal medical institution of the East of Scotland.

IRELAND.

(FROM OUR OWN CORRESPONDENT)

Cecilia-street School.

It was announced last week that the last of the departments of the medical school of University College, Dublin, working in the old Cecilia-street School of Medicine, was finding accommodation in the college buildings in Earlsfort-terrace, and that the old premises—which had housed a medical school for almost a century—were about to be vacated. In 1836 the existing premises came into the possession of the Apothecaries' Hall, which there established a medical school. This had various vicissitudes, but about 1850 its fortunes dwindled, and a year or two later it was closed. The premises were then purchased by the recently established Catholic University of Ireland, and a medical school was again opened. It continued in full work until the establishment of the National University of Ireland in 1908, when it became the medical school of University College, Dublin, one of the constituent colleges of the University. Within the next few years most of the departments were transferred to the new college buildings in Earlsfort-terrace, and the transference will now be completed. The history of the school from 1850 to 1908 is one of great courage and zeal, overcoming almost incredible obstacles. The school was unendowed, and unable either to expand in space or to equip itself adequately, but during all these years it gave a sound training in medicine to successive generations of students, having sometimes on its books the largest roll of students attending any Dublin school. Its success was only possible by the self-sacrifice and devotion of a series of distinguished teachers.

Before the building of the first school by the Apothecaries' Hall the site had an interesting history. In 1250 it was granted to the Augustinian friars for their first monastery in Ireland, and they continued in possession until the suppression of the monasteries in 1530. The site was then granted to one Richard Nagle, the last Prior, who accepted the reformed faith. It passed through various hands during the next two centuries, and the house which replaced the old monastic buildings was at one time the office of the Down Survey, the first survey of Ireland, carried out in Cromwellian days by the famous Sir William Petty, the founder of the Lansdowne family. At this time the grounds were a physic garden owned by an apothecary named Wetherell, in whose house many of the early meetings of the Dublin Philosophical Society, now the Royal Dublin Society, were held. In 1791 a music-hall was built here, which some time later gave place to the famous Grove-street Theatre, where Peg Woffington first appeared, and where Keane had some of his greatest triumphs. A few fragments of the fabric of the theatre are still seen in the building of the school.

Free State Medical Registration Council.

The vacancy in the direct representatives of practitioners on the Irish Free State Medical Registration Council was filled last week by the election of Mr. William Doolin. His election was unopposed. Mr. Doolin is a graduate in medicine of the National University of Ireland, and a Fellow of the Royal College of Surgeons in Ireland; he is one of the surgeons to St. Vincent's Hospital. He has been for several years honorary secretary of the Dublin Local Medical Committee. He has proved a very competent editor of the *Irish Journal of Medical Science*.

MEDICINE AND THE LAW.

Sale of Practice: Agent's Claim for Commission Fails.

In the Greenwiche County Court on May 7th a firm of medical agents unsuccessfully claimed £22 10s. in respect of the sale of a medical practice. It appeared that the defendant practitioner had at one time

engaged an assistant through the agents. The assistant did not buy the practice but, when the services of a second assistant were required, he introduced a third practitioner who bought it, the new-comer being a personal friend. The plaintiff firm's case was that the defendant practitioner had asked them to find him an assistant who would ultimately buy the practice. The defendant practitioner's case was that the purchaser was not introduced by the agents but was procured independently. The purchaser gave evidence for the defendant. When he first came as assistant, he said, he had no idea of buying the practice; subsequently he himself volunteered the offer to buy. The county court judge accepted this evidence and found against the agents whose evidence, he said, was of the vaguest. The onus was upon the agents to show that through their efforts the sale was brought about. It seemed, however, that the sale was actually brought about quite independently of their efforts. All the agents did was to introduce an assistant; they never introduced the purchaser.

Details of the sale agreement were given during the case, the figures being required in order to justify the amount of the plaintiffs' claim. The price was £2850, including £1100 in respect of the lease. For some reason not readily apparent, the defendant practitioner was cross-examined as to his previous sales of practices. He explained that he left hospital in 1920, set up in practice for himself in the following year in an eastern district of Greater London, and presently sold his practice for £4000. In 1925 he worked up a practice nearer the centre of London which he sold for £1750 with £300 for the lease. He next went to a well-known suburb for two years where he disposed of his practice for £4000. Asked if this plan of building up practices, selling them and moving on elsewhere was usual in the medical profession, the witness replied that it was not unusual; it depended on the temperament of the practitioner; he thought more practices were established by squatting than by buying. The learned judge remarked that the transactions were perfectly legitimate. If the practitioner saw an opportunity of making a profit by sale, he was perfectly entitled to take advantage of it.

SEAMEN'S HOSPITAL SOCIETY.—The annual court of the Society was held at the May Fair Hotel on May 16th, with Admiral Sir Roger Keyes in the chair. Sir Arthur Clarke mentioned the work of the eight establishments for whose upkeep the Society is responsible, and said that the income this year, though £93,000, had fallen short of expenditure by about £2000. Sir Roger Keyes was glad to see present so many friends from overseas, evidencing the wide appreciation there was for the Society's work. The Belgian Ambassador spoke of the great pioneer work done by the Society in the study of tropical diseases, which his countrymen were now following in Antwerp. Dr. C. E. Sundell, senior physician to the Dreadnought Hospital, asked for further support to enable the Society to assist not only the seamen of the mercantile marine but also their wives.

ST. BARTHOLOMEW'S HOSPITAL.—The report for 1929 of the treasurer, Lord Stanmore, recapitulates the story of the great works of reconstruction that are in progress and the "striking and original propaganda" by which it is sought to raise the million of money that is required. It is pointed out that the ten new surgical wards are not an addition but a replacement of a similar number of old wards. The southern extension of Queen Mary's Home will be ready for occupation during the present month and will accommodate 61 nurses; the building will now have 321 sisters and nurses, but since there are 351 members of the nursing staff further accommodation is still necessary. The total income was £198,697 and the expenditure £197,660. The number of new in-patients was 9454, who stayed on an average 21.70 days; the new out-patients numbered 89,616. The hospital's small house property consists of 670 premises producing a gross rental of £19,120; the net receipts from this source, after paying rates, taxes, insurance, management costs, and repairs, were £27,838, or about 60 per cent. of the rentals.

THE FIRST INTERNATIONAL CONGRESS ON MENTAL HYGIENE.

(FROM A SPECIAL CORRESPONDENT.)

(Continued from p. 1096.)

Dr. HERMAN BOUMAN, Professor of Psychiatry and Neurology at the University of Amsterdam, spoke on ALCOHOL AS A MENTAL HYGIENE PROBLEM.

He said that laboratory experiments had shown that even very small doses of alcohol injured the receptive functions—such as perception, memorisation, conception, and attention—in such a way as to cause the incidence of errors. As a result of the appearance of superficial associations without inner contact, the thinking faculty itself became incapable of serving as the basis of any higher mental life and degenerated.

It was important to observe that even in these conditions of slight intoxication self-criticism became less active, and the person tested had the subjective feeling that he had done his work much better than the experiment actually indicated. The result was, therefore, that less accurate perception and more superficial thinking were followed by hasty and inefficient action, which the person tested could not himself adequately criticise, because he had the illusion that he could do his work more easily and better than would be the case in a state of perfect sobriety.

Even very small quantities of alcohol produced a condition that had all the essential characteristics of delirium. The measures taken against alcoholism in the different countries and the organisation of the anti-alcohol movement had come into existence in quite different ways. The aim of an Act in Holland was limitation of "temptation" by restricting, so far as possible, the number of places where strong drink could be sold. This principle had proved sound. In 1877 the consumption of distilled drink per head of the population amounted to ten litres. In 1920 the number of litres per head of the population amounted to only 5.16. An important task remained—to take care of the drinkers who had to be set on their feet again. This was a difficult phase of mental hygiene work. It had been concluded that the best form of organisation for this purpose would be a group of "Consultation Bureaux for Alcoholism." The first bureau was established at Amsterdam in 1900, and since then these institutions had been formed in practically all the greater towns of Holland. In the bureaux a social worker and a psychiatrist shared the work. The bodily condition of the alcoholic was examined, and his mental aberrations, as well as his surroundings, his work, his family, his social behaviour. Though at first exclusively financed through private contribution, the consultation bureaux were now subsidised by the State, the province, and the municipality.

Under pressure of public opinion, the picture of alcoholism in Holland has undergone a gradual change. The admission figures for cases of alcoholism at the clinics have shown a slow but steady tendency to fall, and the mental hospitals have had fewer drinkers among those admitted. Crimes of violence have decreased, and there has been a reduction in the amount of alcohol used per head of the population.

Discussion.

Prof. WILHELM WEYGANDT (Germany) said that since the war alcoholic insanity and criminality had remained lower than in the pre-war years in Germany. This was no doubt partially due to the increased price of alcohol. The number of licensed houses was far too great in Germany; in some industrial towns it was as high as 1 to every 170 persons. He had no doubt that a large percentage of drinkers were psychically abnormal. There was a system of graduated control for alcoholics in Germany ranging from a warning with police probation to institutional care. He thought sterilisation desirable for the hopeless drunkard.

Dr. O. FOREL (Switzerland) said that Switzerland had a very high consumption of alcohol in relation to its population. There was not much organised propaganda against alcohol. In his view legal control on such a matter could never be successful. Negativism was a normal human reaction and any laws to be

effective must have the full support of public opinion. Temperance propaganda throughout the world had not so far been carried out with due regard to the psychology of the public. The temperance reformers had been too severe, too superior, and too dogmatic.

Prof. JAN PILTZ (Poland) said that the campaign against alcohol was a question of national efficiency and should be one of the first planks in the platform of mental hygiene.

Dr. W. TREADWAY, of the Public Health Service of the United States, declined to be drawn into a discussion on prohibition. He said that the various articles and reports on the subject would be available to members of the congress.

Dr. DORIS ODUM (England) spoke of the reduced consumption of alcohol in England since the war. There was a certain amount of regulation of the sale of liquor, but the decrease in drunkenness was largely due to the raising of the standard of living. The question of housing was important in this connexion. The results of experiments in removing slum dwellers into special houses had been extremely satisfactory. The claims of temperance were best promoted by raising the standard of living and by the education of the public in the sense of social responsibility.

Prof. E. RÜDIN, head of the Genealogical Department of the German Research Institute for Psychiatry (Kaiser Wilhelm-Institut), Munich, read a paper on the

SIGNIFICANCE OF EUGENICS AND GENETICS FOR MENTAL HYGIENE.

He said that eugenics investigates how a human being may, with the greatest probability, be brought into the world without unfortunate mental or physical hereditary tendencies. Expressed in terms of social economy, therefore, eugenics means an enormous saving of useless, or partially unsatisfactory, mental hygiene. Prof. Rüdin supplied statistics obtained mostly from personal investigations in his own institution to give an idea of the significance of heredity in the transmission of mental diseases.

If one of the parents is afflicted with Huntington's chorea 50 per cent. of the children will have the same hereditary disease, and the same proportion of the children of parents with dementia præcox or schizophrenia will be mental defectives. If one of the parents is afflicted with manic-depressive insanity fully 33 per cent. of children will be manic depressives, and at least as many will be otherwise mentally abnormal. A large proportion of the children of genuine epileptics are also afflicted, and, as in all hereditary mental disorders, a still greater proportion when the other parent also is not quite normal. Reviewing the anxieties and doubts besetting individuals afflicted with disease who wished to mate, and the methods available for preventing hereditary disease, he believed that voluntary sterilisation (not castration) of the hereditarily diseased or hereditarily defective should be considered, not only because it was statistically, but also because it was individually, absolutely and permanently reliable. It entailed no danger to physical or mental health, nor did it encroach upon the habits of life and the pleasures of life in any way, and would not, if suggested with tact and consideration, produce any psychic trauma.

It was a consoling fact that exactly as diseases and defects were transmitted, so were the tendencies to positive qualities such as talent, and to foster these, thus increasing the public heritage, was one of the chief duties of mental hygiene.

In the course of the discussion Prof. JOUCHTCHENKO (Russia) said that he agreed with Dr. Rüdin on the importance of preventing the reproduction of hereditarily diseased or defective stock. The laws of heredity were not yet fully understood, and it was therefore important to preserve an open mind until more scientific data on the subject were available.

Dr. FRANS ALEXANDER (Berlin) read a paper on MENTAL HYGIENE AND CRIMINOLOGY.

He said that the form of the question, "Why does a person become a criminal?" was due to lack of knowledge. It presupposed that it was natural to

be a righteous citizen and that a special explanation was necessary when people did not respect social regulations. Psycho-analysis, on the other hand, taught that people come into the world with impulses and instincts that were not adjusted to society, and that they were born as criminal beings in this sense, that if a little child could realise the demands of its instincts it would act as a criminal. The entire development of the instincts of the child from the age of 4, 5, or 6 on consisted of a gradual adjustment of the demands of the instincts to the demands of society—a development that no human being finished entirely successfully. The right form of the question was "Why do not people in general become criminal?" or rather "Through what processes of development does the originally asexual child turn into a social being?"

He differentiated between the chronically criminal, whose treatment belonged to the doctors, and the accidentally criminal, who could be influenced by a change of environment. The tendency to criminal instinctual out-break was acquired in the indecisive instinctual conflicts of childhood. In this field it appeared that the two great instinctive qualities that had to endure the disturbances of the equilibrium between renunciation and satisfaction were hunger and love. As in other branches of the study of human beings, the sexual factor has been greatly neglected in the study of criminology up to the time of Freud. Our judges still tried to explain every crime act by consciously rational motives. To them every phantastically construed motive was preferable to the general instinctive-emotional motive which in fact generally determined any action. The behaviour of the psychopathic or chronic culprit betrayed a clearly irrational trait. It could not be explained by a utilitarian motive; this was the difference between the kleptomaniac and the common thief. The second distinguishing symptom of chronic criminals was their stereotyped form of behaviour. The unconscious demands of instinct conquered without any regard for the experiences of the past or for the present situation, and always in the same manner. The third symptom was psychic conflict. Remorse and condemnation of the act came, but too late; even if conscious condemnation of the act was lacking, unconscious expressions of condemnation were found in the form of self-harmful tendencies. The sick man, that is, the culprit, was mostly an intelligent, often talented man, pleasant, universally beloved, a man who, as if driven by an evil spirit, from time to time committed acts quite contradictory to his character. Behind the myth of the evil spirit lay a true observation; the demon was in this case the powerful, compulsively conquering unconscious. While punishment and threats of punishment might have a terrifying effect upon normal law-breakers, who acted with conscious deliberation, all such measures had the exactly opposite effect upon the neurotic culprits, because they had no approach to the unconscious. Because of the ever-present need of punishment felt by the culprits, threats could even lure them to commit the deed. The punishment endured was the very thing to break down the moral repressions of these people, to lessen their sense of guilt, and to encourage them to new offences. This was the explanation of the obstinate tendency of this group of law-breakers to relapse. Nor was change of environment of any avail. Improvement of the outward conditions of life increased the feeling of guilt, strengthened the need of punishment; the tragic mentality of these people made them liable to commit new crimes just after an improvement in their circumstances. Psychopathic culprits belonged to medicine. The aim of treatment was to make conscious the unconscious motives. Only after the control of the conscious ego had been extended over the life of the instincts was it possible to expect restraint of the criminal impulses and to prevent relapse.

Admittedly, however, a certain discontent was characteristic of the civilised man in general, and this discontent—recently called by Freud "discomfort of civilisation"—was relatively independent of mental disease and social position. The increasing organisation of society forced man to an adult life in a higher degree than he could live, and neglected his childish demands. There was an increasing control of the principle of utility and a decreasing of the principle of pleasure. Our mechanical economic civilisation showed this to an extent never before reached. The result was a damning up of the playful, irrational pleasure-seeking formerly associated with human occupations and social activities. This increased the conditions for neurosis and for

crime, if at the same time new outlets were not found. In Dr. Alexander's view the most important social problems of future mental hygiene was the development of such outlets.

Dr. V. V. ANDERSON, Director of Employment, Placement and Personnel Research at the Macy department store in New York City, spoke on the

CONTRIBUTION OF MENTAL HYGIENE TO INDUSTRY.

He said that in the department store to which he was attached about 20 per cent. of the employees were what might be called "problem" individuals, and this was probably true of other business and industrial organisations. This group of persons were either liabilities or potential liabilities to the business man; from it were drawn the repeated transfers from job to job, the resignations and the dismissals.

Nineteen per cent. of the salespeople and 23 per cent. of the non-salespeople gave rise to situations that caused their department heads to question the value of their services to the store. As the psychiatrist saw these individuals, they presented distinguishing physical and mental characteristics. He was impressed with three outstanding causative factors: (a) a maladjusted personality; (b) specialised job disabilities; (c) faulty physical conditions. As the employer saw them, they were production problems, or chronic health problems, or chronic attendance problems, or disciplinary cases—and from his point of view he was better off without them. From the medical and mental-hygiene point of view, however, many of these individuals might, through treatment, be adjusted and become assets to the employer, thus cutting down turnover among employees and increasing production efficiency. The records at the Macy store showed a sufficiently large number of improvements under psychiatric treatment to make the application of such measures profitable, not only in terms of human salvage, but in terms of dollars and cents. Of the last 600 problem cases, 67 per cent. were still in the store, 23 per cent. had been dismissed, 8 per cent. had resigned, and 2 per cent. were pensioned. Of the active cases, 40 per cent. had been adjusted and were no longer problems to their departments, and 14.7 per cent. were still under treatment.

Every department head had tried various methods of dealing with such employees—fatherly lectures, additional training, transfers, and finally dismissals. There could be no denying that it paid in time, money and energy to have each of these employees adequately studied before wasting energy on such methods. As a result of psychological tests and other methods of picking automobile drivers more carefully, driving accidents in the firm had been reduced by 50 per cent.

Mrs. SIDONIE MATSNER GRUENBERG, Director, Child Study Association of America and Consultant in Parent Education of Columbia University, spoke on the

SIGNIFICANCE OF THE HOME IN THE PERSONALITY AND CHARACTER DEVELOPMENT OF THE ADOLESCENT.

She said that during the development from infancy through the subsequent stages of growth, the home stood out as the most important single influence. To-day many are familiar with some of the emotional motives of this family drama, especially the emotional states of the parents in relation to their adolescent children: the mother seeking a husband substitute in her son; the father seeing the mother image in his daughter; parents everywhere hoping to relive or to perfect their own lives through the lives of their children. Thus they centred about their sons and daughters conflicts growing out of their own social strivings, their money strivings, their love strivings, and because of these too often imposed upon their children false standards and expectations. The resulting tensions and fixations were stumbling-blocks to normal growth from the earliest childhood years, but it is in adolescence that they took their most visible toll.

Until very recently this family drama had gone on behind closed doors, and parents were still inclined to resent inquiries from any outsider about what happened in the home. Until recently it had been taken for granted that

with the moral and psychic health of their children parents must struggle alone, although it had long been respectable to seek expert advice in the prevention as in the cure of physical disorders. The modern home had lost certain educational and disciplinary opportunities which existed before the introduction of labour-saving improvements—the discipline of disagreeable but *indispensable* service, the challenge to ingenuity and invention, the daily exercise in adaptability. A good housewife formerly maintained her status and perhaps also her self-respect even if she proved to be a rather incompetent guide for her children; to-day if she failed as a mother she could not fall back upon compensating virtues as cook or laundress. With the father economic competence was still basic, but both parents were coming more and more to be judged by the relationships that they succeeded in maintaining between the constituent members of the home. Although most of their own work had been taken out of the home, parents still influenced children through their reactions to their own standardised drudgery. If children grew up seeing only the disagreeable aspects of the life of labour, aspirations would naturally turn toward means of escape, or the outlook would become one of resignation and dull indifference. The maturing process of the modern child was apt to be delayed by the lengthening of the period of schooling and the consequent freedom from economic obligation. The very unreality of high school and college life artificially prolonged childhood. The allowance and the opportunity to earn should thus be a part of every child's experience. Boys and girls especially at school and college were appallingly unaware of alternatives, almost totally innocent of experience in the making of choices.

It was most important for parents to recognise and to accept, in their own attitudes and their explicit teachings to their children, the fact of a changing order. Many of the deep convictions of yesterday turned out to be parochial customs for which the rest of the world to-day has but a smile of patronage. The same was true of our attitudes toward sex. There remained in our civilisation vital functions which the home—and the home only—could fulfil.

Miss EVELYN FOX, Hon. Secretary, Central Association for Mental Welfare, Great Britain, spoke on

COMMUNITY SCHEMES FOR THE SOCIAL CONTROL OF MENTAL DEFECTIVES.

She said that while every civilised country was making efforts to provide schools and institutions for some of its mental defectives, little had been done toward establishing a system of social service that would be available for all defectives living in the community. She outlined the principles on which such a service should be based. The only really satisfactory criterion of mental deficiency was the social one, and if a person suffered from a degree of incomplete mental development which rendered him incapable of independent social adaptation and which necessitated external care, supervision, and control, then such person was a mental defective. That was the definition given in a recent British Government report. For purposes of training defectives could be divided into two groups: those who must be sent to institutions and those who could be trained in their own homes or by foster parents. The training outside an institution was, in Miss Fox's view, preferable for both imbeciles and feeble-minded of a stable temperament who appeared capable of being controlled and occupied, given a good type of home and intelligent parents or foster parents. Under these conditions, the defective in the home had opportunities of meeting and surmounting everyday difficulties, of adapting himself to varied surroundings, of being thrown with the same people he would meet in later life, of growing up in the same world to which he must later fit himself. The statement was made over and over again in all countries that imbeciles should be trained in institutions. Experience in England had shown that imbeciles and low-grade feeble-minded children with decent homes and in attendance at occupation centres could be successfully trained, and that the possibilities of their social adaptation were at least as great as for those trained in institutions.

Dr. GEORGE S. STEVENSON, Director of the Division on Community Clinics of the National Committee for Mental Hygiene, discussed

THE CHILD-GUIDANCE CLINIC: ITS AIMS, GROWTH, AND METHODS.

He said that the child-guidance clinics now in existence had been created largely within the past ten years. It was their purpose to treat the behaviour disorders of children, such as tantrums, stealing, seclusiveness, truancy, cruelty, sensitiveness, restlessness, and fears. The aim was to produce a more efficient, productive, and harmonious adult and a healthy mental life during the period of development. The clinic worked largely with the pre-school child and his parents, since parental ignorance and early habits and attitudes were major contributors to the behaviour problems of childhood. The clinic maintained a threefold staff, psychiatrist, psychologist, and psychiatric social worker.

The first child-guidance clinic was initiated in 1909 by Dr. William Healy in Chicago. In 1922 the Commonwealth Fund launched its programme for the prevention of delinquency and carried on a five-year term of demonstration and experimentation, and since then the movement had grown at a great rate. The Commonwealth Fund had also created a national bureau for child-guidance work, being the Division on Community Clinics of the National Committee for Mental Hygiene. This bureau coördinated the work of existing clinics and assisted in the planning of new ones. To-day there were about 600 clinics in the United States giving psychiatric service to children. Only about a quarter of these, however, which had a threefold staff, should be considered child-guidance clinics.

Of the 25 outstanding child-guidance clinics, nine were supported by the Community Chest, a coördinating and money-raising organisation for all the social agencies of a community. Practically all child-guidance clinics accepted responsibility for community education in the mental hygiene of childhood. Few community groups, social or industrial, had taken advantage of those reliable mental hygiene facts that could aid them in their jobs. Parents, of course, had the broadest needs. But there were also professional groups—the court, the school, the social service agency, the church, and the doctor—who were daily being given the more serious problems of the children of the community to deal with or advise about. These groups could use the experiences of child-guidance clinics to serve their own clients and patients. The appeal of the work of the child-guidance clinic was such as to tempt unprepared persons to undertake it. Behaviour problems of children could be dealt with by others than psychiatrists, but such work was satisfactory only when the contribution of the psychiatrist to the more complex cases and the importance of the physical condition in all cases were recognised and actually influenced the procedure.

There was a decided shortage of persons to fill positions in child-guidance clinics. At the present time there were attractive positions vacant for psychiatrists. This shortage was the result of inadequate psychiatric education in our medical schools and the lag that appears between demand and supply due to the time required for training. A similar problem existed in respect of psychiatric social workers, but the training centres for child guidance were rapidly increasing.

Dr. OTTO KAUDERS, Assistant, Clinic for Psychiatry and Neurology, University of Vienna, spoke on

SEX AND CIVILISATION.

He discussed the adjustments required between the individual and the community. Human civilisation must ask from each of its participants not only the resignation of the satisfaction of a part of his sexual desires and of his possibilities of sex experiences, but also the resignation of the satisfaction of a great part of his ego, of his instinct for self-preservation, of his desire for power.

Mental sex hygiene did not pretend to influence in a decisive way the special individual laws of cultural development that stamped the sexual life of the time. But while it endeavoured to intervene objectively, investigating and helping practically, in all important points of contradiction and agreement

between civilisation and sex, its ideal purpose was to bring the impulsive human being into harmony with his just desires for sexual happiness and also with civilisation, whose servant it was his duty to be.

MANCHESTER MEDICAL SOCIETY'S LIBRARY.

A GIFT TO THE UNIVERSITY.

THE Manchester Medical Society has given its valuable library to the University, and this transfer of ownership is a landmark in the scientific life of the town. It settles a problem which has been a recurring source of discussion in the local medical world in cycles of about ten years—namely, the possibility of forming a medical institute in the town and removing a big library to it. Founded in 1834, the Medical Society had its quarters in the centre of the town until 1874 when they were moved to the new buildings for the medical school of the Owens College. The college undertook to house the library and to find the necessary accommodation for a reading room and meetings, and to contribute an annual sum for privileges to its staff for use of the society's books and periodicals. This arrangement has been in existence until the present day. The society's library has grown from 1075 to 35,000 or more volumes, and besides these the university has, in the library, another 20,000 volumes purchased out of its own funds or received by gifts, the chief of which were the libraries of the Manchester Royal Infirmary and the St. Mary's Hospitals, each about 7000 volumes. Both these libraries occupied space in the hospitals which was urgently needed for other practical purposes. The cost of maintenance of libraries has greatly increased in recent years because of the price of books and periodicals, and of the latter especially the first-class German journals. Unfortunately the society's income has not grown in like manner and is nearly stationary. The subscription has only been one guinea, attempts to double it having failed owing to the average practitioner not appreciating the value of such a library. The society, therefore, has found itself unable to bear the burden of responsibility for maintaining the library in spite of a large grant from the university. Whilst the library provides many books of interest for its ordinary members it is especially valuable for research, and to facilitate this small sub-libraries in anatomy, physiology, therapeutics, and gynecology have been formed in these departments. It was felt that such a library could never be moved from the centre of research, whatever developments there might be in a scheme for a central meeting place for all the scientific societies of the town. Hence the decision, after anxious deliberation over several years, for the step which has just been taken. The university now owns the library and undertakes its maintenance with a definite annual contribution from the society, in return for which the members of the society have all the rights of use that were asked for and also access to the large general Christie library of the university.

The Medical Society's library contains information of inestimable value to the scientific research worker, and to the would-be medical historian. There are many rarities on its shelves. There are a dozen incunabula, the earliest dated work being 1480 from a Venetian press on an Italian translation of Guy de Chauliac's "Chirurgia Magna" which was the textbook of surgery in several languages until beyond the sixteenth century. Only two other copies of this work are known. There are close on 600 books printed by foreign presses before 1600, 200 being dated before 1550. Fine copies of early editions of all the classical writers in medicine, many in Latin or Greek, are on the shelves, and book-lovers will be delighted with the study of those from the Aldine and Elzivir presses. There are 150 copies of English printers' work before 1775, and 250 before 1700. The earliest dated book in

English is a Herbal, 1548, the author of which is not stated and of which no other copy is known in libraries. Bound up with this, which is in black letter type, are four other tracts in similar type, one being "The Myrrour or glasse of helth," by Thomas Moulton—a "Doctour of dyvynitie," and chiefly concerned with advice about avoiding the plague as derived from the influence of the planets on health and disease. The library has been added to by gifts from its members—a special lot of many hundreds being left to it by the late Dr. Percy Cooper. A new feature of it is a collection of all information of local medical historical value, biographies, portraits, hospital reports. Anything of this nature will be gladly accepted by the library from our readers.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

The following are some 1929 statistics of two county boroughs, one rural and one urban district:—

Name of district and estimated (R.-Q.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (4-5 yr.) mortality.	Maternal mortality from childbirth.
Reading C.B. (97,050)	14.9	14.1*	1.26	1.57	3.3	1.4	50/27	32	2.8
Booth C.B. (80,400)	20.6	13.6	1.34	1.21	3.7	1.3	83/34	64	3.0
Barnstaple R.D. (18,540)	13.8	12.0	0.81	1.56	1.6	2.1	78/—	—	3.9
Ventnor U.D. (4,982)	11.2	16.0	0.60	3.00	2.4	3.2	71/—	36	0.0

* Standardised, 12.2.
Registered stillbirths per 100 live births: Reading, 3.7; Booth, 3.9; Barnstaple, 3.5.

Reading.

Dr. H. J. Milligan reports that the birth-rate is the lowest ever recorded in the borough. He thinks we are approaching a time when the birth-rate will not exceed the death-rate, and the natural increase of population will cease. The death-rate is higher than any recorded during recent years and this increased mortality was the result of adverse weather conditions and the unusually severe epidemic of influenza which prevailed during the earlier weeks of the year. The mortality from influenza was greater than in any year since the pandemics of 1918 and 1919. There was the usual concomitant increase in the deaths from bronchitis and pneumonia, which were nearly double the normal annual average. Further, there was an increase in deaths from pulmonary tuberculosis, which was probably associated with the prevalence of influenza. The infantile death-rate was lower than any hitherto recorded, and would have been still more favourable but for the unusually large number of infant deaths from pneumonia during the influenza epidemic.

The borough council has adopted a scheme which will not only meet the immediate requirements of the Local Government Act, 1929 (which came into force on April 1st, 1930), but will provide in large measure for the further development of the services concerned. The council has appropriated Battle Infirmary, and this involves the disappearance of the term "pauper" in so far as it has been applied to sick persons in the infirmary. The council will also be enabled to effect a closer co-ordination between all

the resources available for the care of the sick and the prevention of disease, as an object apart from the relief of destitution. The records at the V.D. clinic now differentiate between recent infections of syphilis and the later manifestations of the disease, and it is found that new cases of recent syphilitic infection are not numerous. There were only nine such during 1929. On the other hand, there has been a definite increase in the cases of gonorrhoea treated which numbered 79 in 1927, 112 in 1928, and 160 in 1929. The maternity and child welfare work continues to grow and the attendances at centres have increased from 11,000 in 1920 to 28,000 in 1929. Of the 21,386 home visits paid by the health visitors 11,778 were in respect of children aged 1 to 5. The shortage of houses for the working-classes has not been overcome and the housing committee have been unable to rent alternative accommodation for displaced tenants of condemned houses. The committee have, however, made arrangements for the erection of 2000 houses at Whitley. There are still about 2000 applicants for municipal houses and during 1929 an unusually high proportion of the patients admitted to Dellwood Maternity Home were living in rooms. The tuberculosis officer also draws attention to the difficulty in obtaining suitable housing accommodation for tuberculous patients living under unsatisfactory home conditions. Despite all this some progress has been made in closing unhealthy houses and 38 out of 107 houses scheduled for closure have been dealt with during the year.

Increasing attention is being given to the purity and cleanliness of articles of food prepared for sale. There was only one prosecution for the exposure of unsound food for sale and no prosecution under the Sale of Food and Drugs Acts. It seems, however, that the position as to tuberculous milk is not so satisfactory. During 1929 two out of 37 samples were found to be infected, and during the last ten years 27 out of 248. Ten per cent. of the non-designated and unpasteurised milk sold in Reading may thus be expected to contain living tubercle bacilli. The deaths from violence show an increase. Thus there were 64 such deaths during 1929, including 20 suicides as compared with eight or nine in previous years. Dr. Milligan draws attention to the fact that the conditions of life and the prospects of the practice of midwifery are not such as to attract the best members of the nursing profession, and supports his opinion with an analysis of the earnings of the midwives in Reading. The rainfall in Reading during 1929 was remarkable. There were only 21.7 inches as compared with an annual average of between 25 and 26 inches, and of the 21.7 inches 6.33 fell in November and 5.16 in December.

In the school report it is mentioned that through the enterprise of the teachers 22 per cent. of the scholars receive half a pint of milk during the morning session. Increased attention is being given to the teaching of hygiene and the subject now has a definite place in the syllabus of practically all the schools. The erection of the new school clinic will facilitate dealing with the arrears in dental work. A special memorandum by Dr. Agnes Bernfeld, who conducts the ear, nose and throat clinic, will be read with interest by all school medical officers, as it contains a description of the technique of the treatment originated by Dr. Gautier (named by him "diastolisation") and the results obtained by this treatment in Reading during the last two years.

Bootle.

Dr. F. T. H. Wood reports that the birth-rate is lower than ever before, that the increased death-rate was due to influenza and severe cold in the first quarter of the year, and that the tuberculosis death-rate continues as in 1928 to be the lowest yet recorded in the borough. A noteworthy event has been the taking over from the Bootle Health Society of control of the maternity and child welfare clinics. For the purpose the medical and nursing staff has been strengthened, and two additional antenatal clinics have been established and a beginning made with postnatal supervision of

the mother. The new cases at the antenatal clinics numbered 35 per cent. of the total births. Invitations were given to the expectant women attending the clinic to return six weeks or later after confinement for examination; 42 women accepted the invitation, and of these 22 were found to be suffering from morbid conditions requiring treatment and 5 of them were referred for admission to hospital. The child of pre-school age is to receive increased attention and the additional staff and clinic provision enabled 332 such children to be dealt with. It is hoped to extend this work during 1930 and to make further use of the specialist clinics of the educational committee for conditions such as squint, ear discharge, and crippling defects. The improved facilities at the council's new V.D. centre at the Bootle Borough Hospital have resulted in a great increase in the attendances. Of 70 new cases of syphilis 31 had contracted the infection more than 12 months before attending. It is pointed out that the increased work and attendances is not due to a greater prevalence of the disease.

A few years ago municipal building activities were increased. Thus the council erected 74 houses in 1926, 182 in 1927, 305 in 1928, and 340 in 1929. The limit of the needs has, however, not yet been reached, for in March, 1930, there remained 830 of the applications previously tabulated and 625 new ones. A small unhealthy area covering 1.02 acres and containing 60 houses has been represented. Progress is being made with plans for a new health centre in the north of the town to accommodate tuberculosis, maternity and child welfare, and education committee activities. The passing of the Local Government Act, 1929, is being utilised to secure as complete co-ordination as possible of the new and the old medical services. The medical officer of health is also medical officer to the public assistance committee. Deaths from violence numbered 42 and included 11 from suicide. In 1928 45 out of 175 milk samples were found to be adulterated. During 1929, 45 informal and 91 formal milk samples were taken. Of the 91 formal samples 14 were adulterated. Two vendors were fined for selling milk containing added water to the extent of 4 to 5 per cent., while a third was withdrawn on payment of the analyst's fee. Three vendors were fined for selling milk deficient in fat, 31 per cent., 17 per cent., and 8 per cent. respectively. In 6 cases of slighter adulteration the vendors were cautioned. There was one appeal to the cow and one purveyor was fined for refusing to sell to the inspector. The analyst reports that the average of fat in all samples including those adulterated was 3.64 per cent. and of non-fatty solids 8.85 per cent.

Good results are being obtained at Linacre Hospital in suitable cases from artificial pneumothorax. One patient so treated in 1924 has been at work full time ever since. Another first treated in 1925 is now working full time. A third first treated in 1928 has now no symptoms. All these were well-established cases with tubercle bacilli in their sputum.

Barnstaple.

Dr. J. R. Harper notes that the standard of living of the labouring class in his rural district has been improved. Wages have increased, new and more healthy cottages are available, and existing cottages have been reconditioned under the Housing (Rural Workers) Act, 1926. During 1929 the reconditioning of 20 houses was completed and since the Act came into force 49 schemes have been approved. The county council makes hospital provision for small-pox, but Dr. Harper stresses the need for a hospital for other infectious diseases in this area. An important event during the year was the completion of the Combemartin water-supply scheme.

Ventnor.

Dr. R. T. Cooke reports that the urban district council in November agreed to purchase the water undertaking. He remarks that the yield of water at the source is sufficient to ensure the town's popula-

tion a constant supply but that the efficiency of distribution is open to question. The aggregate of bright sunshine for the year taken at the hospital was 2068.6 hours and Ventnor is said to come out best of the 12 stations which send in 12 consecutive monthly returns of ultra-violet light. The sanitary inspector reports that in 1926 the council purchased a housing site for £650 and accepted three contracts for 20 houses, two of which have been completed and the third is well under way. The houses are of the parlour type and of four designs. The cost varies from £460 12s. 5d. to £499 15s. per house.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

MAY 10TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 462 (last week 300), scarlet fever 1991, diphtheria 1303, enteric fever 85, pneumonia 944, puerperal fever 50, puerperal pyrexia 107, cerebro-spinal fever 25, acute poliomyelitis 3, acute polio-encephalitis 1, encephalitis lethargica 17, dysentery 7, ophthalmia neonatorum 117. No case of cholera, plague, or typhus fever was notified during the week.

Of the cases of small-pox, 222 were returned from the County of London—namely, Bermondsey 3, Bethnal Green 41, Canberwell 27, Deptford 2, Finsbury 6, Hackney 21, Hampstead 1, Holborn 1, Islington 12, Kensington 2, Lambeth 3, Lewisham 4, Poplar 27, St. Pancras 4, Shore-ditch 34, Southwark 4, Stepney 25, Stoke Newington 6, Woolwich 1. Outside London small-pox was reported from 16 counties—namely, Derby 3, Durham 3, Essex 50 (of these West Ham 21, Walthamstow 10), Kent 5, Lancashire 13, Leicester 61, Middlesex 16 (of these Tottenham 11), Nottingham 3, Stafford 21, Warwick 1, Wilts 2, Yorks, West Riding 36, Brecknock 4, Glamorgan 14, Monmouth 8.

Of the number of cases in the Infectious Hospitals of the London County Council (the name Metropolitan Asylums Board has disappeared) on May 13th–14th was as follows: Small-pox, 568 under treatment, 22 under observation (last week 648 and 33 respectively); scarlet fever, 2004; diphtheria, 2471; enteric fever, 33; measles, 005; whooping-cough, 60; puerperal fever, 26 (plus 18 babies); encephalitis lethargica, 119; poliomyelitis, 1; "other diseases" 21. At St. Margaret's Hospital there were 18 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 90 (42) from measles, 9 (3) from scarlet fever, 27 (3) from whooping-cough, 49 (16) from diphtheria, 45 (7) from diarrhoea and enteritis under two years, and 33 (5) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London was reported from Birmingham. Fatal cases of measles have dropped below the hundred line for the first time for many weeks: Southampton reported 7, Warrington, Salford, and Rochdale each 4. Birmingham and Liverpool each reported 4 fatal cases of whooping-cough. Six deaths from diphtheria occurred at Liverpool, 4 at Cardiff. Diarrhoea was credited with 6 deaths at Manchester and 4 at Liverpool.

The number of stillbirths notified during the week was 202 (corresponding to a rate of 39 per 1000 births), including 56 in London.

DEATH FROM SMALL-POX.

THE death assigned to Finsbury (Met. Boro.) in the Registrar-General's return for the week ended April 26th was that of a male infant, one month of age, who died at Joyce Green Hospital on April 2nd, the death certificate being filled in thus: Small-pox: pyæmia. Not vaccinated until after exposure to infection. No P.M. The father, Dr. A. E. Thomas tells us, was a commercial traveller, and the infant was sent into hospital with his mother, who had had small-pox for some time undetected. The mother's rash appeared on forehead and wrists on March 18th. On the 28th mother and child were removed to the South Wharf Hospital, and from there to Joyce Green. The baby was being breast-fed throughout and was vaccinated on the day of removal to hospital when he showed no signs of small-pox. These developed after admission to hospital. He was presumably infected by the mother prior to admission.

VITAMIN A AND INFECTIONS.

To the Editor of THE LANCET.

SIR,—I wish to express my concurrence with the views expressed by Dr. A. H. G. Burton and Dr. A. R. Balmain in their paper published in THE LANCET of May 17th (p. 1063) that vitamin A has no anti-infective effect in the sense of Mellanby and Green—namely, that it cannot prevent such an infection as puerperal septicæmia, nor can it cure such a septicæmia once it has been established. The experimental evidence is entirely in agreement with their clinical observations. Since previous observations have not been fully taken into account in the papers by Green and Mellanby, it may be useful to summarise the outstanding facts.

1. Animals kept on a vitamin A deficient diet are particularly susceptible to develop spontaneously infections of a chronic nature by organisms which are not very virulent.

2. The organs which are earliest and most frequently infected are the lungs and intestine (McCarrison, Cramer¹).

3. In the mucous membranes of these organs it has been shown that there is an atrophy of the mucous secreting cells and that the intestinal bacteria penetrate into the lumen of the glands of the altered intestinal mucous membrane, where they proliferate. Figures illustrating this process have been published in your columns.²

4. Animals kept on a vitamin A deficient diet do not differ in their immunological reactions from normal animals nor are they more susceptible to infection by virulent or avirulent pathogenic organisms, when these are introduced experimentally by subcutaneous injection (Cramer and Kingsbury³).

From these observations it seems justifiable to conclude that an adequate supply of vitamin A is necessary to maintain the mucous membranes in a state of full physiological activity, one of their functions being to prevent the bacteria normally inhabiting the lumen of the respiratory and intestinal tracts from penetrating into the body. A deficient supply of vitamin A impairs the functional activity of the mucous membranes with the result that the bacteria are allowed to penetrate into the mucous membranes to proliferate there and to produce a toxæmia. From there they may eventually penetrate into the blood stream, and after having exhausted the humoral defences of the body, set up metastatic infections elsewhere.

An adequate supply of vitamin A is therefore a powerful physiological prophylactic against infections entering by the mucous membranes. It may possibly be of therapeutic value also in the treatment of some chronic intestinal toxæmias and of chronic infections of the respiratory and intestinal tracts, especially where these have been associated with defective nutrition. But that has yet to be demonstrated. There is no evidence, however, that vitamin A can cure infections once the barrier of the mucous membranes has been passed or that it can prevent or cure those infections which enter by the blood stream or by the subcutaneous tissues, as they do, for instance, in puerperal septicæmia. To call vitamin A an "anti-infective" vitamin is as much a misnomer as to call it a "growth promoting" vitamin. It seems unwise to exaggerate the extent of its real action and to make claims for it which cannot be realised. Disappointment is sure to follow. This will discredit the more limited though really effective action of vitamin A of

ANGINA PECTORIS AND CORONARY DISEASE.

To the Editor of THE LANCET.

SIR,—I am grateful to Dr. Poulton for referring me to his Oliver-Sharpey lectures on visceral pain. I had forgotten that in them he dealt with angina pectoris, and I must apologise for criticising his theory of myocardial distension without reference to the whole of the evidence he adduces in its favour. I have now re-read his lectures carefully and with great interest.

In his letter he protests against my regarding myocardial anoxæmia as an alternate explanation to myocardial exhaustion or myocardial distension. I am unrepentant. It is only a half-truth to say that the heart muscle is exhausted in angina pectoris, but to say that the heart muscle is distended is to go far beyond the available evidence. The theory of myocardial anoxæmia offers a half-way house where the cautious student may, for the moment, rest, satisfied that he will not have to retrace his steps. I am, of course, aware that this theory provides no explanation of the actual pain mechanism, and I made no attempt to deal with this part of the subject in my article.

As for my objections (a) and (b). Dr. Poulton himself characterises the evidence in support of his theory as scanty and I have no desire to use a harsher adjective. I think that all the facts he gives in his lectures might be used to support a contrary theory. Take, for example, the case of acute left-sided failure which he and Dr. Campbell so ingeniously investigated. Dr. Poulton believes that the pain was due to stretching of the pain nerve-endings in the right side of the heart. It might equally well have been caused by raised tension in the left side of the heart owing to an inadequate relaxation of the muscle in spite of increased diastolic pressure or by raised tension in the right side due to exaggerated muscular contraction again with increased diastolic pressure. My own opinion (for what it is worth) is that the pain of angina is produced by an anoxæmia of the myocardium which results both in failure of the muscle-fibres to relax adequately and in exaggerated muscular contractions with consequent raised tension and stimulation of pain nerve-endings. Dr. Poulton's theory is, I believe, the correct one for other types of cardiac pain. It is interesting to observe that all these three factors—anoxæmia, imperfect relaxation (retraction), and exaggerated contractions are present in uterine pain in labour, but not in the painless contractions of pregnancy.

Objection (c). I was not aware of Dr. Anrep's work on amyl nitrite; I hope he will publish it so that it may be confirmed by the pharmacologists. It is unfortunate that neither Dr. Poulton nor I can be certain either of the clinical or of the experimental action of nitrite; if we could it would settle these problems.

Objection (d). Here Dr. Poulton misunderstands me, and probably it is my fault. When I wrote that there is no condition occurring in the stomach or œsophagus which is at all comparable to angina pectoris I was thinking only of primary angina pectoris, and I meant that there is no known syndrome in these organs in which there is clinically pain referred to the appropriate segments and pathologically, decay of the arteries supplying them. Now when one considers the difference in function between the heart and the gut would one expect to find such a syndrome.

The viscerosensory reflex which, after Mackenzie, is best called secondary angina, may be initiated in

the higher level of the brain, as in the neurasthenic, or in the lower level of the brain, as in the so-called "vaso-vagal" attacks which occasionally occur in epilepsy, or in any organ in which there is a septic or toxic factor, as in Mackenzie's well-known case of bladder abscess, or in the œsophagus and stomach as Dr. Verdon has stressed, but in none of these organs is there a condition occurring which is at all comparable to the condition of the heart in primary angina pectoris. As Dr. Poulton says, it is often difficult enough to differentiate between primary and secondary angina pectoris, but the attempt must be made both clinically and in a discussion such as this.

I am, Sir, yours faithfully,

Derby, May 10th, 1930.

DOUGLAS HUBBLE.

COMPLEMENT FIXATION IN GONORRHOEA.

To the Editor of THE LANCET.

SIR,—May I be permitted to break a lance with Dr. A. Knyvett Gordon? In your issue of May 3rd (p. 965) he is reported as saying to the Medico-Legal Society that: "The complement-fixation test . . . gave a positive result in only 40 per cent. of cases of true gonorrhœa, and sometimes a false 'positive' was obtained. He did not now perform this test." Other workers have found a much higher percentage in all but early cases, varying from 60 per cent. in uncomplicated cases to nearly 90 in those with complications. Moreover, in a series of 5000 tests Dr. J. O. Oliver and I found the percentage of false positives as low as 0.6. It seems a pity to decry a reaction which may frequently be very helpful and which appears to be highly specific.

I am, Sir, yours faithfully,

T. E. OSMOND.

St. Thomas's Hospital, S.E., May 10th, 1930.

UNDULANT FEVERS OF DOUBTFUL ORIGIN.

To the Editor of THE LANCET.

SIR,—May I warn my colleagues in general practice of the prevalence of a type of fever which must be new to most of us? It has been discussed in your columns and the Ministry of Health has issued an excellent report by Dr. Dalrymple Champneys, but I find that its existence is generally not known to those whose attention does not chance to have been directed to it by some fortunate accident—in my own case by the conversation of a friend in the veterinary profession. This fever, which is due to an organism known as *Bacillus abortus*, has long been known as causing epidemic abortion in cattle, pigs, and other livestock. Epidemic abortion is not a convenient term for use with our patients but we may take advantage of the close relationship between *B. abortus* and *M. melitensis* to call our cases undulant fever.

I have one such case under my care at the moment and the blood agglutinates *B. abortus* in 1 in 10,240 (Dr. A. B. Rosher). On making inquiries I discovered three other cases under the care of colleagues, who kindly permitted me to see them. Their blood reactions were negative, but they were clinically undulant fever. As I am informed that cattle from which the organism can be recovered by no means always give the reaction, these negative laboratory results do not worry me. I have heard of two other cases not in this district and have seen the chart of one. It was typical. I have also called to mind (which I should have done sooner) two cases in this district in which agglutination was positive. One of these was fatal. These two cases occurred about a year ago. It seems fair to describe this disease as prevalent.

The onset of the attack is rather acute and is often accompanied by profuse sweating—a good diagnostic point. Fever ranges to about 102° or 103° F. and after a week or so tends to rule somewhat lower.

There follows another short period of higher temperatures, and this alternation continues with a steady downward trend for as many as eight or nine weeks or more. During this time the possibility of typhoid, paratyphoid, or tuberculosis, inevitably occurs to the mind.

In the cases which I have seen there was no common milk-supply nor (as is sometimes the case) any history of contact with infected pigs or cattle. The disease is rampant amongst cattle all over the country, but its restricted prevalence amongst human beings suggests that milk is not the vehicle of infection.

I am, Sir, yours faithfully,

Sevenoaks, Kent, May 15th, 1930.

GORDON WARD.

Obituary.

CHARLES EDWARD WALLACE BELL,

M.R.C.S. ENG.

THE death of Mr. C. E. Bell on May 13th, at the age of 77, removes a man who played a prominent part in the medical life of Exeter for many years. The youngest son of the Rev. F. Bell, an honorary canon of Truro Cathedral, he began his professional career in Exeter in 1871 as a pupil of Dr. John Woodman at the Royal Devon and Exeter Hospital. In 1876 he was appointed honorary surgeon to the Exeter Dispensary, and ten years later was elected consulting surgeon to that institution. He was its president in 1927, and a member of its committee at the time of his death. In 1888 he was elected surgeon to the Royal Devon and Exeter Hospital, and retired from the active surgical staff in 1916, being then appointed consulting surgeon and an honorary life governor in appreciation of his long service. At the time of his resignation from the active staff he was chairman of the hospital's nursing committee, and remained in that office till 1929. Of other public work it may be mentioned that for many years he was surgeon to the Exeter city police force. During the last part of his life, when he had retired from active practice, the hospital remained Mr. Bell's paramount interest, and he was a scrupulously regular attendant at the weekly board meetings—apart from his work on the nursing committee, in which he took an especial pride. Strong in his convictions, and throughout his lifetime outspoken and critical in his views, he certainly did not court popularity; and though jealous of the prestige of his profession and able to speak with a weight of long experience behind him in matters of medical policy, in his later years he sometimes found himself opposed to the views of his younger colleagues. He therefore tended to become a somewhat solitary figure, especially as Mrs. Bell died many years before him.

Bell was well known locally as a violinist, and music was his chief hobby. His wife was an accomplished pianist and violinist, and during her lifetime many off-duty hours were devoted almost daily to chamber music at home with their friends. For years, moreover, he was the able leader of the first violins in the Western Counties Oratorio, and other local musical societies. He had been in his younger days a good cricketer and Association footballer, and up to the last year or so made a point of supporting Exeter cricket and Association football clubs, and of attending their matches. He had no children.

THE LATE PROF. YAMAGIWA.

Dr. W. Cramer sends the following notes concerning the late Prof. Yamagiwa, whose death we recorded in an annotation last week:—"Yamagiwa's first publications dealt with problems of general pathology, such as inflammation and regeneration of tendons. He also published in 1900 a paper on beri-beri, *Beiträge zur Kenntnis der Kake*, *Virch. Arch.*, vol. clvi.

After a detailed description of the pathological changes found in patients who had died from the disease, he discussed its aetiology. He showed that the condition is not contagious, and cannot be due to a pathogenic organism. He came to the conclusion that it is due to poisoning by food, and that it can be prevented by altering the diet. The article of diet which he incriminated was "bad rice." The cancer problem then attracted his attention, and in 1905 he published a monograph in Japanese entitled the *Histogenesis and Pathogenesis of Cancer of the Stomach*. This was followed in 1911 by a paper on Primary Carcinoma of the Liver, *Virch. Arch.*, vol. cxi., and at a meeting of the Japanese Pathological Society he communicated a paper on the Influence of Heredity on the Incidence of Cancer in Man. In his monograph on gastric cancer he established the following principles: 'For the development of carcinoma, each organ has its own history and its own causation. . . . There are no inborn cancer cells and no specific cancer germs.' In 1915 he published, with his assistant Ichikawa, his classical paper entitled *Experimentelle Studien über die Pathogenese der Epithelialgeschwülste*, *Gewidmet unserem, grossen, lange verwiegten, Lehrer, Rudolf Virchow, aus Dankbarkeit*.

"When, in 1918, two American authors questioned the true malignant nature of the tumours produced by painting with tar over a long period, without having themselves repeated the experiments, Yamagiwa simply replied in a later paper: 'If they do not believe our results they should apply tar to the ear of rabbits with the same patience as we have done, in experiments lasting for months and even years.' The results were soon confirmed by Tsutsui, a pupil of Yamagiwa, who produced cancer in the skin of mice by tar-painting, and they were established as an experimental method by Fibiger, and by Murray and Woglom, who carried out experiments on a large scale. The advantage of the method discovered by Yamagiwa over Fibiger's experiment consisted in the fact that cancer could now be produced in an accessible site, and that all the stages of carcinogenesis could be studied with relative ease. Yamagiwa himself continued his investigations and succeeded in producing in rabbits cancer of the mamma by the injection of tar suspensions into the mammary region.

"It is impossible to over-estimate the importance of Yamagiwa's discovery for the study of cancer. It is not merely that it placed the doctrine of chronic irritation as a cause of cancer on a sound experimental basis, while before it had merely been one of many different theories advanced as an explanation. It also provided cancer research with a method which has given a new impetus to the investigation of the disease, and which, even within the few years which have elapsed since it has been adopted, has enormously increased our knowledge of some of the most obscure and baffling problems of cancer."

FOOTBALL COMPETITIONS FOR HOSPITALS.—The Glasgow Charity Football Club competition this year produced £1656, which has been distributed among local hospitals and similar institutions. Since the competition was begun in 1877 it has provided over £100,000 for these purposes.

PROGRESS OF CONTRIBUTORY FUNDS.—At the annual meeting at Southport last week in connexion with the London, Midland and Scottish Railway Hospital Fund it was reported that the contributions from the members of the staff, numbering approximately 240,000, amounted last year to £141,317, as compared with £100,610 in 1928; the increase was mainly due to the higher rate of the weekly contributions. The total receipts were £189,410. The amount paid to hospitals and kindred institutions was £120,405; railway convalescent homes received £21,801. The latest figures show that more than 86 per cent. of the gas-workers in South London are members of the Hospital Saving Association. The South Metropolitan Gas Company's group, which has 709 contributors, is one of the largest subscribing units in the country. Last year the contributory scheme at the Hampshire County Hospital increased its membership by 2000 to 32,000, its branches to 293, and its income to a little over £11,000.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

MENTAL TREATMENT BILL.

REPORTED TO THE HOUSE OF COMMONS AND PASSED.

THE House resumed, on Wednesday, May 14th, consideration of the Mental Treatment Bill as amended in the Standing Committee.

Voluntary Patients.

Clause 2 deals with the reception, death, and discharge of voluntary patients. Subsection (3) provides that:—

If any person received as aforesaid becomes at any time incapable of expressing himself as willing or unwilling to continue to receive treatment, he shall not thereafter be retained as a voluntary patient for a longer period than one month, and shall, if he has not been previously discharged, be discharged on the expiration of one month from the date on which he became incapable of so expressing himself, unless in the meantime he has again become capable of so expressing himself, or steps have been taken to deal with him either under the principal Act as a person of unsound mind or under Section 5 of this Act as a person who is likely to benefit by temporary treatment.

Colonel WEDGWOOD moved to omit all the words after the words "so expressing himself." He said that this amendment raised the whole question of Clause 5 which provided for temporary treatment without certification. Under Clause 5 doctors would have an opportunity of getting their patients into an asylum without feeling that they were condemning them to long segregation. Therefore doctors being merely human beings would naturally select the more humane way, and gradually there would be more and more people sent to mental hospitals, not because they were certified in a way which would involve risks to the doctors, but because they entered first as voluntary patients and then became temporary patients. He wanted to prevent people who entered as voluntary patients being liable on that account to be suddenly converted into temporary patients. If the Government really had the interests of patients at heart they should accept the amendment.

Mr. ERNEST WINTERTON seconded the amendment.

After further debate,

Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that they were dealing with the case of a patient who feared that he was losing his reason, and then unfortunately actually did so. He then became either incapable of expressing himself, or he became insane. Such cases not improbably might arise. Very often persons who were subject to mental disease knew quite well that they were in danger, and a patient in that condition who was told that voluntary treatment might avert the attack entered as a voluntary patient. But his hopes might not be realised, and he might become either incapable of volition or insane but with volition, though of a misguided nature. Such a person could not remain as a voluntary patient, for the whole essence of the Bill was that voluntary treatment should only be given to those who expressed a wish for it. Something must be done for that kind of patient. In his own interests, and in the interests of the community, he must have care appropriate to his condition. The person in charge was directed in that case to take steps so that the patient might be dealt with under Clause 5. If certified the person would have the usual safeguards of the Lunacy Act, the two doctors and the magistrate, while if he came under Clause 5 the opinions of two doctors were necessary, the relatives had to be informed, and there would be all the safeguards provided in Clause 5 in the case where a person became incapable of volition while a voluntary patient. This amendment was based on a complete misunderstanding of the Bill.

Dr. VERNON DAVIES said that in the majority of these cases the patients were taken away by the relatives, so that there was no possibility of a patient being illegally detained beyond a day or two. The amendment was not only unnecessary but it was dangerous, and he was certain that the Government would not accept it.

Dr. MORRIS-JONES said that this matter had been very carefully examined by the Royal Commission, and he thought that Colonel Wedgwood was unduly alarmed about the clause. Investigations had proved that there had been no illegal detentions. Safeguards were provided, and there was no other alternative but to adopt the clause as it stood.

After further debate the amendment was rejected by 241 votes to 106.

Minor Amendments Accepted.

On Clause 4 (power to lodge relatives and friends of patients),

Mr. GREENWOOD (Minister of Health) moved an amendment providing that relatives or friends of patients lodged in a hospital or licensed house should not be reckoned as patients if they were lodged in a part of the premises not permitted to be used for the accommodation of patients.

The amendment was agreed to.

On Clause 5 (provision for temporary treatment without certification of certain persons),

Colonel WEDGWOOD moved an addition to the clause providing that the Board of Control should upon the signed request of any person who considered himself to be unjustly detained under an application, recommendation, or order, furnish him, or his authorised representative, with a copy of the document.

Mr. GREENWOOD accepted the amendment, which was agreed to.

The Pauper Stigma.

Mr. WINTERTON moved to insert at the end of Subsection (14) the following proviso:—

(a) Section 6 of the Lunacy Act, 1890, shall apply to all pauper patients;

(b) any person appointed by the patient to be present at the consideration of the petition under Subsection (3) of Section 6 of the Lunacy Act, 1890, shall have the right to make representations on behalf of the patient.

He said the purpose of the amendment was to give rate-aided patients exactly the same privileges as were enjoyed by private patients.

Mr. C. WILLIAMS seconded the amendment.

Mr. GREENWOOD said he had explained on the second reading that it was not possible in this Bill to do what was asked in this amendment, because he wanted to achieve the maximum of accomplishment with the minimum of controversy. He trembled to think what he would have had to face if he had done otherwise. He would remind Mr. Winterton that in this Bill they were getting rid of the pauper stigma. Was that nothing? The next big thing which they were doing was to make it possible for people who had hitherto had no other form of treatment than that which followed certification to get the same treatment which the well-to-do were receiving. He was not opposed to the amendment, but his objection to it was that if it were adopted, with all the necessary consequential amendments, they would never get the Bill through.

The amendment was withdrawn.

Board of Control: Unpaid Commissioners.

On Clause 11 (Reorganisation of the Board of Control), Lieut.-Colonel FREMANTLE moved an amendment to provide that on the Board there should be two unpaid Commissioners of whom one should be a layman and the other a laywoman. He said that the unpaid Commissioners on the Board at the present moment were reckoned to be doing good work. He thought it was desirable that there should be still an unpaid unofficial element in order to bring the point of view of the ordinary man and woman into the working of the Board. Public confidence was far more likely to be given to the Board if there were unpaid members on it than if it were simply a body of paid officials.

Dr. VERNON DAVIES, in seconding the amendment, said that the addition of unpaid members would increase the status of the Board of Control and give a measure of confidence to the public that the lunacy laws were being administered in a fair and reasonable manner.

Mr. GREENWOOD said he could not accept the amendment. He was still of the opinion that the principle of appointing lay commissioners was foreign to the spirit of the Royal Commission's report. No one would persuade him that they would have an effective machine if it was composed partly of volunteers. There was no other department of the State to-day which placed heavy executive and administrative responsibilities on an honorary staff. Why then should it be done with regard to the Board of Control? This amendment, he believed, would be injurious to the interests of mental treatment, and he asked the House to reject it.

After further debate the amendment was rejected by 163 votes to 63.

Two Senior Commissioners to be Medical.

Lieut.-Colonel FREMANTLE moved an amendment to provide that two of the senior commissioners, other than the chairman, should be medical commissioners. He said the object of the amendment was to carry out a further proposal in the report of the Royal Commission. Looking at the work of the Board of Control it was quite clear that it was mainly legal and medical. So much was this the

case that the Royal Commission said it might be desirable to appoint two medical commissioners, one having experience of institutional administration, and the other possessing special scientific knowledge. They could not as a rule get one medical man who could fulfil both these qualifications. Dr. VERNON DAVIES seconded the amendment. Mr. GREENWOOD accepted the amendment, which was agreed to.

Status of Junior Commissioners.

Lieut.-Colonel FREMANTLE moved an amendment to provide that the paid commissioners, other than senior commissioners, should be appointed by His Majesty on the recommendation of the Board of Control. He said that this matter might be of only minor importance, but was it right that they should give an inferior status to those commissioners who were going to represent the Board of Control in inspecting mental institutions? They would be called upon to deal with men in the highest position in the profession who were the heads of these institutions, and it would make all the difference in the world if the visiting commissioners had the highest possible status.

Mr. WOMERLEY seconded the amendment.

Miss LAWRENCE contended that it was right that they should mark a difference in status between the senior and junior commissioners. It was not generally the practice to appoint the junior officers in the civil service on the appointment of His Majesty. That was a form reserved for the very highest classes. It was therefore quite unusual and quite unnecessary that the officials who acted in the main as inspectors of the Board of Control should have this special mark of appointment by the Crown.

The amendment was negatived.

Miss LAWRENCE moved an amendment to provide that the junior commissioners should include women as well as men.

The amendment was agreed to.

Proceedings against Doctors.

On Clause 16 (which amends Section 330 of the principal Act),

Miss LAWRENCE moved the omission of the second subsection which deals with proceedings against doctors. She moved the substitution of the following subsections:—

(2) No proceedings, civil or criminal, shall be brought against any person in any court in respect of any such matter as is mentioned in the last preceding subsection, without the leave of the High Court, and leave shall not be given unless the court is satisfied that there is substantial ground for the contention that the person, against whom it is sought to bring the proceedings, has acted in bad faith or without reasonable care. (3) Notice of any application under the last preceding subsection shall be given to the person against whom it is sought to bring the proceedings, and that person shall be entitled to be heard against the application. (4) Where on an application under this section leave is given to bring any proceeding, and the proceedings are commenced within four weeks after the date on which leave was so given, the proceedings shall for the purposes of the Public Authorities Protection Act, 1893, be deemed to have been commenced on the date on which notice of the application was given to the person against whom the proceedings are to be brought.

She said it would be remembered that the Royal Commission pointed out that the protection allowed by law to medical men against whom proceedings were taken was not sufficient, and that many doctors would not sign certificates on account of the difficulties in which they might be landed. The Government resolved to carry out the recommendations of the Royal Commission, and inserted a form of words which was discussed in Committee. As a result of that discussion the Minister of Health promised to meet some of the difficulties and objections raised. The Government had very considerably amended the original clause which provided that a doctor was obliged to apply to the judge for a stay of proceedings. In this new clause proceedings might be conducted in a more appropriate way. Before an action began a judge had to be satisfied that there was substantial ground for it. Many people who had undergone treatment had been discharged partially cured, and they were unfortunately very likely to take legal proceedings. Dr. Hastings in the second reading discussion had said that there were two classes of insane people, and one of them included those people who never believed anyone, and who bore a grudge against everyone. It was quite likely that actions against doctors, and those actions against doctors, and the Government had provided that leave must be given for the initiation of such proceedings against a medical practitioner. She hoped that in its new form the clause would meet the apprehensions expressed by hon. Members.

The amendment was agreed to.

Conflicting Views.

On the motion for the third reading,

Sir B. MERRIMAN said it was an outrage that the third reading of this Bill should be taken at 4 o'clock in the

morning. He did not know whether the House realised that they had passed a clause which almost as an isolated instance deprived a whole class of persons of their right to bring an action.

Dr. DAVIES said he would like to corroborate the remarks of Sir B. Merriman. They were passing a Bill that would affect thousands of people, but they were passing it with a minimum of discussion and a maximum of forced closure. They had not been able to do justice either to themselves or to the people whom they represented. There were many provisions in the Bill which he was perfectly certain would not act as the House wanted them to act. The Bill was going to be detrimental to the treatment of mental disease. It would prevent some people submitting themselves for treatment as early as they should do. The obstinacy of the Minister of Health in refusing to accept changes with regard to the Board of Control would also have a detrimental effect. The responsibility was upon every Member who had forced this Bill through without discussion and without regard for the advice of men who knew what they were talking about. The Labour party jeered at the medical profession, and imputed to them unworthy motives. They did not recognise that the health of the country was in the hands of the medical profession, and that public opinion regarding medical men was not improved by constant ill-informed criticism.

Mr. WINTERTON said of all the people who had the right to complain surely the medical profession had the least. This Bill would probably have never seen the light except for the demand of the medical profession that they should be relieved of certain obligations which most other professions were willing to accept. If he felt that the patients who would come for treatment under this Bill were as secure as the doctors, he would feel a great deal happier.

Dr. MORRIS-JONES said he thought this Bill was a very excellent Bill, and he congratulated the Minister of Health on getting it through. It was a great charter for the poor, who for the first time were given as good a chance as the rich. He could not agree with Mr. Winterton in regard to the privileges accorded to the medical profession. He (Dr. Morris-Jones) emphatically denied that there was anything in the Bill that conferred any privileges on the medical profession.

The Bill was read the third time and passed.

HOUSE OF LORDS.

WORKMEN'S COMPENSATION (SILICOSIS) BILL.

The Workmen's Compensation (Silicosis) Bill was read the third time.

HOUSE OF COMMONS.

WEDNESDAY, MAY 14TH.

Leprosy in the Sudan.

Lieut.-Colonel FREMANTLE asked the Secretary of State for Foreign Affairs if his attention had been drawn to a recent report by the medical secretary of the British Empire Leprosy Relief Association on his visit to the Sudan to the effect that advanced and infectious cases of leprosy were prevalent, that the disease was spreading into British East African territories from the Belgian Congo, that at Cairo as many as 23 per cent. of contacts acquired the disease, and that further spread of the disease could only be arrested by active and enthusiastic development of technical education and administrative action with the concurrence of native opinion, which was well disposed to it, by both missionary and Government agencies under skilled supervision; and what action he proposed to take in the matter.—Mr. DALTON (Under Secretary for Foreign Affairs) replied:—No, Sir. I have not as yet seen a copy of the report to which the hon. Member refers. I will, however, draw the attention of the Government of the Sudan to it. I understand that Dr. Cochrane, secretary of the British Empire Leprosy Relief Association, recently visited the leper colonies at Wau, Temburu, and Yambio, and discussed the position with the officials of the Sudan Government.

THURSDAY, MAY 15TH.

Miners and Fibrosis of the Lungs.

Mr. HOPKIN asked the Home Secretary if his attention had been drawn to the work done at the Beck Laboratory, Swansea, in the investigation of the causes of fibrosis of the lungs of miners in the anthracite district; and, in view of such work, was he prepared to extend this work, so that the staff might give more time to research work in this matter.—Mr. CLYNES replied: I understand that the work

 Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Med. and Surg. Regs. Each £100.
 General Lying-in Hospital, York-road, Lambeth, S.E.—Res. M.O. At rate of £100.
 Gloucestershire Royal Infirmary and Eye Institution.—H.P. and H.S. At rate of £135 and £100 respectively.
 Great Yarmouth General Hospital.—H.S. £125.
 Guildford, Royal Surrey County Hospital.—Res. Med. and Surg. O. and Reg. £250.
 Halifax Royal Infirmary.—3rd H.S. At rate of £125.
 Hampstead Council of Social Welfare, 27, Heath-street, N.W.—Two M.O.'s.
 Hertford County Hospital.—H.P. At rate of £150.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Psychiatrist. Two Med. Regs. Also Clin. Path.
 Hospital for Sick Children, Great Ormond-street, W.C.—H.S. Also H.P. Each at rate of £100.
 Hull Royal Infirmary.—H.S. At rate of £150.
 Islington Dispensary, 303, Upper-street, N.—Res. M.O. £220.
 Kent Education Committee.—School Medical Inspector. £600.
 Also Dental Surgeon. £550.
 King's College Hospital, Denmark Hill, S.E.—Jun. Urological Surgeon.
 L.C.C. Administrative County of London.—Med. Supt. £1000.
 Venereal Diseases Clinic: Chief Asst. M.O. £600. Two Jun. Asst. M.O.'s. Each £350. Hospital Service: Asst. M.O.'s. £300-£400.
 Leeds Hospital for Women.—H.S. At rate of £50.
 Liverpool, Mill-road Infirmary.—Res. Asst. M.O. £200.
 Liverpool School of Tropical Medicine, Pembroke-place.—Research Asst. £400.
 Liverpool, Royal Children's Hospital.—Hon. Anæsthetist.
 London Hospital, E.—Cardiographic Dept. Paterson Research Scholar. £400.
 London Jewish Hospital, Stepney Green, E.—Cas. O. At rate of £150.
 London Lock Hospital, 91, Dean-street, W.—Hon. Surgeon to Out-patients.
 London University, Chair of Physiology.—£1000.
 Manchester, Crumpsall Hospital.—Radiologist. £500.
 Manchester Northern Hospital for Women and Children, Park-rd., Cheam, Hill-road.—Sen. H.S. Also Jun. H.S. £130 and £100 respectively.
 Manchester Royal Children's Hospital.—Sen. M.O. to Out-patients. £300. Asst. S. £50.
 Manchester Royal Infirmary.—H.P. and H.S. Each £200.
 Manor House Hospital, Golders Green.—H.S. £200.
 Margate and District New General Hospital.—Res. M.O. £125.
 Metropolitan Ear, Nose and Throat Hospital, Fiteroy-square, W.—Clin. Asst.
 Miller General Hospital, Greenwich-road, S.E.—Pathologist. £600. Out-patient Officer. At rate of £150. H.P. and H.S. Each at rate of £125.
 National Hospital, Queen-square, W.C.—Jun. Reg. £200. Also Asst. Phys.
 Newcastle-on-Tyne, Royal Victoria Infirmary.—Hon. Asst. to Electrical and Massage Depts.
 Northampton General Hospital.—Asst. H.S. At rate of £150.
 Norwich, Norfolk and Norwich Hospital.—H.S. £120.
 Nottingham General Hospital.—2nd Cas. O. At rate of £150.
 Plymouth, City of.—Deputy M.O.H. £750.
 Plymouth City Hospital.—Res. Med. Supt. £1000.
 Prince of Wales's General Hospital, Tottenham, N.—Hon. Surg. Reg.
 Princess Louise Kensington Hospital for Children, St. Quintin-avenue, N. Kensington, W.—Almoner.
 Queen's Hospital for Children, Hackney-road, E.—H.P. Also Cas. O. Each at rate of £100.
 Rotherham County Borough.—Asst. M.O.H., &c. £700.

Rotherham Hospital.—Sen. H.S. £200.
Royal Free Hospital, Gray's Inn-road, W.C.—H.P.'s and H.S.'s to Special Duty. Obst. H.S. £150. Also Dietary and Obstet. Asst. £100. Res. Anaesthetist to Gynaecological Obstetric Unit.
Royal National Orthopaedic Hospital, 41, Portland-street, W.—Hon. Anaesthetist.
St. Bartholomew's Hospital, E.C.—Physician.
St. Mary's Hospital, W.—Surgical Registrar. £200.
Saint Pancras Dispensary, 39, Oakley-street, N.W.—Res. M.O. £185.
St. Thomas's Hospital.—Physician. Also Physician to Out-Patients. Dent. Also Asst. Dental S. M.O. £100.
Salford Royal Hospital.—H.P. Also Cas. H.S. Each at rate of £125.
Salford, Lancs., Hope Hospital.—Asst. M.O. At rate of £250.
Salford General Infirmary.—Two H.S.'s. £150.
Sheffield Children's Hospital.—3rd Res. M.O. £100.
Sheffield, Jessop Hospital.—Res. M.O. £175.
Sheffield Royal Hospital.—Res. Anaesthetist. At rate of £80.
Sheffield Royal Infirmary.—H.S. £50.
Southampton, Royal South Hants and Southampton Hospital.—Asst. H.S. and Cas. O. Each £150.
South-Eastern Hospital for Children, Sydenham, S.E.—Asst. and Res. M.O.'s. At rate of £100 and £75 respectively.
Southern Rhodesia Medical Service.—3 Asst. and Relieving Government M.O.'s. Each £200.
Sunderland Royal Infirmary.—Hon. Phys. £500.
Swansea General and Eye Hospital.—H.S. Cas. O. Also H.P. Each at rate of £150.
Talgarth, Breconshire, South Wales Sanatorium.—Asst. Res. M.O. £200.
Torquay, Torbay Hospital.—Physician for V.D. Clinic. 2 gns. per session.
Warwick, Warwickshire King Edward VII. Memorial Sanatorium, Herford Hill.—Med. Sup. £800.
West Hospital, Grove-road, Baltham, S.W.—Jun. Res. M.O. £150.
West London Hospital, Hammersmith, W.—Hon. Surg. H.P., H.S., Aural and Ophth. H.S. Also Res. Asst. Cas. O. Each at rate of £100.
Weston-super-Mare General Hospital.—Res. H.S. £130.
Weymouth and District General Hospital.—H.S. £180.
Winchester, Royal Hampshire County Hospital.—Sen. Res. M.O. £200. H.P. and H.S. Each £150.
Widmersley, 27th Hedley Hospital for Crippled Children.—Res. M.O. At rate of £150.
Wigan Infirmary.—3rd. H.S. At rate of £150.
Willesden General Hospital, N.W.—H.P. £100.

Births, Marriages, and Deaths.

BIRTHS.

COX.—On Saturday, May 17th, to Dr. and Mrs. Chare Cox, of 137, Hornsey-lane, N.6, the gift of a daughter.
HEARLE.—On May 13th, at Liskeard, Cornwall, the wife of Dr. H. N. Hearle, of a daughter.

DEATHS.

BALDOCK.—On May 16th, at Earl's Court-road, Alfred Baldock, M.B., aged 80 years.
BELL.—On May 13th, at Southernhay West, Exeter, Charles Edward Bell, B.Sc., L.R.C.P., aged 71.
LUND.—On May 12th, at Germiston, South Africa, Theodor Lund, M.D.
O'GORMAN.—On May 11th, at a nursing home, Dublin, Colonel C. J. O'Gorman, D.S.O., R.A.M.C., of Warminster, Gloucestershire.
RICHARDS.—On May 14th, at his residence, St. Thomas-street, Winchester, Thomas Dechnus Richards, M.R.C.S.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

ESSEX PUBLIC MEDICAL SERVICE.—The (sixth) annual report for the year 1929 shows that the service increases in numbers and in financial stability. On the last day of the year, after deducting cancellations, removals, and deaths, there were 6573 persons to whom payments were being made, representing 19,750 subscribers (7085 adults and 8768 children). Owing to death or retirement eight doctors were taken off the books and eight new members were admitted, leaving 176 names on the books at the end of the year (127 on the active and 49 on the honorary list).

The total amount paid to doctors shows an increase of £646 over that paid in 1928. The average amount paid per person works out at 10s. 1d. The three largest totals collected for individual doctors in each class of district were: metropolitan, £384, £287, £250; urban, £760, £661, £471; semi-rural, £247, £237, £126; rural, £253, £161, £105. Collectors who work on a 16 per cent. commission basis have performed their duties with very little friction; arrears at the end of a quarter average under one-half per cent. of their books, the greater portion of which is collected by instalments in the following quarter. Assets of the service exceed liabilities by £163; the balance-sheet for 1928 showed an excess of liabilities to the extent of £132—an improvement of £285. It is now proposed to pay off the loan from the B.M.A. of £200; the balance of £50 on doctors' loan; and a grant of £50 to the benevolent fund, which supplies bandages, belts, stockings, and other appliances.

Notes, Comments, and Abstracts.

COLLECTION AND DISPOSAL OF REFUSE.

A CHADWICK public lecture was given at the Royal Sanitary Institute and Parkes Museum on May 15th, by Mr. Edward Willis, borough engineer of Chiswick, and chairman of council of the Institute. Refuse, he said, was of three sorts—domestic, trade, and street refuse; originally everything was thrown into the streets where it remained until carted away as manure. The first real improvement was the provision of underground sewers to take the place of open gutters. House refuse which consists of night-soil, rags, ashes and food debris, varies in bulk and weight, in mining districts being three times the weight it is in a southern town, and in summer only half what it is in winter. Metal food-containers provide a problem unknown fifty years ago and empty bottles used for beer, milk and mineral waters are liable to injure employees unless great care is taken. Of all these the debris of food is the most important, for it breeds flies unless collected at least once a week. Next comes trade refuse—cotton waste, rags, grease, carbide waste, paper, wood chips, fish offal—for whose removal the trader should pay. Lastly there is the street refuse, greatly reduced now that horses are 60 per cent. fewer and pneumatic tyres wear less dust off the roads, which are besides better made and surfaced. "But too much litter of paper is left on the streets," said Mr. Willis. "In Germany this is a punishable offence."

Collection of rubbish can only be made in the early part of the day in busy towns, but in residential suburbs throughout the morning. If the shoot (or dump) is within a mile, horse haulage is good; if it is at greater distances motor, rail, or barge transport is required. Refuse is best collected in dust-bins of municipal pattern, placed on the pavement by the occupier and emptied by a strong staff into a slowly passing motor which is covered, as in Westminster. Daily collection is an economy, and much more efficient.

Going on to speak of the disposal of rubbish, Mr. Willis said that dust-heaps were soon found to breed flies, crickets, and rats, and this led to the use of destructors. Town sewage sludge may be burned in these, and the clinker thus formed makes the better cement. Rubbish must be sorted before being put into destructor. There is the risk of bombs, live cartridges, &c., and tins have to be picked out and baled, after which they sell for perhaps 2s. a ton. Iron nails and wire are extracted by electro-magnets and sold separately. Fine dust, sifted out, is used for burning bricks, and in Southwark rubbish is "pulverised" to make manure.

"Controlled tipping" (as at Bradford and elsewhere) is satisfactory in certain places. A site which can be improved is covered to a reasonable depth with rubbish, and this is covered with nine inches of good vegetable soil. The temperature rises to 150° F., and in six months the refuse has become harmless and odourless. Suitable sites are needed, also proper soil and capable and zealous workmen. In the method of salvage, highly developed at Birmingham¹ and Marylebone, the driving principle is the proper utilisation of all waste material, just as in controlled tipping the object is to make the best of waste places.

In the course of his lecture Mr. Willis gave the following figures for the London cleansing services: Area, 117 square miles; population, 4,612,000; approximate cost, £2,200,000 per annum; averaged rate for public cleaning, 11d. in the £1; staff, 8500 persons; amount collected, 1,200,000 tons.

THE MANUFACTURE OF SULPHURIC ACID.

THE importance to chemical industry of an efficient manufacture of sulphuric acid lies in the fact that it is perhaps one of the most widely used of inorganic chemicals; besides being required for the production of artificial fertilisers, such as sulphate of ammonia and super phosphate of lime, it is employed in the manufacture of soda by the salt cake process, and thus in the manufacture of hydrochloric acid as well as in that of practically all other acids, both inorganic and organic; in addition it is employed as a sulphating, condensing, and oxidising agent in the manufacture of many organic chemicals. In view of these facts it is not surprising that the study of the underlying theory of the methods of production with a view to improvement of yield have received much attention, the results of which are incorporated in many bulky text-books. A volume recently published² is to be welcomed on the ground that it contains in small compass all that the ordinary student of applied chemistry needs in the first instance.

permanent relief." Here then was a new idea. The removal of a portion of the prostate was to relieve the obstruction; the bladder muscle would regain its functional activity, and the organ would empty itself naturally. This was to be no palliation or temporary relief such as was the best that other methods could offer, but permanent cure was aimed at. This was indeed flying in the face of authority!

Sir Henry Thompson was present, and a few minutes before had described the method of permanent suprapubic drainage which he had introduced as a new and improved method of treatment. His views on the uselessness of removing the obstruction were well known. It is interesting to see how he took it. I can imagine there was a tense moment when he rose at the end of the debate. He was "much interested in Mr. McGill's operation and gratified by its results." The procedure was a "fresh starting point" and he "should further enquire into it." But there was the spectre of the atonic bladder and he reiterated his well-known views on this subject. Possibly in earlier cases there was an opening for the procedure, but he said this "without endorsing the operation." McGill in reply spoke of the difficulty in removing more than "minute fragments" of the prostate. He agreed in part with Sir Henry Thompson about atony. "Doubtless Sir Henry Thompson was right in placing a limit of time after which the operation would prove useless as a result of the atony of the bladder contingent on the long-standing prostatic disease."

This was in November, 1887. In September, 1886,

about a year previously, Dr. W. T. Belfield,¹⁵ of Chicago, had published a short note on a case in which he performed suprapubic cystotomy for two large calculi in a case of enlarged prostate. He mentions rather casually that: "The patient was so collapsed that no attempt was made to remove the prostatic outgrowth which could have been accomplished without much difficulty." The following year he was more successful. At the Chicago Medical Society on Feb. 7th, 1887, Belfield¹⁶ showed a man, aged 73, who had been dependent on the catheter for a year. "Exploration of the bladder by a suprapubic incision revealed a solid prostatic outgrowth or middle lobe as large as a hazel nut. The pedicle was twisted off with forceps and the growth was removed. . . . The patient has since micturated freely without a catheter and can now almost completely empty his bladder." Another similar case followed in March, 1888. McGill¹⁷ was unaware at the time he published his first case that Belfield had performed this operation. In all his subsequent articles he fully acknowledges the priority of Belfield's case. "Before I conclude, it is right that I should state that Dr. Belfield, of Chicago, is, so far as I know, the surgeon who first performed the operation which I have been describing." This case detracts in no way from the importance of McGill's work. The operation which Belfield so courageously undertook was a sporadic effort which does not appear to have attracted much attention, and which alone would have had little influence on the general trend of surgical thought on the subject. The work of McGill was an organised campaign against the prevailing views and in favour of a bolder and a progressive policy of cure of the retention of urine caused by enlargement of the prostate.

McGill's conception of the anatomy of the condition which he proposed to attack was set out with admirable clearness in his writings. He recognises two parts of an enlarged prostate—namely, the part which lies within the bladder, having passed through the internal meatus, and the part which lies outside the bladder in the normal position of the gland. The former he terms the intravesical portion, the latter the rectal portion. He is quite clear as to what and where the seat of obstruction is. "Prostatic enlargements which give rise to urinary symptoms are intravesical and not rectal," and in none of his writings does he depart from this view.

"Retention is caused by a valve-like action of the intravesical prostate, the urethral orifice being closed more or less completely by the contraction of the bladder on its contents." Treatment of these conditions, to be effectual, should drain the bladder for a time and remove the cause of the obstruction. How is the obstructing portion of the prostate to be removed? His first three operations, from his own description, must have been rather rough-and-tumble affairs without any definite method. It is a piecemeal removal of the growth, partly by tearing with forceps and partly by cutting with scissors or with a strong cutting instrument designed for the purpose. "This is a tedious and not very elegant proceeding; it will, if the operation prove a useful one, probably be improved."

The following year he has got his operation all arranged, and at the Leeds post-graduate course

*A Meeting of the Clinical Society was held
on October 11th, 1887. Dr. Brandegee,
President, in the Chair.*

Present 69 members and 13 Visitors.

*The Minutes of the previous Meeting were read and
confirmed.*

Papers—

The following papers were read:

*Sir Henry Thompson:—Enormous prostate: vesical
calculi, free and encysted. Urine passed for
years by catheter, now by supra-pubic tube
rendering catheterism unnecessary. Patient
in excellent health.*

*(2) Mr A. J. McGill: Suprapubic prostatectomy,
with 3 cases in which the operation was
successfully performed for chronic prostatic
hypertrophy.*

*These papers were discussed by Mr Keith,
Mr Barwell, Mr Morris, Mr Silcott, Mr Bryant,
Mr Bennett, Mr Borlsey, & Mr Thos. Smith.*

Sir Henry Thompson

Mr McGill replied.

Living Speech

*Mr McGill read a paper on the
operation of prostatectomy.*

*Dr J. R. Fowler: Case of Aortic & Mitral disease
with, probably, adherent Pericardium.*

The Society then adjourned.

*W. T. Thomson-Walker
25. Nov. 1887*

Minutes of meeting of the Clinical Society of London, Nov. 11th, 1887, at which McGill's first cases of prostatectomy were presented and discussed.

describes it in detail. "The operation consists of two parts: (1) the opening of the bladder, and (2) the removal of the prostatic valve which prevents the egress of the urine." The removal of the prostatic valve interests us most. We know what the prostatic valve means to McGill. It is the intravesical enlargement of the prostate. A pedunculated middle lobe can obviously be removed with ease, its pedicle being divided with curved scissors. A sessile middle lobe can be removed in the same way, helping the scissors by tearing with forceps. A collar enlargement is removed with greater difficulty. "Care must be taken not to leave any part of the projecting valve untreated." Then he sees that the urethra is patent by passing his finger as far as the first joint into its canal. This is the only description McGill gave of the operation he performed. McGill, as he hoped, improved his technique. The tearing with forceps and cutting with scissors was replaced as far as possible by enucleation with the finger.

How much of the enlarged prostate did McGill remove? There has been a great deal of discussion on this subject, and most of it arose when Freyer, 11 years after McGill's death, claimed to have introduced a new operation by which he removed the whole of the prostate in its capsule. Let us take McGill as his own witness. McGill's descriptions of his operation make it quite clear that he intended to remove only the intravesical portion of the enlarged prostate. There was no object, holding the views he did, in removing anything more. The use of the word "prostatectomy" has led to some misunderstanding. McGill did not claim that prostatectomy meant the total removal of the enlarged gland. "If," he says, "an increased and more prolonged experience shows us that the removal of a portion of the prostate enables patients to dispense with the use of the catheter, we shall have gained a step in the treatment of this condition." Nor did McGill's colleagues and contemporaries regard the operation as anything but a partial removal of the enlarged prostate. His colleague, Mayo Robson, writes thus in support of McGill's operation: "To those who have not done the operation or seen it performed it would seem to be a very formidable matter to remove part of the prostate, but the operation is really simple and more easy than the description would lead one to suppose." At the meeting of the British Medical Association at Leeds in 1889, Regina'd Harrison, always a staunch supporter of McGill, opened the discussion on McGill's address as follows. "It appears to me that the suprapubic operation of partial prostatectomy will occupy a permanent place in the operating surgery of this organ." This seems clear enough, but lest the word "prostatectomy" should be misconstrued we have the comment of Belfield in 1890 on its use to guide us. "The obvious etymological inaccuracy of this term is still of slight moment since the real 'prostatectomy,' extirpation of the entire prostate, is as yet a rare experiment."

MCGILL'S CASES.

In 9 of the 12 cases that McGill published the material removed was very small and was likened to a walnut, a bean, or a small pea. McGill himself referred to the difficulty in getting any but "minute fragments." Two of the cases operated on were obviously malignant and he could not, if he would, have removed the prostate by the method he was using. Three of his cases, however, call for our careful attention—namely, Nos. 9, 18, and 22 in his list. In Case 9 he removed seven pieces of enlarged prostate, weighing altogether 2 oz. 30 grs. I do not think that any surgeon nowadays would consider he had removed the whole prostate if he dug out seven pieces; he would know quite well that he was shelling out separate adenomata, and McGill does not tell us that this went any further than the description of the operations given in the text. In Case 22 he removed the enlarged lateral lobes, the size of a small walnut. McGill employed the term "lateral lobes" in his writings to express the intra-

vesical projection of the lateral lobes, and there is no proof here that he went further than his description of his operation. Case 18 was a different type. "Portions of prostate weighing 2 oz. 40 grs. which surrounded the urethra laterally and below were enucleated in one piece." Here we have a specimen, the description of which resembles very closely that of many of the prostates removed by the methods at present in use. By the courtesy of Mr. J. F. Dobson I was permitted to inspect the historical specimens of enlarged prostate preserved in the museum of the Leeds University. It appears quite clear to me that, with one exception, the specimens of the McGill period represent portions of enlarged prostate and not the whole prostate in the sense that we use the term to-day. No. F.150 "remounted," which corresponds to No. 18 in McGill's list, is different from the others. Comparing it with a modern enucleated prostate, it resembles a medium-sized specimen of the "open variety." The lobes are continuous posteriorly and open along the anterior commissure. The surface is rough, but not more so than that of many of the modern enucleated prostates. If we are to speak of complete prostatectomy, this specimen should certainly rank as a complete enucleation of the prostate.

Did McGill set out knowingly in "a patient obviously dying if left alone" to do a new and more formidable operation than he had described in any of his writings? I think not. He was too good a surgeon to venture on this, and, moreover, he would have described the change in his procedure in the accompanying or subsequent papers. After a careful study of McGill's writings I do not see any evidence that he changed his view that the intravesical portion of the enlarged prostate was the cause of the obstruction he set out to treat and that the removal of the intravesical portion was what he aimed at and was all that was necessary. It has, I think, been claimed that McGill, recognising that he removed the whole of the extravascular portion of the enlarged prostate, adopted the operation of total enucleation of the prostate. Specimens removed subsequent to No. 18, and the absence of any such description in his subsequent writings, do not encourage us to accept this idea, and Mayo Robson's statement criticising Freyer's claims shows plainly that his colleagues did not consider that he removed the whole prostate. McGill died in 1890 at the early age of 40 years. It would be idle to speculate what developments would have been seen at that time had he lived to complete his work, or had his colleagues, with specimen No. 18 and McGill's example before them, had the faith to persevere.

THE PERINEAL OPERATION.

The first note of dissatisfaction with the operation described by McGill comes from Belfield¹⁶ in Chicago in November, 1890. He has reviewed the cases of suprapubic prostatectomy, which has been performed over 80 times, but he finds that "in nearly one-third of cases on record the radical operation failed to restore voluntary urination," and he harks back to the idea of bladder atony. But he detects another cause for the want of success in these cases. "The intravesical projection may in a given case constitute but a part of the prostatic obstruction," and "the discovery and removal of such outgrowths are not necessarily a complete operation." The prostatic urethra should be stretched and explored by the finger and the discovery of a hard mass or rigid ring should be the signal for perineal urethrotomy and incision or excision of the resisting tissue and thorough stretching. Kummel, of Hamburg, had the same experience of McGill's operation, and to overcome it he supplemented the suprapubic excision of tumours by sinking the cautery into the prostatic substance.

Gouley,¹⁷ of New York, was the first surgeon to lay down a formulated plan for perineal prostatectomy (1873). The intravesical enlargement of the prostate is first explored through an external perineal

urethrotomy wound. If a median outgrowth or isolated tumours are discovered the prostatic urethra is dilated and incised laterally and the outgrowths removed, preferably by an *écraseur*. Harrison²¹ recommended a similar operation with subsequent prolonged drainage. Henry Morris took part in the discussion on McGill's cases at the Clinical Society in 1887, and he favoured the perineal in place of the suprapubic route. It was probably on the same afternoon or the next day that McGill visited Morris at the Middlesex Hospital, and Morris²² tried unsuccessfully to convince him that the perineal route was the better.

The first carefully planned perineal operation for the removal of the whole of the enlarged prostate was done by Zuckerkandl²³ in Vienna in 1889. He made a curved prerectal incision, exposed the posterior surface of the organ, incised the prostatic urethra, and dissected the lateral lobes.

Castration.

The year 1893 was to see one of those dramatic changes in the treatment of the enlarged prostate that make the history of the subject so fascinating. Dr. J. William White, of Philadelphia,²⁴ read a paper at the meeting of the American Surgical Association at Buffalo on "the present position of the surgery of the hypertrophied prostate." White favours something less than the removal of the whole intravesical portion, hoping that shrinkage of the rest will take place after the analogy of the removal of a portion of the tonsil. But he notes that in about 20 per cent. of the suprapubic operations the bladder does not regain its power. At the end of an able address comes the idea that for some years almost banished prostatectomy from surgical practice. "It occurred to me some time ago that possibly the analogy between uterine fibromyomata and prostatic overgrowth was a real one. Castration might have the same effect upon the latter that oophorectomy does upon the former and cause a shrinkage or atrophy that would result in the practical disappearance of the obstruction. I might add, finally, that I have not had the courage of my convictions, and have never seriously sought to recommend the operation." Surely no suggestion could be more moderately and tentatively put forward. White must have been surprised at the ready response of surgeons to his suggestion. Others were not so diffident as he, and the operation of castration as a method of treatment for prostatic obstruction was rapidly taken up everywhere.

It is difficult to explain this sudden and practically universal change of opinion if prostatectomy as then practised was a reasonably successful operation. The mortality of suprapubic prostatectomy in McGill's table of 24 cases was 16.6 per cent., and Belfield places the mortality of the operation in 1890 at 13.6 per cent. When it is remembered that cases of enlarged prostate were only operated on when catheter treatment had failed, owing to sepsis or the impossibility of passing a catheter, the mortality is remarkably low, although the weaker ones had probably been weeded out by septic catheterisation. Some other cause than high mortality must have prepared the way for the sudden change of opinion. This was to be found in the late results of the operations then practised. The proportion of cases where the bladder did not regain its power or quickly relapsed after operation was at least 20 per cent. It is likely also that the difficulty of the suprapubic operation had an influence. Surgeons at that time were not so familiar as they became later with the suprapubic route.

White had predecessors in the theory and practice of castration for enlarged prostate, although he did not know of them. Tupper, according to Walker,²⁵ performed orchidectomy with the object of relieving prostatic obstruction on two occasions—namely, in 1882 and 1886. Ramm, of Christiania,²⁶ operated on two men in 1893. Mears²⁷ (1893) suggested vasectomy or section of the vas deferens as a less severe

and mutilating operation, and a number of surgeons took up the operation and published cases. Mental disturbance was observed after castration in 4 to 6 per cent. of cases, and in this respect the operations of vasectomy and castration were about on the same footing. Wood²⁸ and Horwitz²⁹ published lists of cases showing favourable results from castration in suitable cases. Harrison³⁰ (1900) and Rovsing³¹ (1902) recorded cases of vasectomy resulting in cure or improvement. But in spite of the advocacy of many surgeons and the tables of satisfactory results that were published, these indirect operations began to lose their hold on practical surgeons. There were many reasons for this. The mortality which White had expected would be negligible was high (19.4 per cent., Cabot); the mutilation was such that only outstanding success could justify it, and favourable results were to be expected only in a proportion of carefully selected cases. While some improvement took place in suitable cases in a few days, in other cases months elapsed before any change could be detected. Whatever could be expected from a diminution of congestion might be obtained, but whatever might be gained by permanent shrinkage of the prostate was problematical. The number of cases of mental disturbance after castration was very disturbing, and it mattered little that other operations were followed by mental disturbance in feeble old men. White,³² in a retrospect in 1904, says rather pathetically: "Doubtless many surgeons, probably most surgeons, would to-day dismiss castration and vasectomy from consideration, as summarily as I have rejected interstitial injections or transrectal galvanism. It may be that they are entirely right."

Two important articles on prostatectomy appeared during the early part of the period of indirect operations, and after that, apart from a few unimportant articles, there was silence. One was by Nicoll,³³ of Glasgow, on perineal prostatectomy in 1894, and the other by Fuller,³⁴ of New York, in 1895. Nicoll recognised the weak point in the perineal operation—namely, the difficulty in getting the prostate well within reach of the perineum. The bladder was opened suprapubically and the prostate pushed down by the fingers of an assistant. The prostate was then exposed from the perineum, the rectum being displaced backwards. The prostatic capsule was incised and the prostate dissected off the urethra. This was the first deliberate attempt to overcome the difficulty of reaching the gland in the perineal operation. Later on, French surgeons were to attack and solve the difficulty in another way, but they based their work on that of Nicoll. In 1895 Fuller³⁴ summed up surgical opinion in regard to suprapubic prostatectomy and disagreed with it. The argument that the results to be expected from prostatectomy were "indefinite and unsatisfactory is a false one," and is based on cases where the removal of the hypertrophy was incomplete, no attempt having been made to remove the prostatic hypertrophies surrounding the prostatic urethra. "If, however, all the hypertrophies, median, lateral and round about the prostatic urethra are removed . . . the results, as far as the bladder is concerned are, barring mortality, satisfactory." This was a very important step in the attack on the enlarged prostate by the suprapubic route, but little if any attention was paid to it, so strongly did the idea of the indirect operation of White hold the attention of the surgical world. Here for the first time it was laid down that the routine operation of suprapubic prostatectomy must include the "hypertrophies" along the prostatic urethra—in other words, the extravasical or rectal enlargement as well as the intravesical projection.

THE FRENCH WORKERS.

The years 1900 and 1901 saw the renaissance of prostatic surgery. Prostatectomy, both by the perineal and by the suprapubic route, found new advocates, and expanded to become the routine method of treatment of prostatic obstruction. The

handicap of the perineal operation had been the difficulty of reaching the prostate by this route. Nicoll had clearly shown the way in 1894, and now the French surgeons attacked the subject afresh. Albarran³² followed the subcapsular method of Nicoll, but without the suprapubic incision, and drainage was made from the perineum after reducing the redundant prostatic urethra. From this time for some years a number of instruments which served to depress the prostate during the dissection were introduced by Albarran, Fergusson,³³ Lydston,³⁴ Delbet, de Pezzer, Legueu,³⁵ and Young.³⁶ They all followed and gradually rendered more perfect the prostatic retractor or "desencleaveur" of Albarran, which consisted of a two-bladed staff with angled end and passed through the perineum and into the bladder, the blades being then separated so that traction on the shaft drew the prostate down into the perineal wound. Proust³⁷ gave a very clear and detailed account of the perineal operation. The patient is placed in the inverted sitting position, and a transverse perineal incision made and the prerectal space opened up. A broad-bladed retractor draws the rectum backwards, and a small opening is made in the membranous urethra through which the prostatic retractor is introduced into the bladder. The prostatic urethra is opened for its whole length, and the two lobes are separated from the urethra and bladder-base with scissors. The urethra is partly sutured and the bladder drained through the opening. In America, Young,³⁸ of Baltimore, has been the chief advocate of the perineal operation, and it is due to his brilliant advocacy and fine record of results that perineal prostatectomy retains a place among American surgeons.

THE SUPRAPUBIC OPERATION: FREYER.

In June, 1901, Mr. P. J. Freyer³⁹ published four cases of what he described as "a new and at first sight formidable operation for radical cure of the enlarged organ—namely, total extirpation of the prostate." He referred to the valuable work of Belfield and McGill, which he regarded as partial prostatectomy. "The first case was not approached with a view to performing a new operation. It was undertaken as a partial prostatectomy in the first instance." It was only after examining the tissue removed that he came to the conclusion that "the whole prostate in its capsule had been removed." Freyer believed that while the intravesical part of the enlarged prostate might cause obstruction, the extravascular or rectal portion of the enlarged prostate was equally the cause of obstruction, and might exist as a cause of retention without any intravesical enlargement. The operation that he recommended consisted in removing the entire prostate with its capsule, the line of separation lying between the capsule and the rectovesical sheath, the capsule being removed and the sheath remaining behind. At first he believed that he was able to preserve the urethra. Very soon, however, it became evident that the prostatic urethra was torn across and partly or completely removed with the prostate.

This conception of the aim which should be pursued in every case of prostatectomy was a new one. No hint of it appeared in any of McGill's writings. Fuller more nearly approaches Freyer's conception. He has the idea, more advanced than McGill or his followers, that the obstruction is extravascular as well as intravesical, and that it is necessary to remove the enlargements along the prostatic urethra. But he is still removing "as much as possible" from within the lobes. There is no ambition to remove the whole of the hypertrophied prostate within its capsule, such as Freyer set out to achieve. A spirited discussion followed the publication of Freyer's cases and his claim to have introduced a new operation. Only two objections of real importance emerge from a mass of verbiage. Firstly, the operation performed by Freyer was the same as that advocated by McGill, and, secondly, the operation that Freyer claimed to be performing could not be done and the patient

survive. It is a sign of the confusion that existed among some of the disputants that both of these arguments, each destructive of the other, appeared in the same letter. After stating that the operation had been practised by the members of the staff of Leeds Infirmary for years, Mayo Robson continues: "I have no hesitation in describing Mr. Freyer's idea that he extirpates the prostate entirely in its capsule as impracticable from an anatomical point of view. Even if it were possible to take away the entire prostate, it would be unnecessary and undesirable, seeing that a removal of all the hypertrophies affects a cure of the disease."⁴⁰ This letter from Mayo Robson, McGill's chief protagonist, appears to me to be sufficiently convincing that the two operations described by McGill and Freyer were different in conception and different in performance.

The claims of Freyer aroused a new interest in the surgical anatomy of the prostate gland, and a number of investigations on this subject were published during the next ten years by Roberts,⁴¹ Shattock,⁴² Cuthbert Wallace,⁴³ and myself.⁴⁴ The two chief points of interest were the fate of the urethra and the line of cleavage in the enucleation. Shattock examined 12 of Freyer's specimens in 1903, and showed that in cases where Freyer had thought the urethra was preserved, the prostatic and sometimes the membranous urethra was removed with the prostate, and even in those specimens where the gland had been parted anteriorly with the object of preserving the urethra, the urethral and vesical mucosa was present in the specimen removed. "Much of the interest in regard to the urethra," says Shattock, "is now gone, since its preservation is no longer regarded as of any moment." The second point was the removal of the entire enlarged prostate in its capsule. The structures composing the wall of the prostatic bed were the subject of investigation and discussion, principally by Cuthbert Wallace and myself. According to the view of the former, nodules of adenomata in the enlarging prostate pressed aside the prostatic tissue and formed a false capsule in which was embedded atrophied gland tubes, and these layers, which he represented as of considerable thickness, formed the wall of the prostatic bed, the operation consisting merely of shelling out adenomata from within the lobes of the prostate. My view, from examination of post-mortem specimens after prostatectomy, was that the wall of the prostatic bed was formed by thickened rectovesical fascia, and that any prostatic tissue found in it was accidental. I showed that the striped muscle of Henle, which lies between the anterior commissure and the sheath carrying the prostatic veins, appeared in some of the enucleated prostates and marked the line of cleavage as immediately inside the fascial sheath. At a later date (1914) Wade⁴⁵ reviewed this subject, and found that the wall of the prostatic bed in eight cases examined after prostatectomy consisted of muscle and fibrous tissue and compressed gland acini. He saw one post-mortem specimen in which he believed that total extracapsular enucleation of the prostate gland had been accomplished, and stated that "cases, however, are not rare where partial extracapsular removal has been carried out" and, where the specimen is examined after removal, portions of striped muscle-fibre are found on its surface. The former statement agrees with the views of Wallace, the latter with those expressed by myself. It seems that many grades must exist between a thick mass of stroma and compressed gland tissue, and a thin partial layer covering the rectovesical fascia forming the lining of the prostatic bed. A corresponding difference will be seen between the specimens removed by different operators and in different cases.

The method described by Freyer was at once taken up by surgeons all over the world. Dramatic as had been the change in practice from McGill's operation to the method of indirect operations of White, the swing of opinion was still more striking when Freyer published his first cases. It was a matter for comment in the early cases of operation on the prostate that

bleeding was not more severe. Yet even in the early cases operated on by McGill, Robson, Teale, and Littlewood "we read of difficulties from hæmorrhage. In Freyer's cases, while he constantly demonstrated the absence or the control of hæmorrhage at the time of the operation, there was frequently trouble after the return of the patient to bed which was the source of grave anxiety.

Watching these cases, and with an increasing experience of my own, it became evident to me that hæmorrhage, if not the direct cause of death in many cases, was a predisposing factor. Further, I recognised that Freyer's view that the removal of the prostatic urethra was unattended by a risk of a traumatic stricture, while true in the majority of cases, was unfortunately subject to numerous exceptions, and that the traumatic stricture of the urethra which followed prostatectomy was of a nature very difficult to treat. A further aspect, in which the operation Freyer was performing fell far short of perfection, was post-operative sepsis, and I realised that among other points in technique a clean cavity, without capsular shreds or partly detached masses of gland tissue and mucosa, was necessary in order to prevent persistent infection after the operation. With these defects in view I introduced a method "of open operation, in the hope of preventing the occurrence of such complications. The operation was first tried early in 1916, and then in an increasing proportion of cases until the method became my routine practice. The operation avoids placing the finger in the rectum, and hæmorrhage is controlled by free exposure and ligature. All tags, flaps, and nodules that might cause sepsis or post-operative obstruction are removed, and the prostatic-vesical orifice is opened up to prevent contraction.

I did not at that time, or indeed for a number of years later, know that there appeared in the collected papers of the Mayo Clinic "an illustration showing sutures introduced into the prostatic capsule. The legend of this illustration is "Prostatic capsule partially closed by interrupted sutures." There is no description of the operation. In 1917 there is a note by E. S. Judd, of the Mayo Clinic, of dissection of the prostate with the bladder-base exposed.

Attempts to shorten the convalescence and avoid the dangers of an open cystotomy wound after the operation by immediate closure of the bladder have been made by Ralph Thompson "and by Harris. "Harris sutures the posterior lip of the internal meatus to the posterior wall of the prostatic bed and partly closes the internal meatus on a catheter retained in the urethra. The cystotomy wound is then closed.

It will not be out of place here to note the death of Dr. W. J. Belfield, of Chicago, which took place on Oct. 4th, 1929. Dr. Robert H. Herbst, of Chicago, writes: "He was an interesting and forceful teacher, and an inspiration to younger men. He will be remembered as a scholar, a kind and willing counsellor, and a true friend."

DIAGNOSIS OF DIABETES MELLITUS.

By O. LEYTON, M.D. CAMB., D.Sc.,
F.R.C.P. LOND.,

PHYSICIAN TO THE LONDON HOSPITAL.

SHORTLY after obtaining a qualifying degree some 30 years ago I found no difficulty in diagnosing diabetes mellitus. After 15 years of specialised study of that disease I have come to the conclusion that the accepted methods of diagnosis are fallacious, and that many patients said to be suffering from that complaint and treated as such would enjoy better health if they were allowed to eat whatever they desired. No responsible individual would make so sensational a statement unless he were able to supply conclusive evidence to support it. I trust that I shall be able to prove myself a responsible individual.

The first step is to supply a definition of diabetes mellitus, which for many reasons is far from easy. It is unfortunate that complex words convey different ideas to different individuals; before attempting a definition it is, therefore, absolutely necessary to find some basis of agreement. The derivation of the name diabetes mellitus is found in the Greek word *διαβήτης* = a syphon, and the Latin word *mellitus*, of honey. I think all will agree that if a patient is suffering from true diabetes mellitus and is not treated he must develop polyuria and glycosuria unless he die too soon from some intercurrent malady or accident. It is, however, obvious in the very early stages of the disease that the departure from normal may be so slight that the glycosuria may be intermittent and the polyuria may not have developed.

Now if the deterioration in the metabolism be arrested at this early stage, and if this occur without treatment, the question arises whether the patient should be said to be suffering from diabetes mellitus or whether some other term ought to be employed. Seeing that there are arguments in favour of and against the use of different names for the quiescent and progressive stages of diseases, it seems to me that there cannot be any general ruling on the question, but that each condition must be considered separately, depending upon the meaning of the name used. For instance, if an individual is infected with the bacillus of Koch and is said to be suffering from tuberculosis, it may be advantageous to refer to progressive and quiescent tuberculosis; but if one were to refer to the disease as "phthisis," which means wasting, then it would be unwise to say that the patient was suffering from quiescent phthisis. If the disease were quiescent the phthisis would not persist. The term diabetes mellitus to my mind corresponds more with the term phthisis than with tuberculosis, and therefore it should be reserved for the progressive disease and some other name be found for the stationary condition.

Years ago I suggested the name "hypoglycopeny," to denote a diminished power of burning sugar. There are two objections to this word. (1) It is cacophonous. (2) The chief error in the metabolism may be a diminution in the power of storing sugar whilst that of burning carbohydrate may be unimpaired. An alternative term "stationary hyperglycæmic glycosuria" describes the peculiarity and conforms to the term orthoglycæmic glycosuria. In this paper I wish to emphasise the distinction between orthoglycæmic glycosuria or negligible glycosuria; stationary hyperglycæmic glycosuria or hypoglycopeny; and progressive hyperglycæmic glycosuria or diabetes mellitus. The physiologist has little difficulty in framing a definition, and states that diabetes mellitus is due to an insufficiency of insulin. When it is pointed out to him that some cases of disease indistinguishable from diabetes mellitus are not benefited by the injection of insulin, he adds: "or when insulin is prevented from acting." At present, however, he is not able to supply any satisfactory explanation of the failure of insulin to act, therefore his definition is of greater academic interest than clinical value.

The definition I am about to offer is for the purpose of this paper, and I scarcely expect it to be accepted as a universal definition of the disease. "Diabetes mellitus is a disease due to a progressive deterioration of the metabolism, primarily of that of carbohydrates and secondarily of that of proteins and fats. This deterioration may progress steadily, sporadically or fulminantly, and may by medical treatment be arrested or even reversed." The characteristics of the disease are a persistent hyperglycæmia following the absorption of carbohydrate; this hyperglycæmia is often associated with diuresis. Commonly ketosis occurs when the disease is advanced, because the katabolism of carbohydrates is so depressed that the metabolism of fats becomes deranged.

At the present day I need only mention, without going into any detail, that there are many substances besides dextrose which reduce copper when boiled in alkaline solution, and therefore the fact that the urine reduces Fehling's or Benedict's solution does not permit the conclusion that glycosuria is present. (Glycosuria indicates the presence of dextrose in the urine in a quantity recognisable by Benedict's test.) I believe also it is generally recognised that nearly 2 per cent. of true glycosurics are not suffering from any disease but have an unusually low renal threshold for dextrose. These do not develop hyperglycæmia after the absorption of carbohydrates, and are said to have an orthoglycæmic glycosuria. The majority of authors agree that this peculiarity may be disregarded, although a few express the view that persons with a low renal threshold for sugar are more likely to develop diabetes mellitus than those with the normal average threshold. I gather that in America

some believe that a low renal threshold for dextrose protects the patient against diabetes mellitus. My own experience supports neither of these views, but rather tends to show that there is no relation between the threshold and diabetes mellitus, and that a low renal threshold for dextrose neither protects the individual from the disease, nor does it render him especially liable to it. I have seen at least three individuals with low renal thresholds develop diabetes mellitus, whilst amongst my cases of the disease only a very small percentage have low renal thresholds for dextrose, a proportion too insignificant to suggest that there is any actual relation between the two conditions. This latter argument would be rendered void if undoubted evidence could be produced to prove that the renal threshold rises after the development of diabetes mellitus.

The characteristic of diabetes mellitus is the persistence of hyperglycæmia for some time after the absorption of carbohydrate. It has been assumed in the past that all cases in which this persistent hyperglycæmia occurs are suffering from diabetes mellitus. This assumption is to me a logical fallacy almost as striking as saying: "All horses are quadrupeds, therefore all quadrupeds are horses." It is true that most patients who have definite diabetes mellitus develop a persistent hyperglycæmia after the absorption of sugar, but I hope to be able to prove it incorrect to assume that all who have this persistent hyperglycæmia are therefore suffering from that disease.

For the safety of patients of medical men who have not the facilities for studying their cases of glycosuria, a rule has been adopted that any patient whose urine reduces Fehling's solution shall be treated as a case of diabetes mellitus until he has been proved to be free from diabetes mellitus. This rule should never be followed by those who can investigate their cases. I adopted it and only recently have recognised how it has led me astray. In some ways it is like assuming that the accused man is guilty and making him prove his innocence. The majority of countries which adopted this law have realised that it caused more miscarriages of justice than when the individual was assumed to be innocent until proved guilty. There will be fewer errors in diagnosis if those of us who have facilities for investigation assume that cases of glycosuria are not cases of diabetes mellitus until we have evidence of that disease other than glycosuria and hyperglycæmia. In my opinion symptoms are of incalculable value, but the sugar-tolerance test is fallacious in the absence of symptoms, even when all the known errors are excluded most carefully.

Errors in the Sugar-tolerance Test.

The metabolism of an individual is not a constant and unalterable process; from time to time it changes in quantity as well as in quality. One of the most definite and dramatic ways of illustrating this fact is by giving a dog a dose of amyl cyanide. The effect on an average dog is negligible, but if that dog be given small doses of ethyl alcohol for a period and then a dose of amyl cyanide, it will die very quickly. The administration of the alcohol has altered the metabolism to such an extent that it has acquired the power of splitting the cyanide ion from the amyl ion, and the dog is promptly poisoned. Less striking changes occur in man on administering alcohol, nicotine, morphine, and many other substances. The power of storing and/or burning carbohydrate is modified in many ways. It has been found that the concentration of sugar in the blood after the administration of a definite dose of sugar rises higher when the individual is mentally fatigued than when he is rested.

All with experience have had opportunity of noting that the carbohydrate metabolism is depressed by anxiety, as summed up in the epigram: "On Wall Street when stocks go down sugar goes up." The metabolism is also influenced by the preceding activity of various organs. If a healthy man be

put upon a diet poor in carbohydrates for a period before a sugar-tolerance test, the concentration of sugar in his blood will rise higher and hyperglycæmia will persist longer than if he has been on ordinary diet for the preceding four days. The reverse also proves true: if a patient with a depressed carbohydrate metabolism fasts for some time before the test is made, the concentration of sugar in his blood will not reach so high nor persist so long as when he has been allowed an ordinary diet for the four days preceding the test. In other words, the fasted healthy man gives a curve which simulates the diabetic, and the diabetic gives a curve which simulates the healthy; therefore before carrying out a sugar-tolerance test with the object of making a diagnosis, the patient should be on an ordinary diet for some days.

Emotion and pain should be guarded against as far as possible. It is my custom to let the nurse take all specimens of blood, and not to see the patient myself on the day of the test until it has been completed. The blood should be collected as painlessly as possible, using a really sharp spring lancet.

Certain toxins depress the power of metabolising carbohydrate; therefore the test will not prove of value unless all known sources of infection are previously treated and eradicated. I think I was the first to draw attention to this some thirteen years ago. The commoner sites of infective foci are the gums, tonsils, antrum, skin, and bladder. Abscesses may lead to a temporary hyperglycæmia in individuals who fail to show any impairment in their carbohydrate metabolism, even when submitted to tests some weeks after the abscesses have healed.

Many observers attach much importance to the concentration of sugar in the blood after a fast of twelve hours, and hesitate to diagnose diabetes mellitus where this falls to 0.1 per cent. or below. I record one typical case in which this opinion would prove incorrect. The sugar-tolerance test has proved so fallacious in my experience that I have become very cautious in drawing conclusions based upon a single test.

There is another method of investigating patients who excrete sugar whilst on ordinary diet, and this also fails to distinguish between a congenital or acquired stationary hyperglycæmic glycosuria and the progressive condition. The patient is placed upon a diet poor in carbohydrate, which can be poor in energy too because it is not to be maintained for long—e.g., 30 g. of carbohydrate, 50 g. of protein, and 80 g. of fat. Taking the potential carbohydrate of protein as 58 per cent. and that of fat as 10 per cent., the total "G" in that diet would be 67 g. The urine is collected, mixed, and measured every 24 hours and the total quantity of dextrose excreted is estimated. This diet is maintained for three days, and then 30 g. of pure carbohydrate are added to it and continued for another three days. Three or more further additions are made, each of 30 gr. of carbohydrate, at intervals of three days. If the sugar excreted remain a constant percentage of that ingested, the diagnosis of diabetes mellitus is excluded, because a peculiarity of that complaint is that the more carbohydrate absorbed the less is utilised. This method again fails to differentiate between a case of early diabetes mellitus and one of stationary hyperglycæmic glycosuria.

Accurate Diagnosis.

It may be said with fairness that so far this paper is purely destructive, and that a fallacious method of diagnosis which may lead to occasional error is better than none at all. With this criticism I am in entire agreement; therefore I shall complete this article by stating the methods I adopt in attempting to arrive at an accurate diagnosis. My anxiety for making an accurate diagnosis must not be interpreted as any want of appreciation of the paramount importance of arriving at a conclusion as rapidly

as possible. This is easy to understand, since my experience has shown that the chance of recovery from diabetes mellitus is dependent upon the brevity of the interval between the onset of the disease and the commencement of adequate treatment. When a patient presents himself with the symptoms of thirst, polyuria, and glycosuria, he may be suffering from diabetes mellitus, malignant disease of the pancreas, a tumour of the pituitary gland, or possibly diabetes insipidus together with a low renal threshold for dextrose. Hyperglycæmia would exclude diabetes insipidus. It is wise to assume that the patient is suffering from diabetes mellitus until some sign can be elicited suggesting that a tumour accounts for the hyperglycæmia. Very frequently patients who have never had symptoms seek advice stating that they have consulted several doctors and some have told them that they have sugar diabetes, whilst others have said that there was nothing the matter. It is my custom to explain to these that, however learned the physician they consult, it may not be possible for him to collect sufficient data at a single visit to permit him to arrive at a definite diagnosis; that it is not possible to draw a fine line between health and disease; and that when the departure from the normal average is but slight there is one way and one way only of deciding whether it is due to disease, and that is by finding out whether it is progressive.

If there be no necessity for an early diagnosis I rely upon the results of the sugar-tolerance tests taken at intervals, and refuse to diagnose diabetes mellitus in the absence of symptoms until I have evidence that either the power of storing and/or burning sugar is very much below the normal average or that the power is decreasing. If the time which can be allotted to the diagnosis is brief and the sugar-tolerance test equivocal, then I determine the effect of bacterial toxins upon the carbohydrate metabolism of the patient.

In the absence of symptoms, a diagnosis of diabetes mellitus may be made if, after 14 hours' fast, the concentration of sugar in the blood is above 0.2 per cent., or if, after the administration of 50 g. of dextrose, the sugar in the blood rises above 0.3 per cent. and remains above 0.2 per cent. for more than three hours after the sugar has been administered. If the concentration of sugar in the blood falls to 0.12 per cent. or to the level at which it started within two and a half hours, even if it has risen for a time to 0.3 per cent., or perhaps a little higher, the diagnosis should be only tentative in the total absence of symptoms. The patient should be allowed to remain on ordinary diet for an interval of six weeks if no symptoms develop, and then another test should be carried out, resembling the first in every detail. If the second test shows a very material diminution in the power of the patient to store sugar, then after a week's interval a third test should be made; but if the apparent deterioration be inappreciable the interval before the third test should be about three months. If the power of storing sugar has increased during the interval, the diagnosis of diabetes mellitus should be postponed; the judgment of the observer must be exercised to decide how many of these tests are essential. In the absence of symptoms the diagnosis of diabetes mellitus should be made only when evidence of a progressive deterioration of the metabolism has been established.

I believe most patients are willing to undergo quite a number of tests rather than limit their diets unnecessarily for an indefinite time. It is possible that the inclusion of the patients suffering from stationary hyperglycæmic glycosuria amongst the diabetics accounts to some extent for the alleged rapid increase of the incidence of the disease.

Another method of differentiating between stationary hyperglycæmic glycosuria and diabetes mellitus is by noting the effect of small doses of bacterial poisons on the concentration of sugar in the blood. More than 13 years ago I referred to the fact that some patients suffering from moderately severe diabetes mellitus were able to tolerate a much larger

diet after they had had septic foci extirpated from their gums. This observation has been confirmed times without number.

The effect of infection was driven home very forcibly many years ago by a girl of seven years who re-developed intense glycosuria whilst on a restricted diet which had controlled her glycosuria for several months. The incident was pathetic, because the little patient feared that she would be accused of having eaten something outside her diet which she knew was not the fact. On making inquiries, I learnt that her elder sister would be out of quarantine for varicella in four days' time. The recurrence of the glycosuria permitted me to venture the opinion that the patient would develop spots within a few days, a prophecy which proved correct.

This deterioration in the metabolism of a diabetic due to the absorption of bacterial toxins may sometimes be used to assist the diagnosis. A short time ago the gradual rise of the concentration of sugar in the blood of a patient with what was thought to be a subsiding appendicitis led to the decision that an operation ought not to be delayed, and thus the life of the patient was saved. If a dose of bacterial toxins, such as a vaccine against typhoid fever, be injected into a normal individual, there is a tendency for the concentration of sugar in the blood to fall, which may be due to poor absorption. In my limited experience, vaccines have led to a rise of sugar in the blood of patients suffering from diabetes mellitus, and even in those who have apparently recovered from that disease. In a really doubtful case this was tried with a negative effect, but it is too early yet to be certain that the patient's metabolism will not deteriorate as time passes. This method is merely a suggestion which so far has proved promising.

Owing to lack of data I am not in a position at present to state whether stationary hyperglycæmic glycosuria is associated with the complications which occur in diabetes mellitus, but it is obvious that if the view which is in vogue at the moment—that arterial degeneration in diabetes mellitus is due to an excess of fat in the diet—is correct, the patients who are permitted to continue a diet with a normal amount of carbohydrate may escape that devastating complication.

The evidence upon which the above statements are made consists of two series of cases; one giving sugar-tolerance tests which suggest that the patients are suffering from diabetes mellitus but in which the symptoms have not become any worse upon an unrestricted diet; and the other series consisting of cases which, although suffering from diabetes mellitus, give curves very far from suggestive of that disease.

CASE 1.—The first case which led me to realise that the accepted methods were not satisfactory was a spinster, aged about 31, who was nursing her brother, an alleged diabetic. After testing the urine of her brother she tested her own urine, and found that it reduced Fehling's solution. Although she had not suffered at any time from symptoms suggestive of diabetes mellitus, she was treated by a restricted diet, and was sent for further advice. After 14 hours' fast the sugar in her blood was 0.1 per cent., but the percentage rose to 0.25 within 90 minutes, and did not fall to 0.1 until more than three hours after the administration of the dextrose. A meal fairly rich in carbohydrate raised the sugar concentration in the blood above 0.20 per cent. I came to the conclusion that the patient was suffering from very mild diabetes mellitus. The circumstances made it unwise to tell her so or to limit her diet, and she was told to eat and drink whatever she liked for a year, and then present herself for re-examination. The test carried out in Scotland a year later showed that the power of storing sugar was practically normal. After an interval of yet another year the third test was made. The sugar in the blood then rose above 0.2 per cent., and aroused anxiety in the mind of one medical man, but the curve compared favourably with that obtained two years previously, and the patient continues to eat what she likes and to enjoy good health (Fig. 1). If she had been suffering from diabetes mellitus the disease would have made itself evident after two years of unrestricted diet.

CASE 2.—The second patient placed tentatively upon an unrestricted diet was the brother of the first; he was

alleged to have been suffering from diabetes mellitus for five years, and had been treated during that time with a restricted diet. When submitted to a sugar-tolerance test the curve seemed to indicate that his power of storing sugar was below that of the average normal, but only slightly so. I concluded that if he were suffering from true diabetes mellitus and had been treated by diet only, that in all probability the disease would have made progress, therefore I advised him to eat whatever he liked for a year, and then have the test repeated. The test was not repeated, but from time to time I receive evidence that he has not developed hyperglycæmia, and that he has not shown any symptoms of diabetes mellitus (Fig. 2).

CASE 3.—These two cases were completely overshadowed by a third who gave a history of hæmoptysis during the last eight years and glycosuria for three years. He did not complain of any symptoms suggesting diabetes mellitus. On April 4th, 1927, having been on ordinary food for the previous four days, he was submitted to a sugar-tolerance test. The concentration of sugar in the blood rose to 0.3 per cent. and remained there for half an hour. I came to the conclusion that he was suffering from mild diabetes mellitus, and advised him to adhere to a restricted diet and report progress. He did not return for two years, and then told me that for 21 months he had eaten whatever he liked. A repetition of the test showed that his power of storing sugar had not deteriorated, and therefore in my opinion he was not suffering from diabetes mellitus. He is continuing with a normal diet (Fig. 3).

CASE 4.—A man, aged 41, sought advice on Nov. 8th, 1927, because he felt out of sorts. His medical adviser found sugar in his urine. The patient did not complain of any symptoms suggesting diabetes mellitus and had insured his life two years previously, paying the standard premium. On Nov. 9th he was submitted to a sugar-tolerance test, and given 50 g. of dextrose by the mouth. The rise and fall of the concentration of sugar in the blood was within the normal average, but the urine secreted during the test contained 7.5 g. of dextrose, proving that the patient's renal threshold for sugar was below the average. I concluded that he had orthoglycæmic glycosuria, but since he had been free from glycosuria two years ago it seemed wise to keep him under observation. He was advised to eat and drink whatever he liked for a year, and then submit himself to another test. On June 13th, 1929, the test was repeated, and the concentration of sugar in the blood rose to 0.3 per cent., and remained there for half an hour. During this test 11 g. of sugar were excreted in the urine, whilst in the previous test 7.5 g. were excreted. Since the patient felt quite well and did not have any thirst I advised him to make no changes in his life, but warned him that he did not appear to be normal, and therefore he should be tested again comparatively soon. He did not return until Dec. 20th, when the test seemed to justify the advice given. The sugar excreted on this occasion was 5.1 g., which was less than on either of the earlier occasions (Fig. 4). He stated that he had never felt better in his life. He was advised to continue as in the past.

CASE 5.—A married woman, aged 40, had sugar found in the urine by her local medical adviser, who informed her that she was suffering from diabetes mellitus. She was submitted to the usual test on Oct. 4th, 1927; the result shown by the curve suggested some abnormality of the metabolism, although this was not proved. She was advised to modify her diet to a small extent, and from time to time samples of her blood were taken, and the concentration of sugar was estimated (Fig. 5). It was found that she could take 30 g. of carbohydrate at a meal without developing hyperglycæmia. In November, 1928, the test was repeated, and since it did not indicate any progress of the disease she was advised to eat whatever she liked for a time. When the test was repeated in May, 1929, the resulting curve seemed to indicate that the advice to return to an unlimited diet was bad, and that by throwing too much work upon the pancreas the disease had made considerable progress. Having had some experience of abnormal curves and learning that symptoms were completely absent, I advised an unlimited diet for another three months. During that time the patient continued to put on weight and gain strength, and when the test was carried out in August it was found that her power of storing and/or burning sugar was quite as good as when she had first consulted me, and was not so good as earlier. I contend that if I had followed the accepted rule this patient would have been diagnosed and treated as a case of diabetes mellitus.

CASE 6.—A man, aged 45, was seen in October, 1923. He gave a history of glycosuria for eight years. He was content to live on a restricted diet, and was not submitted to a sugar-tolerance test until November, 1928, when he was given 30 g. of dextrose by the mouth. The test suggested

FIG. 1.

50 g. dextrose given by mouth at each test.

Dextrose given by mouth.

some impairment in the storing of sugar, and the patient was advised to continue his restricted diet. Two years later a similar test was made, and also another test with a dose of 50 g. of dextrose. By that time my experience was sufficient to allow me to advise the patient to eat and drink whatever he liked. The test carried out in November, 1920, shows that the advice was good (Fig. 6).

CASE 7.—A man, aged 56, sought advice for pains in the limbs. The diagnosis of diabetes mellitus had been made in 1918 by a very capable observer after the patient had been in a nursing home for three weeks. He had been put upon a restricted diet which he had kept for two years. For nine years before he consulted me he had eaten and drunk whatever he liked. In December, 1928, he was submitted to the test, the result of which is recorded in Fig. 7. I cannot help thinking that the curve obtained in 1918 could not have been much better than the one in 1929, otherwise the diagnosis of diabetes mellitus would not have been made. The nine years of unlimited diet had not led to any appreciable advance of the disease, and therefore this is a case which does not need treatment, and is not one of diabetes mellitus.

CASE 8.—A spinster, aged 40, had a family history of diabetes mellitus. Her symptoms had first appeared in August, 1928, and hyperglycemia had been found. She was submitted to a sugar-tolerance test on Jan. 4th, 1929. The concentration of sugar began at 0.00 per cent. after 14 hours fast, and fell to 0.10 per cent. within two and a half hours (Fig. 8). This curve is not typical of diabetes mellitus; but there was no doubt that the patient was suffering from that complaint. A short time later she caught influenza, and required more than 20 units of insulin twice daily whilst on a diet of 80 g. of carbohydrate and 35 calories per kilogramme body-weight per diem.

CASE 9.—A major, aged 40, was refused for life insurance on

account of glycosuria. A sugar-tolerance test on Oct. 16th, 1927, showed a poor power of storing sugar, but since the patient had been subjected to an anæsthetic comparatively recently, and he did not present any signs of diabetes mellitus, he was advised to take a holiday and to report in six weeks' time. Seven months later a second test was made, and then it was found that the curve was that of diabetes mellitus. The hyperglycæmia was verified on several occasions. Many tests of non-diabetic patients appear to record a poorer power of storing sugar than this patient possessed, demonstrating how unwise it is to attach too much importance to the sugar-tolerance test (Fig. 9).

CASE 10.—A man, aged 49, had had intermittent glycosuria for a short time, and was submitted to a sugar-tolerance test on July 1st, 1924. The concentration of sugar in the blood rose to 0.33 per cent., but fell to 0.125 per cent. within three hours. After three years of unrestricted diet the sugar in the blood at 4.30 P.M. one day was found to be 0.14 per cent. On June 6th, 1929, the patient was submitted to a sugar-tolerance test, which showed very considerable delay in the storing of sugar. The first curve might be described as the lag curve of MacLean. It probably has nothing to do with delay in the activity of the pancreas, but is simply due to an absorption of sugar at a rate greater than the average (Fig. 10). The second curve suggests a slow development of diabetes mellitus, but the patient enjoys good health and has not shown any signs or symptoms of the disease.

CASE 11.—A married woman, aged 30, sought advice for vulvitis, and wore a ring for prolapse of the uterus. Her medical adviser found sugar in the urine. I have seen close upon a hundred cases of orthoglycæmic glycosuria; none of these has had balanitis, and only two vulvitis. A glycosuria accompanied by balanitis or vulvitis will very probably prove to be diabetes mellitus. The patient was submitted to the usual sugar-tolerance test on July 26th, 1929; the concentration of sugar in the blood rose to 0.30 per cent., and had fallen to 0.15 per cent. after two hours. The patient expressed a desire to go abroad in six months' time, and I therefore advised investigation. She was placed upon a modified diet for a time, but was given more than 120 g. of carbohydrate in her

FIG. 7.

FIG. 8.

FIG. 9.

FIG. 10.

FIG. 11.

diet during the four days previous to August 20th, when she was submitted to a second tolerance test. It will be seen that on that occasion the curve was that of the average normal (Fig. 11). She was then given a diet containing 160 g. of carbohydrate, a considerable fraction of which was cane-sugar; she did not develop hyperglycæmia. Another tolerance test on August 26th showed that the curves obtained were too variable to justify a diagnosis. The patient was quite willing to be vaccinated against typhoid and paratyphoid and I made observations on the effect of these bacterial toxins upon the concentration of sugar in the blood. After the injection of the vaccine the sugar in the blood was found to be low. This case is recorded in order to show how inadequate are our methods for diagnosing diabetes mellitus.

Summary.

1. Hyperglycæmic glycosuria is not necessarily diabetes mellitus.
2. The diagnosis of diabetes mellitus in a patient free from symptoms should be based either upon

a very considerable loss in the power of storing and/or burning sugar or evidence that the power is decreasing.

3. A hyperglycemia during protein shock is suggestive of diabetes mellitus.

It is with great pleasure that I record my thanks to Sir Humphry Rolleston for a number of suggestions incorporated in this paper.

VIRUS STUDIES CONCERNING THE ETIOLOGY OF PSITTACOSIS.

By M. H. GORDON, D.M. Oxf., F.R.S.,

CONSULTING BACTERIOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL;
MEMBER OF SCIENTIFIC STAFF, MEDICAL RESEARCH COUNCIL.

NEW and welcome light has recently been thrown on the causation of psittacosis by the experimental evidence brought forward by Drs. S. P. Bedson, G. T. Western, and S. Levy Simpson¹ of the London Hospital, to the effect that the budgerigar can be fatally infected either by suspensions of organs of parrots or by blood taken from patients suffering from this disease. Since the pathogenic principle here concerned is capable of passing through filters that hold up ordinary bacteria, and the disease can be transmitted in series, there would seem to be little doubt that their contention that a filtrable virus is here operating is justified. Suggestive as this new evidence is, however, further proof admittedly is required before the thesis that psittacosis is due to a virus can be regarded as established.

Among the group of nine cases of psittacosis recently described by Sir Thomas Horder and Dr. A. E. Gow² two, Cases 3 and 9, were admitted to St. Bartholomew's Hospital and died apparently of the disease. That circumstance, and the arrival of the bodies of two dead parrots that had belonged to the last case (which I owe to the courtesy of the Ministry of Health), afforded an opportunity of investigation which I now wish to report.

As Sir Thomas Horder and Dr. Gow point out in their paper, both patients failed to give any evidence of infection by *Bacillus psittacosis*. These negative results were confirmed by the examination made post mortem. Nor could any organisms of the enteric group of recognised significance be found. Bacteriological examination of the two parrots was equally negative as regards *B. psittacosis* or non-lactose-fermenting organisms.

Search was next made for the presence of a virus, the materials being injected into budgerigars as recommended by Bedson and his colleagues. Chaffinches were also tried in some of the experiments, but were found to be refractory. In the majority of the tests mice were also used, a pair being injected at the same time with the same doses and then kept in the same stable.

Procedure in preparing the suspensions was as follows. A bacteriological examination was first made of the various organs and when seriously infected with bacteria such as cocci, these tissues were placed in 50 per cent. glycerin in the refrigerator for a week, or else a suspension was made at once and passed through a Seitz filter. If free of bacteria the tissues were used direct as it was felt that a good portion of any virus that might be present would be likely to be held up by the filter, and it was desired to give any pathogenic agent that might be present as good a chance as possible. In making the suspensions a weighed amount of tissue was ground up in a mortar with distilled water sufficient to make a 1:20 suspension, and if filtering was employed this suspension was diluted first to 1:50 because stronger suspensions than that of freshly ground up material

were apt to clog the filter even when first passed through filter paper. Uniformly the filtrates were found to be sterile. The injections were made intramuscularly into the birds, and both subcutaneously and intraperitoneally into mice, care being taken to give not over 0.5 c.cm. by the latter route. The usual dose was 1.0 c.cm. The results have been as follows.

Infection from Human Cases.

Case 3 of Horder and Gow. At the autopsy on Feb. 3rd the spleen was removed, and after a portion of its surface had been seared with a hot iron a piece of the underlying tissue was cut out, suspended in water, and injected into two budgerigars and two mice. One of the birds got ill between the fifth and seventh day, but later recovered. The other died in 21 days and no bacteria could be found in its blood or organs. The mice were unaffected (21 days).

A third budgerigar was inoculated with the filtrate of this suspension of the patient's spleen. It died on the tenth day with sterile organs. A mouse inoculated with a suspension of the spleen and liver of this bird died in 11 days with sterile organs, and a suspension of its spleen in turn killed a further mouse in 17 days again with sterile organs.

Pieces of the lung and brain (pons) of this case were preserved for a week in 50 per cent. glycerin and then ground up and injected into two budgerigars. The bird that received the lung suspension died on the tenth day with sterile organs. The other bird was unaffected. No less than three of the five budgerigars injected with material from this case therefore died and a fourth got ill and recovered.

Case 9 of Horder and Gow. Blood (one part) on the fourteenth day of the disease in four parts citrated saline was injected into two budgerigars, but without effect. It also had no effect on four mice.

The post-mortem examination on Feb. 14th did not take place until 36 hours after death. Spleen suspension, unfiltered and filtered, and secretion taken at the bifurcation of the trachea diluted in broth and filtered were injected into two budgerigars and six mice. One of these budgerigars was unaffected in six weeks, the other died in 38 days with sterile blood and spleen.

Two mice injected with the unfiltered spleen suspension of this patient both died on the thirty-third day with sterile organs. Another pair that received the filtrate of the same material both became ill on the twenty-second day; one died the next day, the other survived till the forty-second day. One of two mice that received the filtered bronchial secretion of this case was dead on the fourth day and contaminated; the other survived till the forty-second day. None of these five mice showed any evidence of a bacterial infection. Nevertheless, passage was successful to further mice by using the spleens of four of them; but in each instance only one of the pair of mice inoculated died, the time taken to produce death being from 10-19 days. In all cases cultures from the spleens of the dead mice were negative.

Properties of the Virus Strains as Revealed by Experiments on Mice.

As the mouse is susceptible, an attempt was made to obtain information by employing that animal, the spleen being used for transference after its sterility had been proved by culture. Passage experiments in this way with the virus derived from the human cases and from the parrots respectively soon brought out the fact that the pathogenicity for the mouse of the virus from the birds was far more active and enduring than that of the virus from the human cases. Thus the virus obtained from the filtered spleen of the first case via the budgerigar came to a standstill after passage through three mice in succession. The filtered suspension of the organs of the second human case caused death in a mouse on the twenty-third day, and the spleen suspension of that animal killed one of two mice injected with it in ten

¹ THE LANCET, Feb. 1st, p. 235, and Feb. 15th, p. 345.

² Ibid., March 1st, p. 442.

days. Two further mice now died in six and ten days, but after another passage the virus lost its potency, and further attempts to obtain a passage virus from mice that succumbed to injection with the organs of this patient or with filtrates therefrom did not succeed for more than one or at the most two generations.

A very different result was obtained with the virus derived from the parrots. In the case of *Parrot I* (which died at No. 9 patient's residence on Feb. 6th), two strains of the virus have been under study. Of these strain A was derived directly from the unfiltered spleen suspension of the parrot. The primary mice both died on the sixth day, the second pair in five days, the next pair in four days, and subsequent pairs have nearly all died in three days. Similar results were given by strain B derived from the filtrate of the same parrot's spleen, where the first mouse died on the tenth day, and subsequent mice in six, four, three, and two days in succession. Both these strains are still as active as ever, A being at its fifteenth passage and B at its tenth.

In the case of *Parrot II* (which came from the same house and died on Feb. 7th), although the primary mice did not die until after 18-24 days, the filtrate of the pooled spleen suspension of the two latter mice killed in nine days, and death in subsequent passages occurred in six days, three days, and two days successively. This virus is also showing no evidence of deterioration, and is now at its eighth passage.

Attention accordingly has been concentrated on the parrot virus, and the following observations were made on mice with strain A of *Parrot I*.

Characters of the Virus Obtained from *Parrot I*.

1. *Pathogenicity for the Budgerigar*.—The virus derived from the spleen of *Parrot I* after passage through two mice in succession was filtered, and the filtrate divided into two parts. One of these portions was heated to 55° C. for 30 minutes. A budgerigar and two mice were then injected severally with 1 c.cm. of each portion with the following result.

Unheated Filtrate: The budgerigar died on the twenty-fourth day; one mouse died on the sixteenth day, the other on the nineteenth.

Heated Filtrate: The budgerigar and one mouse were still unaffected two months after injection; the other mouse died on the twenty-fourth day.

Two mice injected with the spleen suspension of the first budgerigar died in seven and nine days respectively, and in two further passages the mice died in 4-6 days and in 2-4 days successively. By passage, therefore, the parrot virus rapidly increased in virulence for the mouse after recovery from the budgerigar.

2. *Effect of Filtering*.—While this parrot virus is certainly capable of passing through the Seitz filter, comparison of the action on mice of the same suspension of virus before and after filtering has repeatedly shown that the unfiltered virus kills as a rule far more surely and quickly than the filtrate.

Thus in an early experiment the unfiltered virus killed both mice in five days, the filtrate took seven days; after passage, the unfiltered virus took four days, the filtrate nine to ten days, and after further passage the unfiltered virus killed both mice in three days, while the filtrate took no less than 14 days to produce death.

The probable explanation is that the filter retains a proportion of the virus. A parallel experiment with vaccinia virus showed that apparently all of it was retained by the Seitz filter, since a suspension of that virus active to a dilution of 0.00001 c.cm. before filtering became inert. Even when 2 c.cm. of the filtrate was injected into a rabbit's testis no lesion and no immunity resulted.

3. *Effect of Heat*.—The experiments on mice have indicated that while exposure for 30 minutes to 55° C. attenuates the virus, it does not always destroy all of it. On several occasions a proportion of the

mice injected with the heated virus have died generally considerably later than those receiving the raw virus. Passage was recently successful with the spleens of two of these mice that had succumbed late to the heated virus. Vaccinia virus behaves in a similar way when exposed to 55° C. for 30 minutes. The effect of higher temperatures is under investigation; exposure for 30 minutes to 80° C. and 100° C. appears to inactivate the parrot virus completely.

4. *Effect of Desiccation and of Disinfectants*.—The following result was obtained in a preliminary experiment.

Virus control: both mice dead in three days. The same virus after being dried in vacuo and then resuspended; one mouse died in six, the other in 11 days. The same virus after exposure for 30 minutes to 1:10,000 potassium permanganate at room temperature; one mouse died in four days, the other in five. Some of the virus received the addition of 0.5 per cent. carbolic, and was then exposed for 20 hours at 37° C.—a treatment that kills non-spore-bearing bacteria. The single mouse here injected died on the thirteenth day, thus confirming a result referred to in a preceding paragraph. The same virus that was used for these tests was also exposed for 30 minutes to 55° C. One mouse died in 13 days, the other was unaffected a month later when discarded.

It would seem from these results with mice that the parrot virus offers considerable resistance to desiccation and to certain disinfectants.

The effect of adding ether to a suspension of the virus was tried in the following experiment.

The pooled spleens of the mice used for the seventh passage of the virus were ground up in 12 c.cm. of distilled water, and this was divided into two equal parts. One-tenth part of ether was then added to one portion, and both were then well shaken and placed in the cold store for a week. At the end of that time each portion was taken out, shaken up, and after standing for five minutes dilutions were made from each and tested on mice. The dose throughout was 1 c.cm. and the results were as below. (The figures refer to the days that the mice took to die.)

Spleen dilution.	No ether.	Etherised.
1:100	4.4	6.9
1:1,000	5.6	7.9
1:10,000	5.9	8.25

The ether therefore weakened, but did not destroy the virus. Passage was successful from the mouse that survived for 25 days.

5. *Distribution of Virus in Mice that Succumbed*.—The pooled spleens of the two mice used for the fourth passage of the virus were tested on mice in a dilution of 1:100, 1:1,000, and 1:10,000 respectively, and the first pair died in three days, the other two pairs in seven days. The blood and spleen of each of the last pair were then suspended in distilled water, and a series of dilutions made and tested on mice. The results are shown below; as before, the figures refer to the number of days that the mice took to die.

Mouse.	Tissue.	Dilutions.			
		1:100.	1:1000.	1:10,000.	1:100,000.
59 ..	Blood ..	6 ..	7 ..	8 ..	8.
59 ..	Spleen ..	6 ..	13 ..	7 ..	9.
60 ..	Blood ..	8 ..	10 ..	8 ..	8.
60 ..	Spleen ..	4 ..	4 ..	6 ..	7.

S. = Survived.

It would seem that the virus was more abundant in the spleens of both mice than in their blood.

Action on the Rabbit of Parrot Virus After Mouse Passage.

1. *Cutaneous Experiments*.—By employing an aqueous suspension of the spleen of a passage mouse both strains of virus from *Parrot I*, and also that from *Parrot II*, were tested on the shaved skin of the rabbit.

Falling dilutions were made as in the last experiment, and 0.2 c.cm. of each was then injected intracutaneously. It

was found that all three strains produced a raised papular swelling that became bright red in from 40-60 hours, lasted for two or three days, and then faded. The colour of this eruption varies from a faint rose pink to a bright scarlet according to the activity of the strain and also to the particular rabbit. Pale areas appear in some of the papules, but so far no certain vesicles have been seen. The diameter of the papules varies from over a centimetre to a few millimetres according to the dose of virus injected. The local lymphatic glands are swollen and may also be deeply congested. When scarification was tried and the virus applied to the surface of the skin a crop of papules followed, but the result was less definite and striking than when the intracutaneous route was used.

Advantage was taken of this action of the parrot virus on the rabbit's skin to examine once more the effect of passing the virus through a Seitz filter, and also of heat, &c. From present results it would seem that the pathogenicity of the virus for the rabbit's skin is far more easily inactivated by these measures than is its lethal effect on mice, as indicated by experiments in a preceding section; for a 1 per cent. suspension of mouse's spleen containing virus active on the rabbit's skin up to a dilution of 1 : 10,000 gave no result at all, either after being filtered, or after being heated for 30 minutes to 55° C. A comparable test carried out with vaccinia virus gave a broadly similar result.

The papular eruption produced by the parrot virus when injected intracutaneously into the rabbit bears a close resemblance to that excited under similar circumstances by certain strains of herpes virus of human origin.

2. Action on the Rabbit's Central Nervous System.—In case of each of the three strains of parrot virus suspensions of the spleens of passage mice in distilled water were injected intracerebrally into rabbits in a dose of from 0.1 to 0.2 c.cm. followed by 1 c.cm. of the same material intravenously. Further particulars and the results were as follows.

Parrot I, strain A, eighth passage mice spleens pooled, 1 : 100. The rabbit died in 48 hours. Parrot I, strain B, sixth passage mice spleens pooled, 1 : 100. The rabbit became paralysed on the third day and died the same day with convulsions. Parrot II, fourth passage mouse's spleen, 1 : 50. The rabbit became ill on the fourth day; it developed some head retraction on the seventh day and died on the eleventh. After death the meninges in two of these rabbits showed some congestion, but no other naked-eye changes were observed. The meningeal secretion and the heart's blood of all three showed no bacteria either in films or cultures. A repeat experiment was carried out with Parrot I, virus strain A, in order to see the effect of passing the virus through a Seitz filter and of heating the filtrate for 30 minutes to 55° C. The rabbit that received the unfiltered and unheated virus became paralysed on the fourth day and died on the fourteenth with sterile blood and meningeal exudate. The rabbit that received the unheated filtrate went off its feed for a few days, but developed no obvious paralysis and recovered. The third rabbit was unaffected. Both the last two rabbits are alive and appear to be quite normal at the present time—over six weeks since injection.

Sections have been examined of the central nervous system of the rabbits that succumbed to the parrot virus. All of them show evidence of meningitis, the exudate being chiefly composed of lymphocytes, and the meninges slightly thickened at places. In the case of two of these rabbits there is also some evidence of encephalitis—e.g., besides a pronounced degeneration of the nerve-cells occasional cuffing of the vessels in the white matter, and very rarely a few small inflammatory foci.

In the case of two of the rabbits that succumbed to intracerebral inoculation of the parrot virus a preliminary attempt was made to ascertain the distribution of the virus by titrating dilutions of the blood and organs on a rabbit's skin, and in the case of the first rabbit this was supplemented by inoculating mice with dilutions of 1 : 1000 and 1 : 10,000 of the blood, urine, spleen, brain, and nasal mucous membrane. The results given on the rabbit's skin indicated that the virus was more active and abundant in the spleen and nasal mucous membrane than elsewhere, and mice that received the 1 : 10,000 dilution of both these materials succumbed with sterile spleens from which the virus was successfully passed to further mice. These observations,

however, afford merely an indication, and require to be confirmed and considerably extended before an adequate picture can be obtained of the distribution of virus in rabbits that succumb to its action.

The above experiments refer to the parrot virus alone. An attempt was made to infect a rabbit intracerebrally with the virus obtained from the spleen of Case 9 of Horder and Gow by using a suspension of the spleen of the second passage mouse, but the result was unsuccessful. This same virus also produced only a slight colourless swelling when injected into the rabbit's skin.

Control Observations on Normal Birds of the Parrot Tribe.

Through the courtesy of Colonel A. E. Hamerton, pathologist to the Zoological Society of London, and of Mr. Seth Smith, superintendent of the Society's Gardens, it has been possible to make some control observations on normal birds of the parrot tribe killed accidentally. The spleens of these birds were taken out by Colonel Hamerton in course of his routine post-mortem examination, and kindly forwarded to me. On arrival these spleens were ground up in distilled water in the same way as the spleens of the parrots associated with Case 9 of Horder and Gow and injected into mice.

The birds examined in this way consisted of a normal example of the Amazon parrot *Amazona aestiva*, the kind that has been especially under suspicion in regard to psittacosis. The spleens have also been examined in the same way of a blue and yellow macaw, a rose-crested cockatoo, a Tovi parakeet, and four normal budgerigars. The mice, of which six were used for the first bird—the Amazon parrot—and two for each of the others, were kept under observation for a month. When a mouse died cultures were made from its spleen, and, if negative, passage was tried to further mice.

The result of this investigation was as follows. Of the eight birds examined six gave negative results. In the case of one of the budgerigars, however, one of the two primary mice injected with the spleen suspension died on the sixteenth day with a sterile spleen. Passage was successful to a pair of mice that succumbed on the tenth day and from them to a further mouse that died on the fifth day. This virus produced a moderately typical eruption on the skin of a rabbit, but it seems to have become attenuated latterly since the more recent mice have successfully resisted its action.

The other positive case was that of the blue and yellow macaw that was not quite a normal bird, as it had (as Colonel Hamerton pointed out) a mycotic deposit in one of its air sacs. One of the pair of mice inoculated with the spleen suspension of this bird died on the nineteenth day with sterile spleen. Both of a pair of mice to which transfusion was made died in four days, and from them passage has been successful through seven generations. The virus at present shows no signs of deterioration, but appears to be increasing in virulence for mice. This macaw virus when injected intracutaneously into the rabbit produces a bright red papular eruption indistinguishable from that excited by the virus strains from the two parrots associated with Case 9 of Horder and Gow. A rabbit injected intracerebrally with the macaw virus became paralysed in its front legs on the third day and remained in this condition for ten days, after which convalescence set in, and it is now able to move its front paws quite well and is gaining in weight.

Intracerebral Inoculation of Mice.

The neurotropic capacity of the parrot virus revealed by the rabbit experiments appeared to afford a possible explanation of the mode of death of certain passage mice that developed a form of general motor paralysis towards the end. Observations are now in progress in which the effect is being determined of the parrot virus when inoculated by the intracerebral route.

In an experiment with strain A, of Parrot I, during its fifteenth passage, one mouse received the usual dose of

1 c.cm. of the virus in the routine way by the peritoneal and subcutaneous routes, and another received one-tenth of that dose intracerebrally. Both mice were dead by the third day, and the abundance of virus in the brain and spleen of each was determined by preparing dilutions of each organ from 1:100 to 1:10,000, and injecting 0.2 c.cm. of each into the skin of a rabbit. The result showed that both spleens contained the virus up to the 1:10,000 dilution, and that the brain of the mouse injected by the usual routes gave a negative result with the 1:100 dilution, whereas that of the other gave a positive result up to a dilution of 1:1000. In a parallel experiment with strain B from the same parrot, a mouse that received the virus by the usual routes died on the seventh day, and another that received one-tenth of the dose intracerebrally developed on the same day a complete flaccid motor paralysis limited to its hind quarters, and died the following day.

Comments.

Confirmation, therefore, has been obtained of the presence of filtrable virus in two cases of psittacosis, and in two parrots associated with the second case.

The outstanding feature of the experiments reported in this paper is the manner in which the strains of virus obtained from the parrots associated with the second case of psittacosis have maintained and increased their virulence by passage through mice. The dermatropic and neurotropic affinities displayed by this virus after mouse passage for rabbits suggest that it may belong to the same group as the herpes virus. The relation between that virus so frequently carried by human beings, and the present one derived from parrot forms one of the problems calling for investigation.

The virus derived from the human cases has not so far displayed the same degree of pathogenic stability for mice as that derived from the parrots. Experiments are at present in progress in which strains of herpes of human origin are being passed through mice, and the first of these strains has come to a standstill after passing through three mice in succession. Further experiments on this question are required, and also observations in which blood and material from human beings suffering from various febrile conditions are investigated in the same way. The mouse may prove to be a more valuable means for the isolation and study of viruses than has hitherto been realised.

AN EXPERIENCE WITH AVERTIN ANÆSTHESIA IN GYNÆCOLOGY.*

By JAMES YOUNG, D.S.O., M.D., F.R.C.S. EDIN.,

GYNÆCOLOGIST TO THE ROYAL INFIRMARY, AND PHYSICIAN
TO THE ROYAL MATERNITY AND SIMPSON MEMORIAL
HOSPITAL, EDINBURGH.

THE efforts continually being made to improve our anæsthetic drugs testify to a general sense of dissatisfaction with the present methods of surgical anæsthesia. It must be a matter of common opinion that the fact that such drugs as chloroform and ether are still in common use for complete anæsthesia is eloquent testimony to the poverty of our present resources. The saturation of every tissue with such irritant and toxic materials, as the only available method of bringing under control the specialised sensory apparatus of the body, is so crude and so unscientific as to carry with it its own condemnation, and to deserve no greater sanction than that implied in the exigencies of the early and necessary developmental phases of every art. The discomfort and even dread that their employment often provokes, the damage to the vital organs, and the common post-operative sickness and pulmonary complications which they are apt to induce, add much to the torture of the patient and to the anxiety of the operator.

Any method of general anæsthesia which professes to provide safety of induction, whilst eliminating much of the accessory danger and discomfort, is worthy of most serious attention. An experience with avertin, though still limited and experimental, has encouraged me in the belief that with this drug we may possess such an improved method of administration.

Avertin was introduced to British surgery in 1929, first by Morrin,¹ of Dublin, and, later, by Blomfield and Shipway,² of London. The latter workers carried out a test with the drugs at the instance of a conjoint committee set up by the Medical Research Council and the Section of Anæsthetics of the Royal Society of Medicine. All these anæsthetists speak of its potency and its potential dangers, but at the same time they express their belief that it is "a valuable addition to the drugs at the disposal of the anæsthetist, and that if used with due care and moderation its advantages can be taken advantage of with perfect safety."

Method of Administration.

The method which I employ follows closely that laid down by the manufacturers and the anæsthetists above mentioned. On the evening before the operation the bowel is washed out with an enema. No subsequent enema is given on the morning of the operation, as any fluid retained may interfere with the dilution of the anæsthetic solution. One hour before the operation one-eighth of a grain of a morphine salt is given hypodermically. In the earlier cases a quarter of a grain of morphine was used and respiratory depression was sometimes marked, in one case causing anxiety. Since halving the dosage the respiratory depression has been less pronounced, and in no instance has there been reason for worry. Some observers state that they have with advantage discarded the preliminary sedative entirely.

The avertin is supplied as a liquid in which the drug is held in solution by amylene hydrate; each cubic centimetre of the fluid contains 1 g. of avertin. The amount to be given is accurately proportioned to the body-weight, the safest maximum ratio according to common finding being 0.08 to 0.1 g. per kg. of the patient's weight, the smaller dosage being employed for weakly individuals. The makers supply a detailed chart by which the quantities can be easily and rapidly determined. The drug, measured out freshly for each patient, is added to distilled water heated to 40°C. and shaken to make a solution of 2½ to 3 per cent. The temperature must not be raised beyond this, otherwise there is the risk of hydrobromic acid being produced; this is irritating to the bowel. To exclude the presence of this material one or two drops of a 1 in 1000 solution of Congo-red are added to 5 c.cm. of the avertin solution. When the impurity is present the colour turns blue. I may add that on no occasion have we ever found it necessary to discard the solution as prepared for use on account of the presence of this impurity.

The anæsthetic is administered before the patient is removed from bed. It is introduced slowly into the rectum half or three-quarters of an hour before the operation by means of a soft tube passed in about four inches. The patient lies on the side to prevent sagging of the jaw and tongue. It is advisable for the anæsthetist to be present or immediately available throughout the administration, although in general we have found it both safe and expedient to leave the actual administration itself to a nurse who has experience in the procedure.

Amongst the strongest commendations of the drug are the ease, comfort, rapidity, and certainty of the anæsthesia. The psychical strain and unpleasantness inseparable from inhalation methods are absent. In the certainty and rapidity of its action it is superior to the rectal ether method. Consciousness is often lost in a few minutes. The maximum anæsthesia is attained in about half an hour, and for this reason the operation should not be commenced before at least this interval has elapsed. In about 25 per cent. of

* A paper read before the Edinburgh Medico-Chirurgical Society on March 5th.

the cases the anæsthesia is sufficiently profound for a minor and in a smaller proportion for a major operation. Ordinarily the anæsthesia requires to be supplemented by the inhalation of ether or gas and oxygen. My practice is to employ ether, as this has a stimulating action on the blood pressure which in some cases shows a marked tendency to fall with avertin. The amount of supplemental ether required varies in individual cases and according to the type of operation. It is usually much less than that required for ordinary inhalation anæsthesia, and even for a lengthy operation no more than one ounce may be necessary. It is interesting that avertin tends to obliterate the corneal reflex, while leaving the pain and other sensations active, so that a patient who appears sufficiently deep in anæsthesia may respond to the irritation of the towel clips.

The anæsthesia of avertin has been aptly likened to the unconsciousness of deep sleep. It usually lasts for about two hours and may last much longer, the patient waking naturally, though usually the sensations remain dulled well into the evening. There is usually no post-operative nausea or sickness. At the most this rarely troubles the patient more than once or twice, and quickly subsides.

Chart showing blood pressure during operations conducted under avertin anæsthesia. A = completion of administration of avertin; E = start of administration of ether; O = commencement of operation; Ep = injection of 0.5 c.c.m. ephedrine hydrochloride; F = end of operation, patient removed to bed. The upper line of each graph represents the systolic pressure, the lower the diastolic. The actual readings are given along the ordinates; the divisions on the abscissa are intervals of 10 minutes. The shaded portion represents the period during which the patient was under constant observation, while the unshaded portion to the left gives the pressure half to one hour before avertin administration, and that to the right the pressure about 10 o'clock next morning. The time relations of the unshaded portions are therefore not exact.

Notes on Cases.—CASE 1. Mrs. H., aged 38. Wt. 9 st. 6 lb. 5.9 c.c.m. avertin, 4 oz. ether. Pelvic floor repair. No ephedrine given. CASE 2. Mrs. R., aged 42. Wt. 6 st. 3 lb. 3.9 c.c.m. avertin, 3 oz. ether. Supravaginal hysterectomy. No ephedrine. CASE 3. Mrs. M., aged 45. Wt. 9 st. 13 lb. 6.1 c.c.m. avertin, 2½ oz. ether. Pelvic floor repair. Half an hour after the exhibition of the avertin the systolic pressure had fallen 54 mm. and 1 c.c.m. ephedrine was administered. CASE 4. Mrs. M., aged 39. Wt. 6 st. 1 lb. 3.8 c.c.m. avertin, 1 oz. ether. Dilatation and curettage. The peculiar drop of the diastolic curve to the abscissa indicates that there was no cessation of sounds heard over the brachial artery, nor any qualitative change from a "third" to a "fourth" sound. A loud bruit was heard without any compression on the limb. This disappeared soon after the patient was returned to bed, and she did not show any signs of distress.

The dominating advantage of the drug is its lack of toxicity. It has apparently no damaging effect on the heart or liver. It has a depressing action on the respiration, which becomes slower, sometimes with stertor. Overdosage, it would seem, tends to paralyse the respiratory centre and several such cases have been recorded. I have had one case of marked cyanosis and a tendency to respiratory failure in a woman who was left unattended for some minutes after the administration. The condition may have been due to a mechanical blocking of the upper tract with the tongue, a risk especially to be looked for during the anæsthesia. In this instance the administration of carbonic acid gas quickly rallied the patient.

The Influence of Avertin on Blood Pressure.

In many instances avertin causes a lowering of the blood pressure. In our experience this has been more frequent and at times more pronounced than that appearing in the descriptions either in the manufacturers' brochure or the records of the other British investigators. Blomfield, for example, states that a drop of 10 to 15 mm. is to be expected, whilst Shipway records that in his experience the fall was about 16 mm., the maximum being 30 mm. Hg. The makers' brochure refers to the average fall as 20 to 40 mm. Hg. In my cases there has been a range of variation from nil to as much as 100 mm. Hg. In women with normal pressure I have on several occasions found a drop from 150 or 140 systolic to well under 100, and on one occasion there was a drop of the systolic pressure from 190 to 90, and in another from 180 to 90. These experiences are represented on the graphs (Figs. 1 to 4) prepared by Dr. W. P. Kennedy, of the Physiology Department of Edinburgh University, and may be dependent upon the fact that operative interference with the female genitalia has a special tendency to lower the systemic blood pressure. On this question further research is clearly required. In all of these cases the recovery of the pressure was satisfactory after the hypodermic administration of pitressin or ephedrine. In only one instance was the drop in pressure associated with any other alarming phenomena, and we are coming to regard the fall in blood pressure with increasing equanimity. The pulse tends to vary directly with the systolic pressure.

Analysis of Results.

I have used avertin in a total of 345 unselected hospital and private cases. There were 70 operations involving opening the abdomen, including hysterectomy 25 times, ovariectomy 6, salpingo-oophorectomy 7, and appendicectomy 8 times. There were 48 operations for vaginal prolapse, and 2 for excision of the vulva for carcinoma. The remainder of the operations were, for the most part, minor operative procedures—e.g., dilatation and cauterisation of the cervix (57), curettage for exploratory purposes (20), radium insertion in cervical cancer (33), emptying the uterus in cases of abortion (6), and plastic operation for vesico-vaginal fistula (2).

There were two deaths, a mortality of 0.6 per cent. Our previous hospital mortality in 1799 successive cases, with ether alone or in combination with chloroform as the routine anæsthetic, was 34—that is, 1.9 per cent. The report of the Royal Samaritan Hospital for Women, Glasgow, for 1928 shows a mortality of 31 in 1836 gynecological operations or 1.7 per cent. The details of the two fatal cases are as follows:—

CASE 1.—A para-8, aged 52, had a history of down-bearing for 20 years, and of a protrusion from the vulva for five years. Retention of urine necessitating catheterisation had been present. There had been intermittent bleeding since the menopause five years previously. Suddenly, on August 29th, 1929, a large mass prolapsed from the vulvar opening, extending down as far as the knees. On admission the pulse-rate was 116. The tumour mass consisted of a markedly infected and sloughing fibroid tumour about the size of a fetal head and, at the upper end, of an enlarged and inverted uterus and prolapsed vagina. On August 30th

the general condition was considered to be fairly satisfactory, and the fibroid was removed and the uterus reinvaginated from below. With the object of removing the damaged and infected uterus, supravaginal hysterectomy was carried out. The blood pressure was not recorded until the end of the operation at 11.30 A.M., when the patient was collapsed, and the pressure was 60/40 mm. Hg. Submammary saline and intravenous gum saline were administered while she was in the operating room. In spite of the usual cardiac stimulants and pitressin, she sank rapidly and died at 11 P.M.

CASE 2.—A para-4, aged 40, had a history of an abdominal swelling for one year, whilst for ten days there had been vomiting, acute pain in the right iliac fossa, and fever. At the operation on Oct. 2nd, 1929, the omentum and bowel were found to be densely adherent over a mass occupying the lower abdomen and pelvis, and during separation pus escaped. The anatomical outlines were obscure, the surmise being that we were dealing with an infected ovarian cyst. The mass was removed with difficulty, and the remaining cavity was packed with gauze. At the end of the operation the pulse-rate was 96, and the general condition was very satisfactory. During the day the pulse-rate rose steadily, and by evening was 100. She collapsed and died next day at 3 P.M., about 28 hours after the operation.

In neither case was an autopsy obtainable but we may, I think, conclude that in neither was the avertin the determining cause of the fatal issue. Neither showed the deepening coma and respiratory involvement that accompany the known toxic actions of the drug. In each case we were dealing with patients presenting a grave operative risk and in both we are faced with the futility of attempting after the event to determine how far a different method of treatment might have led to a more favourable conclusion. In each case, as it so happens, it would be as possible to argue in favour of some surgical procedure other than that actually selected as it would be to argue that different anaesthesia, for example gas and oxygen, might have improved the prognosis. My own conclusions, after a careful study of both cases, is that the avertin in neither can be definitely incriminated. The first case, however, raises the question of the appropriateness of this drug in a patient suffering from severe pre-operative shock.

Both cases belong to our early series and our subsequent experience, embracing as it has done a considerable number of similarly poor operative risks, with the discovery that a falling pressure can be controlled by ephedrine, has increasingly tended to the conviction that in eliminating the toxicity and the pulmonary complications attendant on ordinary inhalation anaesthesia we can now embark on severe operative procedures with an added confidence. In these respects my views coincide with those of others who have used avertin.

Reduction of Post-operative Sickness and its Risks.

Throughout there has been practically a complete absence of post-operative nausea and sickness, even in those cases in which as much as 8 to 10 ounces of ether has had to be administered during a lengthy operation. This seems to be explained by the narcosis, which is prolonged for some hours after the operation, allowing the elimination of the ether to occur whilst the centres are still in a dulled state. In no instance have there been such gastro-intestinal complications as acute dilatation of the stomach or paralytic ileus. This relative absence of post-operative sickness is one of the most important advantages of avertin, an advantage which it shares with spinal anaesthesia. It adds much to the patient's comfort during the early post-operative period and it is a fact of supreme importance in operations in the abdomen and on the pelvic floor, where trauma of the wounds due to straining may have serious effects. We have been especially impressed with the advantages of avertin in plastic operations on the pelvic floor, which constitute a relatively large proportion of our cases. It is known that these operations for prolapse are not devoid of risk, the special danger being hemorrhage and sepsis. It may safely be presumed that the retching consequent on inhalation anaesthesia, by leading to a straining

of stitches placed in wounds which often imply deep dissection in vascular areas, is an important cause of trauma and post-operative hemorrhage and of the sepsis that may result. Further, an associated infection predisposes to the risk of tetanus, of which we have recently had some tragic examples in Edinburgh after pelvic repair operations for prolapse. I discarded ordinary inhalation anaesthesia some years ago in such operations in favour of spinal anaesthesia with stovaine. Latterly, with the advent of avertin, I have used this drug with the minimal amount of ether it requires. This combination is superior to spinal anaesthesia in that it eliminates both the pain and distress of the actual administration and the paresis of the bladder with the prolonged need for catheterisation that may follow on the latter method. I still retain spinal anaesthesia, however, as the routine procedure in Caesarean section, because of the specific outstanding advantages it possesses of diminishing the bleeding from the uterine wound. This kind of natural hemostasis seems to depend upon the removal of the inhibitory control of the central nervous system, allowing the sympathetic to exert its constrictor action on the muscle and vessels of the uterus. With its use Caesarean section becomes a relatively bloodless operation; shock, a factor of supreme moment in many cases, is diminished; whilst the discarding of inhalation anaesthesia reduces the most potent danger in this operation—a danger especially great where sepsis is already present—namely, post-operative bronchitis and broncho-pneumonia. During an experience of over four years with spinal anaesthesia in Caesarean section I have had complete immunity from these pulmonary complications, and this result is especially significant in view of the fact that in a considerable number the operation was carried out in emergency and, therefore, potentially infected cases.

Altogether I have carried out 143 repair operations for vaginal prolapse with spinal anaesthesia, and 48 with avertin and ether—that is, a total of 191 cases without a death, and practically without pulmonary trouble, local hemorrhage, or sepsis. There are few records showing the mortality risks of prolapse operations with other anaesthetics. Our own previous figures of 340 cases, with ether alone or combined with chloroform as the routine anaesthetic, show a mortality of 6, or 1.7 per cent. In three instances the cause of death was sepsis, in one tetanus, in one bronchitis, and in one heart failure. The Samaritan Hospital of Glasgow shows a total of 326 prolapse operations with six deaths—that is, a mortality of 1.8 per cent. during 1928. In two instances the deaths were caused by pneumonia, and in one each by acute dilatation of the stomach, septicæmia, pulmonary embolism, and hemorrhage.

In a further effort to reduce the post-operative risks, I have for some time been carrying out additional precautionary measures. To reduce the risk of gastro-intestinal complications and of inhalation of septic matter into the lungs, an effort is made in every case to eliminate obvious focal sepsis in the teeth and tonsils and, in the case of pelvic repair operations, every patient receives a preliminary preventive inoculation of a stock streptococcus and *Bacillus coli* vaccine. By this vaccination I believe I have reduced the risk of cystitis and pyelitis, a risk which is especially present in cases in which prolonged catheterisation is required. The possible advantages accruing from these measures have, of course, to be placed beside those claimed for the anaesthetic procedures in any attempt to assess the benefits of the total operative routine.

Pulmonary Complications.

Our records, if we include the original series of prolapse operations carried out under spinal anaesthesia, comprise a total of 488 cases with two deaths—that is, a mortality of 0.4 per cent. There is no mortality from pulmonary complications, no broncho-pneumonia or lobar pneumonia, and only a small unrecorded number of cases of mild bronchitis. One

patient developed a passing pleurisy several days after the operation. This is especially significant since a relatively considerable proportion of gynaecological patients consists of stout unhealthy women in late middle life. This especially applies to those suffering from prolapse, in whom immobilisation on the back naturally predisposes to pulmonary stasis and congestion. It is common knowledge that inhalation anaesthesia, especially with ether, is apt to determine pulmonary complications. There are, on the other hand, few satisfactory records on which the measure of these risks with differing anaesthetics can be judged. Fuller³ has recently published an analysis of the operations carried out at University College Hospital during 1927 which shows 124 cases of lung complications in a total of 1478, or 8.5 per cent. The mortality from these causes was 20, or 1.8 per cent. In 1332 cases ether was employed with a 6.9 per cent. incidence of pulmonary trouble; in 204 chloroform was used with an incidence of 6.8 per cent., in 179 local and regional anaesthesia with an incidence of 3.9 per cent., and in 16 gas and oxygen with a rate of 6.2 per cent. Of the seven cases exhibiting lung troubles after local or regional anaesthesia, four had definite and two a suggestion of previous lung complaints, which clearly determined the choice of anaesthesia. Fuller's analysis shows that women are less apt to suffer than men, the respective incidences being 6.8 and 17.8 per cent. A further feature of interest is that the risk had no intimate relation to the length of the operation, but was signally dependent upon site. These figures bring out in a very startling way the risk of post-operative lung complications in surgery and, whilst they show that such factors as site of operation and sex are significant, they cannot but raise in a very acute form the question as to how far the choice of anaesthetic plays a dominating part. For an accurate verdict on this matter, however, it is essential to obtain large records of approximately similar classes of case in which different anaesthetics are employed. This becomes especially apparent when the greatly differing mortality from operations on different sites is noted. In Fuller's figures, for example, the mortality from pulmonary causes in upper abdominal operations was 3.3 per cent., and in lower abdominal operations 1.1 per cent., whilst in major operations on the mouth, pharynx, and larynx it was 23.1 per cent.

At the present moment our lack of knowledge tends to place us in the invidious position of refusing the services of one anaesthetic because of the dread of immediate disaster, when in reality by our choice we may inadvertently be multiplying many times the total risks to our patient. Only by an assessment of the total advantages and disadvantages, including the risk per 1000 cases, both immediate and from such subsequent causes as toxæmia and lung complications, inherent in each anaesthetic, can we hope to escape from the present unscientific position in which the choice of anaesthetic must often be largely a matter of personal bias on the part of operator or anaesthetist. Meanwhile I am satisfied that in avertin we possess a method which is unequalled for safeguarding the patient against the mental distress and physical discomfort commonly associated with anaesthesia, and that, at the same time, its administration in combination with a reduced ether inhalation, if carried out with care, is efficient and safe. Further, the comparative figures, although admittedly still limited in their scope, suggest that by means of avertin we are protecting the lives and promoting the recovery of our patients.

Conclusions.

1. Employed according to a method tested by experience, avertin is a safe anaesthetic.
2. From the point of view of the patient's sensations, both during induction and in the post-operative phase, it is greatly superior to inhalation methods.
3. With it, post-operative sickness and pulmonary complications are minimal.

4. The special dangers are those that arise from respiratory depression and lowering of the blood pressure. In this series these risks have not proved serious, and were outweighed by the great advantages gained in other respects.

5. In about 75 per cent. a greatly reduced inhalation anaesthesia with ether has been used to supplement the avertin, and with this the results have been satisfactory.

Clinical and Laboratory Notes.

A CASE OF INTUSSUSCEPTION IN ACUTE LYMPHATIC LEUKÆMIA.

By J. H. THOMPSON, M.B. LOND., F.R.C.S. ENG.,
RESIDENT MEDICAL OFFICER, BOLINGBROKE HOSPITAL LONDON;
AND

M. M. POSEL, M.B., M.R.C.P. LOND.

As we have only been able to find one recorded case of intussusception in lymphatic leukæmia,¹ we think the following account may prove interesting.

The patient, a girl aged 4 years, was brought to the Bolingbroke Hospital on May 10th, 1929, complaining of colicky abdominal pain and constipation lasting for three days, accompanied by frequent vomiting during the last two days. The pain was chiefly centred about the umbilicus and upper abdomen. The temperature was 98.4° F., the pulse-rate 90, and the respiration-rate 20. The child was well developed and, in spite of a drawn, anxious expression, had a high colour in her cheeks. Her tongue was dirty but moist, and nothing unusual was found in the mouth, pharynx, heart, or lungs. The abdomen was slightly distended, particularly in the central part, and a vague mass was felt extending across the abdomen at about the level of the umbilicus. The mass was mobile and tender. Rectal examination was quite negative. A soap enema resulted in the passage of a large constipated stool, but the pain and vomiting continued and the mass remained.

A diagnosis of acute obstruction, possibly due to an unusual type of intussusception, was made and laparotomy was performed.

At the operation some clear straw-coloured fluid was found in the peritoneum and the mass proved to be an "enteric" intussusception, consisting of jejunum; the apex was to the right of the middle line and could be felt in the gut about nine inches from the neck. The intussusception reduced with ease to the last two inches and then only with great difficulty. The gut composing the apex appeared to be doubtfully viable, and moreover a small tumour about half an inch in diameter could be felt at the apex. This tumour, arising in the gut wall, felt firmly elastic and sessile. As it seemed likely to be a sarcoma, the gut was resected, its continuity being repaired by side-to-side anastomosis. The abdominal incision was closed without drainage. No splenic enlargement was noticed at the operation.

The patient, though in poor condition immediately after the operation, responded extremely well to ordinary anti-shock treatment. On the third day she had a good bowel action, and her abdomen caused no anxiety after the first 48 hours. It was noticed that, for so rosy-cheeked a child, she seemed to be strangely listless and apathetic, but in view of her excellent recovery from such a severe operation we failed to associate this with the insidious onset of leukæmia. She was discharged 28 days after her admission, her wound soundly healed.

Dr. W. Newcomb kindly examined the resected gut and reported that the tumour consisted of partially infarcted small intestine with considerable extravasation of blood into all coats. The mucosal surface was secondarily infected

¹ West Lond. Med. Jour., 1920.

with numerous pyogenic organisms, and there was a considerable infiltration of leucocytes. Dr. Newcomb was of the opinion that the hæmorrhage was secondary to this, and he failed to find any evidence of leukaemia in the gut itself.

A fortnight later the child was readmitted complaining of pain in the right leg of two days' duration. Her parents reported that since her discharge she had been in poor health but without any definite symptoms, apart from listlessness; there had been no vomiting and the bowels had been well open and the stools normal in colour.

Her temperature was then 101.4° F., her pulse-rate 130, and her respiration-rate 40. She looked ill, was pale, listless, and uninterested in her surroundings. There were a few petechia over the left clavicle and on the left arm. The mucous membranes were pale. There was no bleeding from the gums, nor was the mouth ulcerated. The fundus oculi, heart, and lungs were normal, and nothing abnormal was found on clinical or skiagraphic examination of the right leg. The spleen was now easily palpable about two inches below the costal margin. The liver was not enlarged, and there was no palpable enlargement of the lymphatic glands anywhere.

An examination of the blood, for which we are indebted to Dr. A. Piney, revealed: 2,752,000 red corpuscles; 28,600 leucocytes; and 70,000 platelets; hæmoglobin percentage of 45; and a colour-index of 0.83. A differential count showed: neutrophile myelocytes, 0.0 per cent.; monocytes, 1.2 per cent.; lymphocytes, 86 per cent. (and of these 84 per cent. were small non-granular); lymphoblasts, 1.3 per cent.; premyelocytes, 0.0 per cent.; and Turk cells, 0.7 per cent.

The child was treated with deep X rays, but with no benefit, and she was taken home, where she died a few days later. No autopsy was possible.

Unfortunately, no cytological examination of her blood was performed at the onset of her illness, and therefore we have only presumptive evidence that she was suffering from leukaemia before the operation. But, judging from the analogy of the very occasional occurrence of intussusception in what are eventually established to be cases of Henoch's purpura, we believe that we are justified in recording this as a case of intussusception arising in acute lymphatic leukaemia.

We wish to thank Mr. V. Zachary Cope and Dr. Stanley Wyard for permission to publish this case.

FOUR CASES OF SONNE DYSENTERY.

By H. E. MANSELL, B.M. OXON.,

WANDER RESEARCH SCHOLAR AND REGISTRAR TO THE CHILDREN'S DEPARTMENT, WESTMINSTER HOSPITAL.

The organism first isolated and described by Sonne¹ in 1915 has been widely recognised abroad. In 1924 Smith² reported its occurrence in Scotland, while two years later Frazer, Kinloch, and Smith³ concluded that it was the most common cause of dysentery outbreaks in Aberdeen. It was not described in England until 1926 when Channon⁴ described a case, and her case was atypical in not fermenting saccharose. Subsequently cases were reported by Clayton,⁵ Evans,⁶ and Clayton and Hunter,⁷ and Nabarro⁸ showed that *B. coli anaerogenes*, which he had frequently isolated at the Hospital for Sick Children, was identical culturally and serologically with *B. dysenteriae* Sonne. Kerin⁹ in his review of the subject concluded that the organism was a serological entity, distinguished from the *dispar* group by the fact that it was indol negative and xylose negative.

The present account relates to a small outbreak of dysentery in the children's ward of the Westminster Hospital, in which *B. dysenteriae* Sonne was isolated from the faeces in all four cases.

CASE 1.—A boy, aged 14, was admitted on Nov. 24th, 1929, with a history of diarrhoea of two days' duration. He came direct from an institution, of which he had been an inmate for the previous four weeks, and it has been found on inquiry that there were no other cases of diarrhoea there at the time,

and none developed subsequently. His temperature on admission was 102.4° F., and he presented a picture of extreme dehydration with sunken fontanelles and scaphoid abdomen. His illness ran a severe course for six days with moderate fever and 7-8 daily stools containing blood and mucus, after which he made a rapid recovery. Treatment during the early stage consisted in the oral administration of half-normal saline. This case was undoubtedly the source of the outbreak, which involved the three other children within four days.

CASE 2, aged 14, was convalescent after drainage of an appendix abscess, and developed fever (102.7°) and mild diarrhoea with blood and mucus in the stools on Nov. 26th. The acute stage lasted 48 hours, and recovery was rapid.—CASE 3, aged 14, a case of tonsilectomy, was discharged on Nov. 25th, and was readmitted the following day because of the onset of diarrhoea with the passage of fetid stools containing blood and mucus. Temperature on admission was 101.4°, and the diarrhoea and fever lasted for four days.—CASE 4, aged 12, a case of pyelitis, had a rise of temperature to 100.4° on Nov. 26th, and during the night passed six stools containing blood and mucus. The temperature was normal on the following day, and there was no further diarrhoea. In all four cases fat was withheld from the diet during treatment.

The stools were sown on MacConkey plates, and in each case bluish-white colonies were isolated, which showed the following characteristics. In subculture the surface of the growth became rough. Mannite, glucose, and maltose were acidified in 24 hours. Gradual and persistent acidity occurred in litmus-milk. No indol formation could be demonstrated. The times taken to form acid in lactose and saccharose are given in Table I.:

TABLE I.

Case.	Lactose.	Saccharose.
1	8th day.	Doubtful trace.
2	9th day.	10th day.
3	7th day.	11th day.

Emulsions of the organism in saline from agar slopes were agglutinated against the five Oxford Flexner sera, and also against the Oxford Sonne and polyvalent Flexner sera. The results are shown in Table II.:

TABLE II.

Case.	V	W	X	Y	Z	Polyvalent (1/5 of full titre).	Sonne (full titre).
1	—	—	—	—	—	+	+
2	—	—	—	—	—	+	+
3	—	—	—	—	—	+	+
4	Not done.					—	—

The organism isolated from Case 4 died rapidly in sub-culture and provided material too scanty for agglutination purposes.

Dr. A. D. Gardner, of the Oxford Standards Laboratory, has very kindly repeated the examination of the organisms and confirmed my findings.

The points of interest in this outbreak are firstly the extreme rapidity with which a case of dysentery may light up infection in a ward in spite of the most rigid precautions, and secondly the mild nature of the symptoms, which appears to be the rule in infection with *B. dysenteriae* Sonne. That a fatal result may ensue, however, is shown in the cases reported by Evans⁶ and by Clayton and Hunter.⁷ My thanks are due to Dr. Donald Paterson for permission to publish these cases, and to Dr. Braxton Hicks for his help and advice during their investigation.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY.

A MEETING of this Subsection on May 14th, with Mr. CECIL ROWNTREE in the chair, was devoted to a discussion on

RADIUM IN CARCINOMA OF RECTUM AND COLON.

SIR CHARLES GORDON-WATSON said that in 1927, in reporting to the subsection a series of 15 cases extending over less than three years, he had shown a woman, aged 37, whose fixed inoperable annular growth was treated by colostomy followed by perineal exposure and radiation with needles. This patient had gained much in weight, and was now in good health without any sign of recurrence. The case demonstrated that adenocarcinoma was not radio-resistant; also that when surgery was regarded as either hopeless or inadvisable, radium could, for the few, give a cure. But increased experience had shown that the percentage of failures in operable growths did not justify treatment with radium in preference to surgery, in the present state of knowledge, unless surgery was contra-indicated on general grounds, or unless the patient would not submit to colostomy and excision. Though he had treated over a hundred cases of carcinoma of the rectum with radium in five and a half years, he still felt that he required more experience before he could express definite opinions about the methods to be adopted or the likely results. But it would be useful to record some impressions.

A great stumbling-block was the difficulty of approach. If surgical access was easy, a good reason must be advanced for preferring radium to radical surgery. Some operable cases which seemed to offer good prospects had either responded and relapsed, or had failed to respond appreciably to radium, so that radical treatment by surgery was subsequently needed. How far preoperative radiation was a factor in preventing recurrence could not yet be stated. Dr. Cuthbert Dukes's recent work on the classification of rectal growths examined after excision had raised the question of the treatment of early operable growths. Dr. Dukes distinguished between the "A" case, in which there was as yet no infiltration of the muscular coat, the "B" case, in which infiltration had not passed beyond the muscular coat, and the "C" case, in which there was involvement of the perirectal tissues. His figures, based upon 100 cases, seemed to show that there was no danger of lymphatic spread in an "A" case or a "B" case, and therefore that local resection might be all that was needed to effect a radical cure. Dr. Dukes maintained that local resection might be accomplished, under the most favourable conditions, with restoration of function and without a serious stricture or a permanent colostomy. If, said Sir Charles, this could be established as surgically sound, considered from the point of view of risk of recurrences, it would be necessary to promise a high percentage of success with radium if radiation was to be given preference. At present this promise could not be given. Sometimes an operable growth which had been treated without colostomy retrogressed to a point, and then seemed to remain stationary owing to chronic sepsis.

Inoperable and Borderline Cases.

Individual standards of operability varied, but there was general agreement in defining the advanced inoperable case—i.e., the large, fixed, annular growth, which had infiltrated through the rectal wall in all directions. It was recognised that after colostomy—in the absence of liver metastasis—both the general and the local condition of the patient usually improved. If colostomy was followed by irradiation, it might not

always be easy to say whether general and local improvement was the result of irradiation or colostomy or of both. Sir Charles's own experience showed, even in cases submitted to colostomy some months previously and to irradiation, that rapid and marked general improvement followed irradiation, even in the absence of any definite local changes. The outstanding problem was to secure adequate and uniform irradiation, and for this a combination of methods was sometimes necessary. If at the time of colostomy the growth extended above the perineal reflection, it was essential to treat this portion from the abdomen, either by radon seeds or radium needles. The glandular area in the mesorectum was treated at the same time. Very large and advanced growths should not be dealt with by the posterior open operation, owing to the risks of perforation and secondary sepsis. Often these cases were much relieved by perirectal and intrarectal attack. In several instances an operable or borderline case had been treated with radium with such improvement that radical excision could subsequently be done. Thus it seemed that borderline cases offered the most useful field for irradiation, either as a forerunner of excision or as affording some prospect of cure.

Dealing with abdominal irradiation, Sir Charles said he began treating high rectal growths with radium through the abdomen in January, 1928, and had now treated 26 cases by the abdominal route. The method was not without risk, and he had lost one case from peritonitis. Great care was needed to avoid puncture of the bowel, which was more likely with needles than with seeds. The first stage of the colostomy was carried out at the conclusion of the radiation. When he used radium needles within the abdomen he had them filtered with 0.8 mm. of platinum.

Recurrence after Radiation.

The speaker's experience was that recurrence was more likely after using radon seeds than after using needles, perhaps because the needles gave a more uniform intensity, though this defect in the seeds might be partly mitigated by adding more radon at short intervals. He had no doubt that primary irradiation increased radio-resistance to secondary applications, and improvement of technique was a necessary condition to further advance.

In young people rectal carcinoma grew rapidly, metastasis was early, and the end-results of surgery were not good. An actively growing carcinoma in a young subject responded well to radium, and far better than a slowly growing carcinoma in an elderly subject. If a growth was adequately barraged with radium and showed little evidence of retrogression after two months, it was probably useless to repeat the irradiation; but if the growth responded to radium and retrogressed, further irradiation could be carried out, on the ground that the first dose was probably insufficient. Secondary irradiation was less likely to produce a good final result than an adequate primary irradiation, and it was more likely to produce neuralgic pain, which might be lasting. The criteria of a correct dose were: absence of sepsis, a well-marked radium film, rapid resolution of growth, restoration of normal epithelium, and a limited fibrosis. Radium had its uses, also, in improving both the local and the general conditions of an inoperable case, so that operation then became feasible. The treatment of cancer of the rectum by radium was still in the nursery stage.

Sir Charles Gordon-Watson exhibited his cinematograph film showing the operative procedure.

Discussion.

Dr. A. LACASSAGNE (Paris) said that neither new nor old techniques of radiotherapy had brought about the cure of rectal cancer, and the removal of this disease still remained primarily surgical. During the last ten years 50 patients were treated for this condition by radiotherapy at the Radium Institute of Paris, but most of the cases were so advanced that extirpation was out of the question.

Some of them when they presented themselves at the Institute had already been treated by other means. With the help of surgery, two of the patients had remained free of their cancer for four and eight years respectively. His view was that the poor results obtained in rectal carcinoma from radium were due to the low radio-sensitivity of adenocarcinoma of the rectum. The general conclusion of himself and his colleagues was that for malignant growths in this part of the body surgery remained the treatment, and hence radiotherapy was used only as a palliative in inoperable cases. The two favourite means of application were transcutaneous irradiation and telecurietherapy.

Mr. STANFORD CADE agreed that correct surgical excision of these growths gave the patient as good a chance of cure as could at present be hoped for. A similar statement was once made, however, in regard to buccal cancer; therefore, the attitude of the profession towards cancer of the rectum might conceivably be altered in a few years' time. In the selection of cases for irradiation the points which should influence the decision were: operability, the age and general condition of the patient, and the possibility of obviating colostomy. One difficulty was to avoid radium burns, for in order to irradiate strongly enough to bring about retrogression of the growth the strength had to be very near the toleration point of normal tissue. The growths needed pure gamma rays; when the multiple method was used beta rays were given off in the area. Filtration and screening were of the utmost importance. The intensity should vary with the nature of the cell concerned, with the presence or absence of mitosis, and its secretory activity. There was a threshold of intensity and one of time, and if these were not reached irradiation would be a failure. Uniform intensity could be gained by using the actual radium salt. Radium was the only means of treating cancer of the rectum which offered the possibility of avoiding colostomy, but for annular growths colostomy was unavoidable. Insertion of radium into the lumen of the bowel was the least satisfactory method of application; it could be no more than a palliative in otherwise unsuitable cases; it should then be supplemented by the inter-rectal interstitial method. Treatment by "bomb" irradiation was still under trial, and he did not think that generalisations could yet be made about it. Results should be classified as immediate and remote. In a small percentage of cases no obvious sign of disease remained three or four years after the use of radium; radium lessened hemorrhage, pain, and discharge, and if metastases occurred, they did so later than if it had not been used. Of 700 inoperable cases treated in this way 150 survived and remained in good health for quite an appreciable time.

Mr. J. P. LOCKHART-MUMMERY remarked that the radium treatment of cancer of the rectum must still be looked upon as experimental. Many of the results had proved disappointing, though occasionally brilliant results were seen. Filtration should never be less than 0.8 mm. and it might be well sometimes to go to 1.0 mm. With less than 0.8 mm. there was too much necrosis of the tissue surrounding the needles. His experience was that small doses given for a long time gave better results than large doses for short periods, and ten days was a better period of application than seven days, other conditions being equal. The greatest difficulty at present was that of dosage. The milligramme-hour formula he regarded as useless; to be of service the formula should include the cubic capacity of the growth, but as there was no means of measuring this it was better to go on without a formula. His own suggestion for a formula was cubic capacity of growth, multiplied by the number of milligrammes of radium, multiplied by the number of hours. Access was not difficult when the growth was low down on the posterior wall of the rectum, but with growths on the anterior wall, or high up, there were great difficulties. In the case of anterior wall growths he separated the

rectum from the prostate (in the male) and from the vagina (in the female), and placed lead foil covered with rubber tissue or other protective in front of the needles to prevent damage to bladder or urethra or the posterior vaginal wall. In women he preferred not to approach the growth through the posterior vaginal wall itself; it was better to dissect up the vaginal wall. For growths in the upper part of the rectum it was necessary to secure free general mobilisation. A large incision should be made, and the coccyx should be removed, and also, if necessary, a portion of the sacrum, the rectum also being mobilised as much as possible, so as to allow the needles to be accurately placed. He did not pack the wound, but closed it with threads inside it temporarily, and when the needles had been removed he drained freely in all parts. The lines of spread in the lymphatics could be treated at the same time. The greatest difficulty was experienced in irradiating the abdominal cavity. Here radon seeds were best, for needles placed in the abdominal cavity caused some peritonitis. He did not think preliminary colostomy was always necessary. One of the greatest difficulties was to deal with the wound after irradiation; the wounds presented a yellow "vasleather" slough on the whole surface, and they were very indolent. Treatment with antiseptics was useless and was liable to cause hemorrhages. They were best treated, he thought, with light packing with vaseline gauze, or gauze soaked with oil. Overdosage with radium was liable to cause excessive fibrous tissue formation, and many of the early failures were due to overdosage rather than to underdosage.

At present the best results were obtained in the early operable cases, in which radium was used because there was some contra-indication to resection. But he did not think that radium treatment for rectal cancer had yet given such good results as to justify its use as a substitute for operation, though it might be useful in conjunction with operation in allowing more local resections to be carried out. By using a combination of the two methods he had several times saved a patient from colostomy, and the results had been satisfactory. The best results he had seen had been in cases of epitheliomata; here the disappearance of the growth began any time after the first six weeks, and, in a good case, it was then rapid. The site of the growth became normal tissue and was smooth and soft, and there was no sign of there having been a growth. Radiation was particularly suitable in very old people who, usually, were not good subjects for surgery, and if the growth was detected fairly early colostomy would not be needed. Radium in the treatment of rectal cancer had definitely established itself as a means of getting rid of the growth in suitable cases, but at present its greatest use seemed to be as an auxiliary to surgery.

Mr. W. S. PERRIN said that many of his inoperable growths in this region were substantially relieved by radium. He preferred the needles put into the abdomen, but they could be put in from the outside through the skin round the anal margin. He referred to his use of radium in four operable cases. The first was in a man aged 63, whose growth was 4 cm. in diameter and was on the posterior rectal wall, a typical adenocarcinoma. He was given 6000 mg.-hours. The perineal wound healed in a month, and he was back at work in two months. He had been kept under observation 20 months, and remained well, except for a small lump, a piece of which was pronounced to be normal tissue. Another was a man aged 48, with a similar growth, and he had 6800 mg.-hours. Later he had two small sinuses which took four months in healing. Three small lumps remained, which Mr. Perrin tried to get rid of by means of radon seeds. On failing to do so he then resorted to diathermy. In neither of these men was colostomy performed. The third patient was a woman aged 60. Ten months ago he gave her 6800 mg.-hours irradiation, but the growth was unaffected. She remained in hospital two months,

then went to a convalescent home, but returned with the wound broken down and a perineal fistula, with the faeces discharging through the perineum; indeed in a lamentable condition. He did a colostomy upon her, and the wound was not yet healed. The fourth case was, like the third, operated upon ten months ago, and the patient was a woman, aged 56, with a larger growth. She was given 7600 mg.-hours, and she had severe pain. The perineal wound did not heal, and she had to have a colostomy. After that experience he did not feel justified in recommending radium for operable growths of the rectum if surgery was possible.

Mr. LIONEL NORBURY commented on the way in which apparently similar growths reacted differently in different patients. He exhibited a specimen from a case which had failed to react to radium, and the only reason he had gleaned for this was that the growth was very colloid, and so was radium-resistant. There was a great field in the direction of increasing the radio-sensitivity of growths. In deep X ray therapy effects were enhanced by painting the area with fluorescein, or giving that substance in capsules by the mouth.

Mr. E. T. C. MILLIGAN said radium offered a means of treatment with the hope of good results in carcinoma of the anal canal and anus. When radium burns followed treatment of rectal growths by this method, the conversion of the burn into a diathermy burn would abolish the pain and produce healing. He was indebted for this valuable advice to Dr. James, of America.

Dr. JAMES confirmed this last remark, and referred to several cases.

Mr. W. TURNER WARWICK said the majority of growths seemed to react better to a small dose used for a long time than a large dose used for a short time. In assessing the type of growth, he thought the layer involved and the type of tissue reaction should be taken into consideration. Until these matters were placed on a standard basis he did not think one could even begin to argue whether radium was suitable or unsuitable.

Dr. CUTHBERT DUKES pointed out that the classification which had been made of these growths into A, B, and C was from the point of view of prognosis, not as to how the radium should be given. It had been found that there were no lymphatic metastases until the growth had spread into the perirectal tissues. The grouping of these growths according to the type of malignant cell was of no use in rectal growths because they were always heavily infected by bacteria.

The PRESIDENT in closing the discussion referred to the great duty of the surgeon to fortify himself with all possible information so that he could best advise educated people about their particular case. These patients had an especial horror of colostomy, and would avail themselves of anything which would obviate it. Team-work would, it was hoped, succeed in bringing to a practical issue the important question of radio-sensitivity.

SECTION OF UROLOGY.

At a meeting of this Section on May 22nd, with Mr. FRANK JEANS, the President, in the chair, a discussion took place on the

TECHNIQUE AND RESULTS OF PROSTATECTOMY.

Mr. KENNETH WALKER, in opening, said he had for some time been impressed with the differences in technique followed by surgeons in England in doing prostatectomy. The nearer one got to perfection the less was there likely to be variation in practice, and the fact that technique varied so greatly surely meant that perfection was still a long way off. He hoped speakers would lay stress on their failures and difficulties rather than on their triumphs.

The three major difficulties encountered in convalescence after this operation were hæmorrhage, sepsis, and perhaps post-prostatic obstruction.

Hæmorrhage he regarded as the most serious of these. In earlier days when doing the Freyer operation he tried packing when oozing occurred, and there were many failures from it, one of the chief disadvantages being the necrosis and the unpleasant state of the bladder and urine when the packing was removed. Then for two years he employed bags, but he had several cases in which bags did not satisfactorily control the hæmorrhage; in many cases they did not exert uniform pressure on the prostatic cavity. When Sir John Thomson-Walker read his paper on the open method of prostatectomy, it was clear that it was a step in the right direction; it was an attempt to convert a blind method into one of precision and control under the eye. But, though the operation was often excellent, there were cases for which it was manifestly unsuited—at any rate in the speaker's experience—for the extra time required was dangerous or might be fatal. Some had prostates very low and difficult to expose, and for these he had given up the operation. From Australia had recently come an attempt at even greater precision, by Harris. Mr. Walker had not yet had enough experience of it to enable him to pass a final judgment on it, but he knew that with a sharp boomerang needle considerable hæmorrhage could be caused by putting into position lateral sutures for obliterating the canal.

The surgeon must vary his technique with the particular patient. Wherever he could Mr. Walker performed the open operation; and he did not spend a long time in trying to secure bleeding points deep in the prostatic cavity. If bleeding did not cease after placing the suture he packed lightly. Recently, in the cases not suited for the open operation, he had gone back to packing, because he found that with a tube and mercurochrome frequently instilled the severe sepsis could be got over. Hæmorrhage might occur three, five, or more days after removing the packing, apart from secondary hæmorrhage, so he now left the pack in for six or seven days. The chief disadvantage of that was that it increased the amount of painful spasm from which the patient suffered. He did not tie and leave in a catheter at the time of the operation, but he found a catheter was useful a little later in draining the rather septic bed of the prostate, and, still later, during the final stages of convalescence and the healing of the wound. He had had too many cases in which the bladder mucous membrane had become adherent to the scar, and so required secondary suture. He asked what was the reason for that.

Three Operations Compared.

Mr. SWIFT JOLY said that the cases he had dealt with at St. Peter's Hospital could be grouped under three main operations. The first was the old Freyer operation, of which he had had 198 cases, with 19 deaths (9.5 per cent.). Four of those deaths occurred the first day after the operation, and were due to a combination of shock and hæmorrhage. Next he began packing his cases, having special packs made of vaseline gauze soaked in acriflavine. This method was used in 159 cases, and among these he had had 14 deaths (8.8 per cent.). In this series none of the patients died immediately after the operation; one death occurred as soon as the packing was removed, but the other fatal cases were in the second or third week. The third operation, of which he had had considerable experience, was that of Thomson-Walker, and it had given him the best results of any. He had done this in 207 cases, and the deaths numbered 17 (8.4 per cent.). In changing from one operation to another he had experienced a gradually decreasing mortality. In the last series of cases the deaths were from the following causes: one from a possible pulmonary embolism on the ninth day; one from myocarditis 15 days after operation; one from influenza in the third week; four from pneumonia or broncho-pneumonia (two of these died during an epidemic of influenza in the ward and two from pyelonephritis). With the use

of the Thomson-Walker method the immediate deaths were wiped out; he attributed this result to more perfect hæmostasis and to the fact that cases were certainly less septic. With the use of the flaving pack the chief trouble was pain, and there was liability to hæmorrhage after removal of the pack. Hæmorrhage was more common in convalescence when packing was employed than when it was not. He would now be sorry to go back to any operation other than the Thomson-Walker, especially as the ensuing shock was practically negligible. A series of blood pressure examinations showed that when local anæsthesia was employed there was no fall of blood pressure during the preliminary incision and the cutting into the bladder, but there was a fall during the enucleation of the prostate, and the fall continued during the stitching up of the prostatic neck and carrying out the general toilet of the wound. Then the blood pressure rose again. After the Freyer operation nearly every patient had a permanent pyuria; but by means of a flaving pack one could get rid of that in a month. Now, after doing the Thomson-Walker operation, 20 per cent. to 30 per cent. of the patients had clear urine when they left the nursing home or hospital, and it was clear still a month after they left the hospital. And this was the only operation after which he had not had recurrence at the neck of the bladder after operation. He had tried, at one time, what was practically a Harris operation, but there was a bad secondary contraction afterwards. The flap he made lived, but the stitches cut out and the urethra separated from the bladder. In another case the flap became septic and sloughed away, and the patient was worse off than before. The prostatic bed was not an ideal site for doing a plastic operation. It was well known that in plastic surgery complete asepsis was a *sine qua non*, but that could not be obtained in this region after prostatectomy.

Technique and Management.

Mr. JOHN EVERIDGE said the preliminary treatment of the patient before doing prostatectomy was very important. A few days spent in hospital or nursing home before the operation was a great advantage; it enabled the patient to get accustomed to the surroundings and the diet and the regulation of the bowels. The mouth should be clean, and if defective teeth were present they should be removed before the operation if possible. The anæsthetic he preferred was light open ether with novocain infiltration of the rectus muscle. He liked stovaine for these cases. He regarded the Thomson-Walker operation as ideal. When it was properly done, post-operative obstruction was almost impossible. If that operation was not possible, he carried out a two-stage operation, the second one possibly having to be delayed as long as three weeks. After the Thomson-Walker operation post-operative hæmorrhage was to a large extent prevented, though in some cases there was oozing from the bottom of the cavity. For that he employed a light gauze packing. At one time he had avoided using a bag, since it might cause a disarrangement of the sutures; but he had now returned to it. Prolonged pressure with the bag meant a risk of sepsis. When a bag was not used, there were advantages in tying in a catheter for this made continuous or intermittent irrigation possible. Most of his deaths following this operation had been due, directly or indirectly, to hæmorrhage. A common post-operative complication was fleus. He put a small tube into the rectum in these cases at the end of the operation to facilitate escape of flatus; furthermore, nourishment could be introduced into the rectum through the tube. In 150 cases he had eight deaths, due directly or indirectly to hæmorrhage. In most of these the patient was being looked after by someone else at a distance away, and perhaps more expert care might have prevented some of the deaths. In two death occurred within 36 hours of the operation; hæmorrhage had been going on all the time. Two deaths occurred from hæmorrhage

when the gauze packing was removed; in four the hæmorrhage came on at about the sixteenth day after operation, when the wound was almost healed. In four primary shock killed the patients. One death was from pneumonia, and one (on the fourth day) from embolus. In that series his mortality was 10.7 per cent. After the one-stage operation his deaths were 9.7 per cent., and after the two-stage 12.3 per cent.; but the latter was chosen in the worst cases—i.e., those with a higher mortality risk.

Mr. CLIFFORD MORSON said he was a supporter of the open method of suprapubic prostatectomy, not only for adenoma or simple enlargement of the prostate, but also for carcinoma. His technique was similar to that introduced by Sir John Thomson-Walker, except that he did not tie in a catheter at the time of the operation. The catheter, he considered, added to the patient's discomfort; it did not drain well, and served no useful purpose if a posterior flap of mucous membrane had been successfully dealt with. As regards immediate results, Freyer's operation gave mortality rates so low that they had never been surpassed. But prostatic obstruction occurred afterwards too frequently, and the Thomson-Walker technique had eliminated that. Rapidity of operation was very important. Hæmorrhage did not cause shock, but rough handling of the tissues did. The danger of infection of the seminal vesicles had not yet been eliminated; it was caused by fracture of the ejaculatory ducts at the time of the enucleation. Within a short time these ducts were sealed up and the seminal vesicles then presented perfect culture tubes. To excise these vesicles at the operation unjustifiably increased the severity of the procedure. To prevent orchitis he had for nine years been isolating and dividing both vasa; he had been able to promise his patients they would never have orchitis. In the last 128 cases of prostatectomy carried out by him at St. Peter's Hospital—excluding private cases—26 were complicated—e.g., by stone, stricture, or diverticulum. The remaining 102 included cases of pre-operative retention and uremia. Of the 26 with stone, &c., two died, giving a mortality of 7.69 per cent. Among the other 102, seven died (6.8 per cent.). These 128 patients were in hospital for an average of 28.5 days.

The Thomson-Walker Operation.

Sir JOHN THOMSON-WALKER said that the operation he advocated consisted of a long incision, and enucleation with the fingers, after the Freyer method, the placing of the patient in the Trendelenburg position, exposure of the base of the bladder, removal of nodules and tags, and enlargement of the opening from the bladder into the prostatic cavity, followed by control of the hæmorrhage, either by a continuous suture or by a suture round each vessel which was seen to be bleeding. If this did not stop the bleeding he did not prolong the operation by looking for bleeding points, but packed round the catheter which he had drawn into the bladder. After that it was important to prevent pelvic cellulitis. He always retained a catheter to aid washing out, not for drainage at this stage; more and more he did continuous irrigation, and that was easy with a retained catheter and with bags. Bags were very useful in after-treatment; boric crystals were placed in the box, and when the urine trickled down it formed with the crystals a boric lotion, thus producing an antiseptic atmosphere round the end of the catheter, and he also dressed the penis. He had a preference for constant irrigation with very weak nitrate of silver solution, and that could be carried on three or four days after the operation.

The objects of his operation were to prevent sepsis, to control hæmorrhage, and to prevent obstruction, and he thought it went far to prevent those three grave complications. During the last six years his private patients had passed urine on the eleventh day after the operation, on the average, and the wound was dry on the sixteenth day. He agreed that not

all cases could be treated by this method; there was no operation in surgery into which every case could be fitted. In cases of severe infection of bladder and kidneys it was necessary to drain the bladder by suprapubic cystotomy. When secondary prostatectomy had to be done he used the Freyer method. In very old and feeble patients, or those with serious complications, such as bronchitis, his object was to get through the operation as quickly as possible; placing the patient in the Trendelenburg posture might be too severe, and he did the operation by the closed method. In the 11 years 1919-29 he had done 472 prostatectomies for simple enlargement, and his mortality was 5.2 per cent. He thought that the mortality figures in private cases were better than in hospital cases because the patients were treated in separate and cosy rooms, and were attended by expert nurses and the surgeon. This expert attention was also given in St. Peter's Hospital. It was not necessary to retain the packing longer than 48 hours. If, on removing it, bleeding occurred, the pack should be replaced. He agreed about the danger of ileus as a complication, but thought it was due to toxæmia.

Further Discussion.

Mr. G. E. NELIGAN said he did not encourage his patients to pass urine within three weeks, especially as healing took quite that time, and urine was an irritant fluid. His mortality in 100 cases was 5 per cent. Secondary hæmorrhage took place in two cases, and each of those started passing urine before three weeks. The hæmorrhage was controlled by a Pilcher's bag, and one of the patients had incontinence afterwards. In three cases there was inflammation of the vas, but it did not go as far as the testicle, for he had cut the cords. Four had pulmonary embolus, of which one case was fatal, and four were found on section to have carcinoma in the adenoma.

Mr. H. P. WINSBURY WHITE remarked that until the urological surgeon had gained considerable experience he would be wise to do the two-stage operation.

Mr. JOCELYN SWAN agreed about the importance of making a long incision, to permit the surgeon to see everything; he also attached great importance to anchoring the prostate before dealing with it. Pilcher's bag he had found of great use; he put it in after the operation and anchored it to the right thigh, and then put two tubes into the bladder—one large, one small. He always drained the prevesical space with corrugated rubber. He expected his wound to be healed in 17 days. He did not hesitate to insert a catheter and use it for drainage.

Mr. CYRIL NITCH said that in 100 cases he did the one-stage operation in 41, with 9 per cent. mortality, and the two-stage operation in 59 with a 10 per cent. mortality. In his 100 cases secondary hæmorrhage occurred in seven, and epididymitis in eight.

The discussion was continued by Mr. S. G. MACDONALD, Mr. J. B. MACALPINE, Mr. E. W. RICHES, Mr. E. T. C. MILLIGAN, Mr. HOPE CARLTON, Mr. HAROLD DODD, and the PRESIDENT. Mr. KENNETH WALKER replied.

HOSPITAL ACCOMMODATION AT WORCESTER.—An official report has been issued of a conference upon the hospital accommodation of the city of Worcester between representatives of the corporation, medical men, and Worcester General Infirmary. Dr. A. J. B. Griffin, the city medical officer, pointed out that the existing services were unable to meet the medical and surgical needs of the citizens, and suggested that the pressure might partly be met by using the Shrub Hill Infirmary, formerly the workhouse infirmary, which would involve an improved nursing and an augmented medical staff. The conference decided in that sense, and the details will be settled later. Meanwhile the public assistance committee has had the word "Workhouse" chipped from the stone tablet on the front, and the words "Municipal Homes" substituted.

Reviews and Notices of Books.

HEREDITY IN MAN.

By R. R. GATES. London: Constable and Co. 1929. With 87 illustrations. Pp. 385. 24s.

THIS is in effect a completely revised and much enlarged edition of the author's "Heredity and Eugenics," published in 1923; the section on twins and the inheritance of twinning is omitted and we are promised a full treatment of the topic in the next edition. After a general account of the theory of Mendelian inheritance, there follow chapters on stature, hair and eye colour, and blood groups, and nine chapters on various diseases and defects; acholuric jaundice is quaintly placed among "metabolic defects" instead of in "diseases of the blood system." We then have a chapter on the inheritance of mental differences and finally, the longest and to many people the most interesting, on racial crossing. The whole is an extraordinary mine of information, and Prof. Gates has succeeded as well as could be expected in writing up a catalogue as a readable tale. The book is written quite frankly from the Mendelian point of view, and Prof. Gates has little to say of the mass studies of statistical biometry, though we should have thought that, at the lowest valuation, these had contributed something substantial to our knowledge of the inheritance of stature and of length of life; the latter incidentally appears to be nowhere mentioned, though we are told on fair authority that it is one of the best proved examples of an intensely heritable quality in man. Prof. Gates's outlook doubtless reflects his considered opinion of the constitution of living organisms, that they are made up of discrete heritable units. But it also has a definite and very useful object—to persuade those who make observations on human inheritance that they cannot possibly neglect the Mendelian point of view and must in observing and recording constantly bear in mind the possibility of alternative inheritance and segregation. At the end of the book he gives some striking examples of the segregation of racial characteristics in human hybrids. He accepts the main races of mankind as good species in the ordinary zoological sense, and points out on the one hand how man's wandering habits have led to a great deal of racial mixture and on the other how his liking for stopping at home has resulted in stabilisation and apparent purity. He marshals much evidence to show that the crossing of widely divergent human races produces on the whole an inferior progeny liable to various disharmonies, and it seems evident that if all mankind is to be mixed up into one hybrid race the process should proceed by gradual steps rather than by the direct union of nordic with negro. Such are some of the subjects which are discussed, and we heartily commend the book to all who are interested in human beings. The investigation of human inheritance is difficult and slow, but a great deal of progress has been made in recent years, and it is more certain than ever that it will soon be one of the most important parts of preventive medicine.

MALE DISORDERS OF SEX.

By KENNETH M. WALKER, F.R.C.S., late Hunterian Professor, Royal College of Surgeons of England; Lecturer in Venereal Diseases, St. Bartholomew's Hospital; Surgeon in charge of Genito-Urinary Cases, Royal Northern Hospital, and St. Paul's. London: Jonathan Cape. 1930. Pp. 191. 5s.

THIS book on sexual disorders is written for the general practitioner, not from the standpoint of a psychologist, but from that of a genito-urinary surgeon who calls psychology to his aid whenever he

considers it necessary. The general scope of the work will readily be grasped from an enumeration of the headings of the main chapters, which deal with such subjects as impotence, prevention and relation to marriage, homosexuality, masturbation, continence, and sterility. Mr. Kenneth Walker has approached these subjects with a knowledge of their deep importance from the psychological as well as the physiological standpoint, and has maintained a just balance between the conflicting fields of suggestion, medical treatment, and surgical interference. He discusses the controversial points involved with an admirably balanced judgment, which is particularly valuable in the section dealing with Voronoff, Steinach, and the claims of organotherapy in impotence. The chapter dealing with continence is sane and helpful. So much intemperate writing has circulated round this that Mr. Walker's sensible views are refreshing. Another important section is that dealing with sterility in the male, its detection and treatment. This is a subject which is attracting more attention than formerly, the comfortable old view that sterility was practically always the fault of the woman having been proved inaccurate.

It must have been difficult for the author to compress so much material into the space allotted him, and indeed in some places the text shows signs of excision. We should have liked to have seen the name of Acton, the British pioneer in this subject, mentioned somewhere in the text, and for a bibliography, however brief, we should have been grateful. But, apart from these mild criticisms, we have nothing but praise for the book. It is a practical work which should be in the hands of every practitioner.

TUBERCULOSIS.

The Modern Surgical Treatment of Pulmonary Tuberculosis. By BERNARD HUDSON, M.D. Cantab., M.R.C.P. Lond., Medical Superintendent, Victoria Sanatorium, Davos-Platz, Switzerland. London: Jonathan Cape. 1930. Pp. 128. 5s.

OPERATIVE procedures in the treatment of pulmonary tuberculosis have shown striking advances under modern technique and Dr. Hudson deserves congratulation for an excellent summary of the present position. The limitations as well as the advantages of each procedure are discussed impartially and the views expressed are mostly those of the author himself, based on his considerable experience as a physician at Davos and Montana. The first half of the book is devoted to artificial pneumothorax, the indications and contra-indications are mentioned, and methods of dealing with various complications are described. Of special interest is an account of Dr. Maurer's method of cauterising pleural adhesions. The value of oleothorax in maintaining the collapse of the lung is indicated. Thoracoplasty is a more serious procedure but in skilled hands is now far less dangerous than it was a few years ago. It should not be advised unless the patient has fair resistance, as indicated by the presence of fibrous tissue. A preliminary phrenectomy is usually performed. The possibilities of plombage or pneumolysis are also discussed, but this, like the old operation of external cavity drainage, has largely fallen into disuse.

The book is well written and contains a great deal of information in a small space.

HANDBOOK ON TUBERCULOSIS.

By B. S. KANGA, M.D., D.P.H., Medical Officer, Turner Dispensary and Visiting Medical Officer, Turner Sanatorium, Bombay. London: John Bale, Sons and Danielsson, Ltd. 1930. Pp. 150. 5s.

THIS little volume has been written to place before medical students and practitioners in India a summary

of modern views on tuberculosis. The author has included all forms of tuberculosis, separate chapters being devoted to disease of the bones, joints, eye, ear, and other systems. It follows therefore that only the briefest space could be given to each subject and that much matter of the first importance has had to be omitted. Some of the views expressed are not now accepted by most authorities, but in most doubtful questions alternative opinions are given.

PHYSIOLOGY OF ORAL HYGIENE AND RECENT RESEARCH.

Second edition. By J. SIM WALLACE, D.Sc., M.D., L.D.S., Lecturer on Preventive Dentistry, King's College Hospital. London: Baillière, Tindall and Cox. 1929. Pp. 228. 10s. 6d.

THE second edition of this book has been enlarged considerably by the addition of various lectures and contributions to discussions. That part of the book which appeared in the first edition in 1923 has, however, been reprinted in extenso, without revision, with the result that certain statements about vitamins which represented views then have now become out of date. Dr. Sim Wallace's views have become almost classical. The reiteration of his teaching has doubtless been an important factor in gaining some measure of acceptance for it, though it has deprived this volume of any fresh appeal. The persuasiveness which characterised his earlier books is lacking and the sober, reasoned criticism which he used to apply to other theories of dental caries is replaced by a more carping attitude. Is there really such antagonism between Dr. Sim Wallace's views and those which are based on animal experiments with diets varied in their vitamin content? Granted that the immediate cause of dental caries is the fermentation of carbohydrate foodstuffs in contact with the teeth would it necessarily follow that the structure of the teeth is unimportant? While there is much clinical evidence to support Dr. Sim Wallace's theory that the sticky quality of the food promotes caries, yet every dentist is familiar with cases in which the quality of the food fails to explain a susceptibility to caries. Equally, every dentist sees cases in which the principles of prevention, as laid down by Dr. Sim Wallace, are flagrantly violated and yet there is an immunity to dental caries. On clinical grounds it appears to us difficult not to believe that the structure of the teeth is intimately bound up with the question of susceptibility and immunity to dental caries. The experimental work of Prof. and Mrs. Mellanby strengthens this belief, but even if this work had never been done, there would be abundant reason to think that defective structure was an important predisposing factor in the production of caries.

CORONARY THROMBOSIS:

Its Various Clinical Features. By SAMUEL A. LEVINE, Senior Associate in Medicine, Peter Bent Brigham Hospital, Boston, Mass. London: Baillière, Tindall and Cox. 1929. Pp. 178. 13s. 6d.

THIS book brings under one cover the information contained in the literature on coronary thrombosis, a condition which till comparatively recently was not generally recognised as a clinical entity. In addition to reviewing the etiology and the various clinical features, including electrocardiographic changes, the events of an acute attack are described and atypical forms and complications are considered together with differential diagnosis. The question of treatment is discussed in more detail than in any previous publication known to us, several points of particular interest being introduced. It is suggested that in the event of extreme pain, where morphia has

failed to secure relief, light ether anaesthesia may be used; in this country some practitioners might hesitate to adopt this humane suggestion for fear that, should death occur, a coroner's court might find that it had been accelerated by the anaesthetic. Dr. Levine notes that oxygen is of definite value in cases with gross oedema and cyanosis. Stimulation of the heart in the early stages is considered inadvisable; the sluggish contractions are to be looked on as a safety mechanism and for this same reason digitalis should be withheld at the early stages of the illness. Among the complications demanding special treatment the author mentions ventricular tachycardia, the onset of which can, he considers, be diagnosed in some cases without an electrocardiographic record; quinidine is the drug to use in this emergency which, if untreated, will probably prove fatal. A very complete description of the morbid anatomy of coronary thrombosis is given by Dr. Levine, and a large section is devoted to a series of case reports. In his historical survey Dr. Levine notes that we are indebted to the careful observations of practising clinicians rather than to the work of experimental investigators for our knowledge of this disease.

MEDICINE AND THE LAW.

Workmen's Compensation: the Certifying Surgeon's Certificate.

MINER's nystagmus, as is well known, is one of the diseases which, ever since 1907, has been included in the third schedule of the Workmen's Compensation Act. Disablement due to this disease is, by virtue of Section 43, equivalent to personal injury by accident arising out of and in the course of employment; compensation is recoverable from the employer who last employed the man during the 12 months in the employment to the nature of which the disease was due. The Section further provides that the date of disablement is to be such date as the certifying surgeon certifies as the date on which the disablement commenced or, if he is unable to certify such a date, the date on which the certificate is given. There has been doubt whether the certifying surgeon's certificate of the date of disablement was conclusive. This doubt has now been resolved by the highest judicial tribunal in a Scottish case (*Wilson's and Clyde Coal Co. v. Flynn*, reported in the *Times* of May 21st) in the following circumstances.

In 1925 a miner was disabled by miner's nystagmus and, after a period of total incapacity, was paid £70 in discharge of his claim. In February, 1927, he was employed underground, and in the following November he was again disabled from the same cause and, after a period of total incapacity, was again paid £70 in discharge of his claim. From that point he was unemployed until on Feb. 14th, 1929, he went to work for the appellants as an underground miner. The arbitrator, from whose findings the above facts are taken, found that on the last-mentioned date the man was still suffering from miner's nystagmus and had not recovered from his previous disablement. After working for two hours the miner complained of headache, left the pit, and did not return. Four days later the district certifying surgeon certified him to be suffering from the disease and to be thereby disabled from earning full wages in that employment; the certificate stated that disablement began on Feb. 15th. An appeal to the medical referee was dismissed. The arbitrator refused compensation, holding that when the miner entered the appellant company's employment in 1929 he was suffering from the nystagmus contracted before November, 1927, and that thus his disablement in 1929 was not due to his employment by the appellants during the statutory period of 12 months before the 1929 dis-

ablement. This finding raised the question whether the arbitrator could go behind the certifying surgeon's certificate and say that the date of disablement was some date different from the date in the certificate. The Court of Session in Edinburgh by a majority decision declared that on the interpretation of the Act the certifying surgeon's certificate is final and conclusive. The House of Lords says that this view is correct. The result has been represented as likely to cause the employers to suffer hardship, if not indeed injustice. The certifying surgeon is not exactly a judicial authority. He does not hear the parties. He gives the employers no chance of listening to the case which the workman puts before the surgeon or of adducing evidence on their own behalf. This is hardly consonant with natural justice. Nor are the immediate employers the only persons interested; there may be a liability on earlier employers for whom the workman has worked in the past 12 months. However, as usual, the judges are not concerned with what Parliament ought to have said but with what Parliament did say. Unfortunately, what Parliament said seems liable to lead, as in the present case, to an inequitable conclusion.

New Inventions.

AN IMPROVED RADIUM NEEDLE INTRODUCER.

THE instrument consists of a hollow trocar A, with a bevelled needle point. The trocar is slotted on its upper surface, and in it passes the stylette B. C is a revolving cylinder which measures $1\frac{1}{2}$ in. in length, and contains 12 chambers each slotted on their outer surface. These chambers are for the reception of the radium needles. Each chamber is loaded with a threaded needle before use, and the threads are

drawn out of the slots on the outer surface, and pass beneath the small metal flange D which anchors them until they are required. E is the handle by which the instrument is held. The trocar is first introduced into the tissues with the stylette in position. When the required depth has been reached the stylette B is withdrawn. The catch F is a restraining catch and prevents it being drawn out completely. The cylinder is then rotated until the first chamber comes into line with the trocar. This point is automatically regulated by a ball catch. G, the stylette, is then pushed home, and the threaded needle is forced through the trocar into the tissues, the thread lying in turn in the slot on the upper surface of the chamber, and then in that of the trocar. The stylette is then withdrawn, the cylinder again turned until the next chamber is engaged, and a second needle introduced. Or the trocar may first be withdrawn and reintroduced at a fresh spot. The instrument saves much time.

Messrs. Down Bros., St. Thomas's-street, London, S.E., are the makers.

THE LANCET.

LONDON: SATURDAY, MAY 31, 1930.

THE EVANS CANCER CURE.

It is lamentable that the jury failed to agree in the action brought by Mrs. AMELIA BURRELL against Mr. DAVID REES EVANS, an unqualified medical practitioner and the proprietor of an alleged formula for the cure of cancer. Mrs. BURRELL's case was that the defendant promised to cure her permanently in three months by herbal treatment. She charged him not only with negligence but also with fraud. The grave feature of the case was that, before the defendant's treatment began, Mrs. BURRELL was in an operable condition, but, after three months' treatment, she was inoperable and incurable. After several days' trial Mr. Justice CHARLES left three questions to the jury: (1) Did the defendant make fraudulent misrepresentations to induce, and did he induce, the plaintiff to enter into a contract to be treated by him? (2) Did he warrant to cure her permanently in three months and was the warranty broken? (3) Was he negligent in his treatment of her? After being absent from court for three hours the jury said they could not agree on the first and third questions; as to the second question, they considered Mr. EVANS did not warrant to cure Mrs. BURRELL in three months. Describing this inconclusive result as extraordinarily unfortunate, the judge had no alternative but to discharge the jury. The plaintiff, of course, is free to recommence her action before another jury. A subsequent application on Mr. EVANS's behalf for judgment on the issue of contract was refused, the costs of the application being awarded to Mrs. BURRELL.

Regrettable as is the waste of time and money which the requirement of unanimity among jurymen occasionally imposes, the action has brought to light facts of wide interest. We now know from Mr. EVANS himself that his formula for the cure of cancer was accidentally discovered by his father (a farmer) and his uncle who, after experimenting with various remedies, successfully cured their brother of cancer of the lip. In his early days, the plaintiff tells us, he helped his father and uncle who dealt at Cardigan with 200 patients a day, working from 9 A.M. till midnight and only breaking off for tea. We know that Mr. EVANS has four formulae in all: one of them he uses for curing duodenal ulcer, an ailment which, he explained to the judge, is of the same family as cancer. We know that he was educated at the Cardigan County School and not at any university or hospital, even though the literature which he circulates may suggest the contrary. We know that the testimonials which he publishes are not spontaneous and that his booklet, entitled the Cardigan Cancer Cure, can be judicially described as "sodden with misstatements." Suggestions were made during the trial that the orthodox medical practitioners were jealous of the success of the Evans cure and declined to put it to the test. On the other hand, Prof. LAZARUS-BARLOW, for over twenty years director of cancer research at the Middlesex Hospital and a member of the Cancer Committee of the Ministry of Health, gave evidence that Mr. EVANS had (after questions had been asked in Parliament about his cancer cure) been invited to appear before the

committee. He came and brought with him printed and written documents, sworn statements, and photographs of cases which he wished to submit to the committee for investigation. The committee communicated with medical officers of health in the towns where the alleged cured patients resided, asking for information about the cases. In the majority of instances the patients were dead or had disappeared. In only two or three cases could the medical officers get definite evidence, and there was nothing to lead them to suspect that the suggested cure had ever taken place. The committee reported that they had not found sufficient evidence to carry the matter further.

Part of the publicity which the Cardigan Cancer Cure has enjoyed has been due to an article in *Light* by Mr. HANNEN SWAFFER who, in the evidence he gave for the defendant, described himself as a very well-known investigator of facts. We do not know the jury's opinion of this article but we know what the judge thought of it. "How any responsible journalist could write such wicked, misleading nonsense dealing with so terrible a thing as cancer," said Mr. Justice CHARLES, "I cannot conceive. I asked him 'do you know anything about cancer or how to recognise cancer?' and he replied 'I know nothing.' Yet he deliberately told the public that the defendant showed him photographs of malignant growths and cancers in bottles; I daresay the defendant did nothing of the kind." The evidence in the case, and the jury's inability to come to a decision upon the merits of the Evans treatment seem to show that there are many people who so trustfully believe in the magic of a secret and miraculous cure that they prefer the ministrations of an unqualified practitioner to all the known developments of medicine and surgery. Even their credulity is taxed when Mr. SWAFFER's article tells them that "Little is done in hospitals except to perform operations which only delay inevitable death." Mr. EVANS himself, it may be, viewed the prospects of the recent litigation with anxiety. At any rate he transferred his money into his wife's name a month after the issue of the statement of claim. Nevertheless he can claim that the jury accepted his statement that he did not warrant to cure Mrs. BURRELL permanently in three months. Simultaneously with these civil proceedings in London in Mrs. BURRELL's claim for damages, a herbalist named JAMES MASSEY was being tried at Manchester Assizes on a criminal charge of manslaughter. The prosecution called evidence to show that the accused, an unqualified practitioner, had treated a woman for some months and by criminal neglect and ignorance had aggravated her cancer; if properly treated, she would probably have recovered. He was found guilty and was sentenced to 15 months' imprisonment.

PUERPERAL SEPSIS.

In the middle of the eighteenth century CHARLES WHITE, the father of modern midwifery, conducted his practice in the poorest parts of Manchester for 25 years without losing a single case from puerperal fever. ROBERT COLLINS stated in 1835 that he did not have a single death which he attributed to this cause among 10,785 deliveries in the last four years of his Mastership of the Rotunda Hospital. On the other hand, WHITE said, "It is evident that by much the greater part of the sex will do well even under the worst treatment," and it is this problem which is so baffling. Why is it that a slight slip in technique will kill one patient, while others will recover without any symptoms after "the

the whole, concordant results.⁴ Of those who have investigated the histology of post-morbillar encephalitis some have found a purely hæmorrhagic encephalitis. Others have discovered a pathological picture which resembles so closely that of post-varicellar or post-vaccinal encephalitis that it must be grouped with them (F. WOHLWILL, 1928; and J. G. GREENFIELD, 1929). This group is characterised by zones of demyelination surrounding a large proportion of the vessels in the affected regions of the brain and spinal cord, and to it the name of "acute disseminated encephalomyelitis" has been given. This name, or to be more precise "fleck-like or disseminated myelitis," was used by C. WESTPHAL in 1873 to describe the condition of the spinal cord in two cases of acute myelitis following small-pox (probably the first cases of the kind to be examined histologically), and it therefore bears the authority of age. While it is sufficiently descriptive of the pathological process, a more precise and less elastic term would be better. For there has been a recent tendency in Germany to include in this group cases which have not the sudden onset of those which follow small-pox and vaccination and in which the lesions are less definitely perivascular in arrangement. There seems to be no doubt, however, that some cases of acute myelitis which have no relationship to a specific fever may present a pathological picture of this type. Two cases are described by GREENFIELD in the current number of the *Journal of Pathology and Bacteriology* of acute myelitis following a febrile attack labelled "influenza" in which changes in the spinal cord resembling more or less exactly the lesions found in post-vaccinal encephalomyelitis were found. Such cases should certainly be included within the pathological group of "acute disseminated encephalomyelitis"; but it is less easy to assign a nosological position to the encephalitis which follows other febrile conditions. Encephalitis following German measles has lately been described in France by DEBRÉ, TURQUETY, and BROCA,⁵ and last year in our own columns by J. H. E. BROCK. In their sudden onset and in their symptoms—which included neck rigidity, trismus, and myoclonic twitchings with unconsciousness—they resembled many of the cases which follow measles, but recovery was always rapid and complete. The fatal cases of scarlatinal encephalitis have usually been found to be hæmorrhagic in nature. Hæmorrhagic encephalitis also occurs after "influenza" and apart from specific fevers, and bears little or no histological resemblance either to disseminated encephalomyelitis or to encephalitis lethargica. The cases of "encephalitis" or of acute cerebral symptoms which may occur in the course of whooping-cough must, according to HILLER and GRINKER,⁶ be assigned to a different cause—viz., thrombosis or spasm of small blood-vessels. They have had the opportunity of examining a case in which hemiplegia came on without any relationship to cough, so that the cerebral ischæmia which produced the symptoms could not have been due to a purely mechanical cause. Other writers have found a hæmorrhagic encephalitis in whooping-cough as in other infectious diseases.

The encephalitis or meningo-encephalitis of mumps has perhaps more claim than any of the others to a direct relationship with the virus of the disease.

Not only are cases of encephalitis more common in this than in any other infectious disease (nine cases of encephalitis among 476 of mumps were reported by R. L. HADEN in America in 1919), but a lymphocytosis has been found in the cerebro-spinal fluid in a number of cases which presented no nervous symptoms. The most interesting cases are those in which the nervous symptoms either precede or replace the parotid swelling. Cases of the latter kind have lately been reported by WEISSENBACH, BASCH, and BASCH,⁷ who point out that, in the absence of an epidemic, or of the development of the typical parotitis in contacts, it may be impossible to make the correct diagnosis. The severity of the initial cerebral symptoms and the presence of a high lymphocytosis in the cerebro-spinal fluid may give rise to needless alarm, for recovery is almost always rapid and complete. A few cases have, however, proved fatal. The direct causal relationship between the encephalitis and the virus of the disease which is suggested by these observations is substantiated by the experiments of MERVYN GORDON, who in 1914 reported that he had produced a fatal meningo-encephalitis in monkeys by intracerebral inoculation of filtered saliva from cases of mumps.

It is clear, therefore, that encephalitis following the acute specific fevers may be of various forms. Not only may those which follow one fever differ from those which follow another, but more than one form may follow one kind of fever. More knowledge is needed on these points and on the controversial question of the causation of acute disseminated encephalomyelitis. In the meantime we shall be wise if we restrict the latter name to the cases in which a histological examination shows that this form of encephalitis is present, and reserve our judgment as to the nature of the encephalitis which may follow varicella and rubella.

"No quid nlmis."

EPSOM COLLEGE.

THE Council of Epsom College have instructed Messrs. Pite, Son and Fairweather, the well-known hospital architects, to prepare detailed plans and specifications and to obtain tenders for a new school sanatorium of 50 beds, estimated to cost approximately £25,000. It is hoped that the building will be completed in the autumn of 1931. With this decision the programme of improvements and extensions, commenced in 1924 and carried on steadily ever since, will be concluded except for relatively minor additions. Since that date there have been erected the war memorial chapel, a large chemical block, a new games pavilion, and a fine covered rifle range, with numerous other extensions to existing buildings. The erection of the new sanatorium will permit of the present one being turned into an additional house for 40 boys, bringing the total number of boys up to 440, and so enabling the admission of at least a moiety of applicants who now have to be declined. Sketch plans of the sanatorium were reproduced in these pages on Dec. 3rd, 1927, and only small modifications have been introduced into the final plans. These follow closely the lines on which the Ministry of Health consider that a model school sanatorium should be built, and the Council have received valued assistance from medical officers of other leading public schools in their aim to provide

such a building as will meet all likely needs for years to come.

Up to date only some £8000 has been received in response to the special appeal made to the profession; for this the Council have to thank generous individual donors, the British Medical Association, THE LANCET, the medical staffs of a number of hospitals, various societies and other bodies; it is hoped that still others will help to swell this sum materially, so that the Council may not have to draw largely on funds that they are anxious not to deplete. It is still open to a donor of £10,000 to give his own name or the name of any person whom he desires to commemorate to the main sanatorium, and a donor of £5000 may do likewise to a single block, while a large ward may be named for £3000, or a small ward for £1000, and a single bed for £100. All donors of ten guineas and upwards are entitled to votes, proportional to their donations, at the annual elections of Foundations and Pensioners, and such donors become life governors of the College.

Donations will be gratefully received at the Epsom College Office, 49, Bedford-square, London, W.C.1.

LYMPHATIC ANASTOMOTIC CHANNELS.

MANY anatomists are aware of inadequacy in the standard accounts of lymphatic drainage from particular regions or organs. These accounts do not meet the requirements of clinical work, usually because little or no stress is laid on the anastomoses between lymphatic fields. The lymphatic vessels of any region or structure have a developmental or segmental value, and their drainage paths are interconnected as are those of veins. The vessels are associated closely with the veins of a part and show, with these, those evidences of long descent which are often obscured in arteries. Dr. O. W. Roberts, in the April number of the *British Journal of Surgery*, calls attention to what he terms "the dorsal lymphatic system" as a common secondary anastomotic path along which the infection of a growth may extend to far distant parts. This anastomotic utilisation is a necessary consequence of the rapid obstruction of the direct path, and indicates the need for recognition of anastomotic fields. Though the dorsal lymphatic system has not been described, so far as we know, by previous writers, we have no doubt that Dr. Roberts is right in his postulate. The system might almost be assumed on general grounds; it would correspond with the intraspinal venous drainage, issuing intersegmentally, and the plaques of growth mentioned by Dr. Roberts would correspond with laminar radicles of the issuing spinal veins. Under these circumstances the associated glands would lie near the azygos veins—in other words, would be in the posterior mediastinum—and the infections as he describes them would follow of necessity. The broad and generalised results brought out in this paper, founded on the observation of 700 cases of malignant growths, cannot fail to be of interest; with regard to the dorsal system the pathologist has been able to go further than the anatomist, although the latter has good grounds for assuming its existence.

NUTRITION OF THE YOUNG IN FRANCE.

THE question is often raised whether individual taste and traditional habit are trustworthy guides to the choice of an adequate dietary. The answer so far as the civilised races of mankind are concerned is almost certainly no; for modern machinery and transport have made it possible for men to live cheaply on incomplete yet palatable foods which may in the long run induce profound bodily disturbance. In every civilised country at the present time the feeding of the population is being examined critically in the light of nutritional research, with particular attention to the child and adolescent, in whom the results of faulty diets are more easily recognised. In France, the traditional home of the culinary art, a proposal has been put forward for

the appointment of a Commission to inquire into the optimum dietary régime for children of various ages. The National Federation of Domestic Instruction is strongly in favour of the proposal, and its President, Mme. Moll-Weiss,¹ has appealed to the Académie de Médecine for support. Preliminary observations have convinced her of the need for comprehensive inquiry. She finds that the food given to children resident in institutions is monotonous and deficient in accessory factors, and only too often the same criticisms are applicable to the diets of children living at home. The breakfast of bread and coffee, almost universal, is condemned as quite inadequate to support a child through a morning of hard work. The midday meal usually comprises soup, fish or meat, a vegetable which is almost always of the dried variety, and cheese or cake; fresh vegetables and fruit are rarely served, and there would appear to be a genuine shortage of accessory factors in the diet as a whole. There is no uniformity in the quantities of basic foods allotted to children in different institutions. In one school a daily allowance of two ounces of dried vegetables is given, in another four ounces; here the meat ration may consist of two or three ounces of cooked meat, there one pound of raw meat. While it is recognised that a varied dietary is of the greatest value for any child, Mme. Moll-Weiss thinks there must be some limits to the variations in the quantities of essential basic foods compatible with optimum physical development. The feeding of young recruits in the services is considered to leave much to be desired. Not only do their dietaries fall short of the modern standards in respect of their choice of foods, but their meals are served in such primitive fashion that the young men must form the impression that food has no other function to fulfil than to satisfy hunger, whereas it would not be difficult to train them during their years of service into good feeding habits which would be of permanent value in improving the standard of nutrition throughout the country. The proposed Commission would be expected to formulate guiding principles on the nutritive requirements of the young; their recommendations would then be broadcast by specially trained teachers of domestic science familiar with the principles of hygiene, expert in constructing diets and cooking. It would be their task to see that the overlay of nutritional science does not banish from dining room and refectory the variety, the elegance, and the originality of the meals for which the French nation has so long been famed.

TUMOURS OF THE LACRYMAL GLAND.

DISPLACEMENT of the eyeball downwards without much proptosis usually suggests a frontal mucocele or a periosteal tumour, but it may also be due to a tumour of the lacrymal gland. This is a comparatively rare condition and the fact that a good many cases have been recorded in the literature is no proof to the contrary. Dr. W. L. Benedict² records that within the last three years five patients have been operated on at the Mayo Clinic for so-called mixed tumours of the lacrymal gland. These tumours are usually surrounded by a rather dense capsule, are slow in growth, lie in close contact with the superior orbital wall in the lacrymal fossa, may or may not involve the gland itself, and are easily removed by a brow incision when they are small. There are records in the *Transactions of the Ophthalmological Society of the United Kingdom* of these cases from 1882, when the late Mr. Henry Power showed a case under the title Fibro-sarcoma. Up till quite recently most of the cases have been called "endothelioma," but other titles have been "adenosarcoma," "lymphosarcoma," "cylindroma," and "adenocarcinoma." Perhaps the best plan is to use the non-committal term "mixed tumour," for the

¹ Bull. Acad. Méd., 1930, clii., 417.

² Proceedings of the staff meetings of the Mayo Clinic, April 30th, 1930.

pathologists are no more agreed as to their origin now than they were 30 years ago. The point of practical importance is that although these tumours in the majority of instances are non-malignant, in a certain number of cases they do recur locally and may even become malignant. Mr. Leslie Paton recorded a case in 1910 in which recurrence took place in the glands of the neck with a fatal result. The treatment while the tumour is still small is easy by means of a brow incision, but sometimes surgeons have had recourse to Krönlén's operation. In case of recurrence, exenteration of the orbit has sometimes been necessary. In 1916, after a second recurrence, Mr. Finzi employed radium with apparent success. Recently, in Dublin, Miss E. Maxwell (in 1929) treated a case, first with X rays, and then with radium, but the eyeball had, ultimately, to be removed. In a case which was shown by A. Hugh Thompson² in 1902 in which the ordinary surgical removal had been performed, and the lacrimal gland removed at the same time, a second orbital growth of a precisely similar nature but much smaller was removed 11 years later and there was no further recurrence. Dr. Benedict states that these tumours contain adenomatous, myxomatous, and myxosarcomatous tissue with occasional regions of bone or cartilaginous tissue. Some of them have a distinctly glandular structure, but they may be quite separable from the lacrimal gland and may arise either from accessory glands or possibly from embryonal tissue in the orbit, involving the lacrimal gland secondarily.

TREATMENT OF WAR STRAIN.

In a recent issue attention was drawn to the position of the neurasthenic ex-Service man when called upon to answer a police-court charge; his mental condition was often ignored and seldom investigated thoroughly. In civil life he was at an equally grave disadvantage, since employers were chary of engaging a man in an unstable nervous condition. Under the presidency of Sir Frederick Milner, the Ex-Services Welfare Society attempts to restore to such men their capacity to encounter the stresses of modern life. It is as disheartening for the society as for the man himself to find that he is unable to succeed in a post which has been found for him; and if it seems certain that commercial employment, with its attendant atmosphere of competition, will prove too great a strain the man is offered work in the society's industrial colony at Leatherhead. Neurasthenic patients, when working under conditions which relieve their anxiety, are painstaking and thorough, and at least capable of supporting themselves. The minimum wage offered by the society to those employed is £2 5s., but several of the men earn as much as £3 10s. New trainees are maintained free of charge at the associated hostel, and receive a weekly bonus of 7s. 6d. while training. Electro-radiant Thermega blankets and pads are manufactured at the industry, and are sold at a cost which compares favourably with foreign products of the same kind; as the directors and secretary of Thermega Ltd., are voluntary workers holding unsalaried posts it is possible to enter into successful competition with rival firms. Any profits go to the development of the industrial scheme. Medical and psychological treatment of the more serious cases is carried out at the society's homes; in many cases excellent results have been obtained among men who were previously incapable of supporting themselves. Lack of accommodation has proved a serious handicap in the past, but the society has recently taken over a new property, Eden Lodge, at Beckenham, where it will be possible to admit at least 40 more patients. The society undertakes, in addition, financial and advisory assistance; as the man with an anxiety neurosis is little likely to profit by any treatment if he is concerned for his family during his stay in hospital, the society undertakes the charge of

those dependent on him while he is under treatment. The freedom from anxiety on this score is found to benefit the patients considerably. In several cases where an early mistake in diagnosis or ignorance of his just dues has left the patient with an inadequate pension, the society has been able to make successful representations to the Ministry for an increase. The constructive work of the society, which makes a responsible productive citizen of the neurasthenic who has been dependent on others for years is of economic value to the whole community; the importance of such a metamorphosis to the patient himself can scarcely be imagined.

IMMUNITY TO WHOOPING-COUGH, CHICKEN-POX, AND RUBELLA.

THE first results of a research into the factors which control the spread of epidemics of chicken-pox, whooping-cough, and German measles were communicated to the Section of Epidemiology of the Royal Society of Medicine on May 23rd by Dr. Percy Stocks. After showing how recent work on diphtheria, scarlet fever, cerebro-spinal fever, acute poliomyelitis, malaria, and measles had fixed attention once more on the state of immunity of the attacked population as the main controlling factor in the spread of these diseases, Dr. Stocks described a new and simple statistical method of using the notification records of any infectious disease to elucidate the changes which take place in communal immunity. Hitherto it has been impossible to make more than a guess as to why certain children contract such diseases as whooping-cough or chicken-pox whilst others escape. The possibilities are inherent immunity, latent immunisation, or avoidance of infection, but there has been no evidence on the relative parts played by each of these factors. When compulsory notification of an infectious disease has been in force for some years in an area, and school records of contacts to cases of this and other diseases have also been kept, it should be possible in the future without employing any elaborate statistical processes to settle these points and thus to go far towards understanding the characteristic features of epidemics of different diseases and the most hopeful lines of preventive work. The method described by Dr. Stocks consists in (1) a study of the *index of apparent infectiousness*, which he explained in THE LANCET of April 12th, p. 786, and (2) a study of the *subsequent behaviour of contacts* over a period of years—compared with control groups of children not so intimately exposed to infection or immunisation. A simple application of the first method to the notification records of diphtheria in St. Pancras showed that, on the assumption that one-third of the children in the exposed population escape contact with infection, the proportion of those who are immunised by latent processes to those exhibiting clinical signs of the disease is approximately 5 to 1, a result which agrees with conclusions reached by Schick tests. A similar calculation for scarlet fever led at once to an equation between the proportion of children who retain an inherent immunity and the ratio of latent immunisations to clinical cases which was in close agreement with an equation deduced independently from records of Dick tests—thus if one-quarter to one-third of the children born retain an immunity after their first year, as these tests suggest, the ratio of latent to clinical cases is three or four to one. Dr. Stocks applied the methods also to records of notified cases of whooping-cough, and contacts to them, in Wandsworth and Holborn; he arrived at the conclusion that in this disease latent immunisation is non-existent or of very little importance, and further that the great bulk of children who escape whooping-cough in urban areas do so by virtue of an inherent immunity rather than by avoiding contact with infection. With reference to chicken-pox, seven years of notification records in Paddington showed an inverse relation between the size of the mid-

²Trans. Oph. Soc., 1902, p. 252, and 1912, p. 79.

summer and autumn epidemics; school closure for the summer holiday did not account for the cessation of epidemics in August and their recrudescence in October, which were characteristic features of the years under review. Analysis of notification records and of the after-histories of contacts suggested that a certain proportion, possibly a quarter to a third, of children born retain an inherent immunity to chicken-pox, and that latent immunisation protects others—possibly another quarter. The ratio of latent to clinical cases was not likely to be greater than about one to two, but Dr. Stocks considers it necessary to analyse more data before this can be asserted with confidence. The St. Pancras records of German measles when examined by the first method seemed to show that, as in measles, latent immunisation is a controlling factor, but further work was also required here. In submitting these preliminary results Dr. Stocks urged the importance of preserving the original notification records, especially of those diseases which are only notifiable in a few areas, for useful advances in our knowledge of the mechanism of epidemics might follow a proper statistical treatment of these records over a series of years.

A NEW AUSTRALIAN SCHOOL.

THE new School of Public Health and Tropical Medicine in Sydney, which is shown in the accompanying illustration, was opened on March 6th by the Hon. Frank Anstey, Minister for Health for the Commonwealth of Australia. It will carry on the

diploma of education, and of tropical hygiene in the diploma of anthropology. The courses for the diploma in public health and for the diploma in tropical medicine have already been commenced, and a diploma of tropical hygiene is contemplated. A library to deal with public health and tropical medicine is being built up from a nucleus, previously existing at Townsville, which it is hoped will be complete in all Australian aspects.

REGISTER OF BIOPHYSICAL ASSISTANTS.

THE first register of biophysical assistants published by the Society of Apothecaries of London contains the names of 463 persons, arranged both alphabetically and topographically, who have been given a diploma by the Society. This first batch of diplomates have been admitted without examination, having offered satisfactory evidence of experience extending over two years in a hospital or three years in private practice in administering physiotherapy under medical supervision. The conditions under which the diploma is held involve an undertaking that biophysical assistants will not undertake the treatment of any patient except under the direction and control of a doctor, that they will not advertise in a professional sense except in the recognised medical and nursing papers, will not sell goods to patients in a professional capacity, or accept secret commissions on the sale of goods. Their diplomas are returnable to the Society of Apothecaries if these regulations are contravened. In the future,

School of Public Health and Tropical Medicine, University of Sydney.

work of the School of Tropical Medicine which has been in existence since 1907 at Townsville, and its inauguration follows a recommendation made by a Royal Commission of Health, which issued its report in January, 1926. The commission proposed that a chair of preventive medicine should be established with an adequate department of tropical hygiene, and that the University of Sydney should be selected for this purpose. It also recommended that a feature of the work should be a collection and condensation of the records of the medical administration of the Pacific Islands. The school is housed in its own building within the university grounds, close to the medical school. Erected at a cost of £35,000, it provides for departments of parasitology, entomology, bacteriology, pathology, and chemistry, whilst sections dealing with physiology, industrial hygiene, epidemiology, vital statistics and sanitary engineering are contemplated. The school will be under the control of a council composed of representatives of the Commonwealth Government and the University of Sydney. Dr. Harvey Sutton has been appointed director. It will provide especially for the post-graduate training of public health personnel, but will also include special non-medical courses of school hygiene in the

recruitment to the register will take place by examinations, of which the first is to be held next month. The course of training is to extend over 18 months, of which at least 12 months shall be occupied in clinical instruction. The syllabus for Part I. includes anatomy, physiology and physics, and for Part II. the theoretical principles concerned with electricity, the various types of current used in medicine, radiant heat, light therapy, and medical diathermy. Chartered masseurs and masseuses will be exempt from Part I., and members of the Chartered Society of Massage and Medical Gymnastics who hold the Society's certificates in medical electricity will be admitted to the register of biophysical assistants on signing the necessary undertaking and paying the required fee.

The establishment of the register arose out of a suggestion made to the Society of Apothecaries of London by a committee of the British Medical Association, following a resolution by the Representative Body, who were concerned for the protection of the public from the risks of physical treatment by untrained persons. The need for qualified technicians has become an urgent problem since the popularity of rays of different wave-lengths has reached and even overtaken that of electric currents. The

manipulation of radium and the adjustment of X ray apparatus have such obvious dangers that quite untrained persons are not, perhaps, likely to attempt these procedures. It is doubtless for this reason that the registration of technicians skilled in handling radium and X rays has been considered less urgent; moreover, the Society of Radiographers to some extent fills the need, since its members undertake to work only under medical supervision. To switch on lamps which emit rays, visible or invisible, on the other hand, seems a simple job, and many are tempted to assume that it calls for no special skill. The fact that the erythema caused by large doses of ultra-violet light does not appear at once, but is delayed for some hours, is an additional reason for demanding an experienced administrator. The Biophysical Advisory Committee who have compiled the regulations for the examination, include: The Master of the Society, Lieut.-Colonel C. T. Samman, Dr. J. D. Bailey, Dr. A. E. Barclay, Major-General D. J. Collins, Prof. W. E. Dixon, F.R.S., Sir William Hale-White, Dr. C. B. Heald, and Dr. F. D. Howitt. We have no doubt that practitioners will appreciate the convenience of knowing that members of the register have a sound grounding in electrical and light therapy, and will gladly employ them.

SCHOLARSHIPS FOR STUDENTS OF MENTAL HEALTH.

THE Child Guidance Council announces that by the generosity of the Commonwealth Fund it is able to offer six scholarships of about £181 each to students taking the Mental Health Course of the London School of Economics and Political Science (Department of Social Science and Administration). These scholarships are given in order to assist suitable candidates who would otherwise be unable to take the course, and in selection of candidates consideration will be given to their previous experience of social case work, and to the type of work which they wish to pursue after training. The scholarships are open to those wishing to undertake social work for children or adults at child guidance and hospital clinics, at mental hospitals, and in associations for the care of mental defectives. They are also open to hospital almoners, children's workers, and probation officers. The chief subjects of the course are psychology, psychiatry, and social case work, and it is held during the autumn session and the subsequent vacation. Further particulars may be had from the secretary of the council, 7, Buckingham Palace Gardens, S.W.1.

AN ITALIAN JOURNAL OF LABORATORY TECHNIQUE.

A NEW monthly periodical published in Naples is likely to prove a useful supplement to books on laboratory methods in this and other countries by putting on record the newest investigations. The journal is edited by Prof. Luigi D'Amato, of Naples, and the editorial committee contains, besides those of well-known clinical pathologists in Italy, the names of J. J. R. Macleod (Aberdeen) A. Castellani (London), and H. G. Wells (Chicago). The first issue, which is before us,¹ contains an article by Dr. G. Emanuel of Berlin, on the colloidal mastic test in the diagnosis of neuro-lues. This test, which is of easy technique, is regarded as useful in the differential diagnosis of the various morbid types. In an article by Dr. L. Cattaneo of Pavia, the author proposes a modification of Hackenthal's method for the discovery of cow-pox virus in the blood. He centrifuges the blood made incoagulable by means of heparin, decants the plasma, adds a few drops of extract of fresh organs to the sediment, leaves it for an hour at a temperature of 37°C. and takes off the thin film which forms on the surface of the clot. The virus is

found in large quantity in this thin pellicle of leucocytes and platelets. Prof. A. Lustig of Florence contributes a review on the analogies between the bacilli of undulant fever and contagious abortion. He discusses the work done at the institute of general pathology in Florence, and agrees with Favilli that the components of the genus *brucella* are different types of the same germ and that the bacillus of Bang, generally not pathogenic for man, may at times become so, and assume characteristics absolutely identical with those of *B. melitensis*. Prof. G. Sollazzo of Milan describes the use of phenol-alcohol in the Wassermann reaction and pleads for more extensive observations on the method of Ninni and Molinari. There are editorial articles on Kolmer's reaction and ultra-filters, and summaries of medical literature arranged under classified headings. The longer articles have been resumed in Italian, English, French, and German.

VIRUS DISEASES AT THE ROYAL SOCIETY.

THERE were two exhibits at the Royal Society's conversazione at Burlington House on May 14th which were of unusual interest to medical visitors. Both dealt with virus diseases. Mr. S. R. Douglas and Miss J. Marchal, from the National Institute for Medical Research, showed a number of naked-eye and microscopical specimens illustrating a new disease they have found in mice. It was originally recognised by observing that certain stocks of laboratory mice were particularly liable to a swelling of one hind foot followed by gangrene and loss of the end of the leg. Attempts to transmit the infection by bacteria cultivated from the lesions were unsuccessful, but if an affected foot was mashed up and filtered through a porcelain bacteria-proof filter the disease could be readily transferred from one mouse to another by inoculation of the filtrate. It was afterwards found that the disease was more widespread than the gangrenous lesions suggested; mice may suffer and die from it without losing a foot, the constant lesions in all animals being necrosis of liver and spleen. This implies that the name of "infectious ectromelia" chosen by the discoverers is not altogether happy, and in any case "ectromelia" is normally applied to a congenital defect rather than an acquired condition. Would it not be better to avoid the pitfall of a definitive name altogether and call it simply "Marchal's disease"? Another striking feature is the number and size of the "inclusion bodies" which occur in the cytoplasm of epithelial cells in the skin, pancreas, and salivary glands, occasionally also in connective tissue. In some of the sections shown they were so large and formed such a large proportion of the tissue that it looked as if their extraction and analysis ought to be possible.

The other exhibit dealt with plant viruses, particularly tomato mosaic, and came from the Rothamsted Experimental Station under the charge of Dr. J. Henderson Smith. Two points in particular were illustrated, of which the most strikingly objective was again the characteristic inclusive bodies as they develop in the epidermal hairs on the leaf. They here reach such a large size that they are easily seen with the low power of the microscope, and their growth and evolution may be precisely followed. In their early stages they are made up of amorphous granules, but later on there is distinct evidence of the separation of protein crystals. It is not supposed that the bodies actually are the virus, but that the virus upsets the colloidal equilibrium of the cell contents with the separation and finally crystallisation of some of the protein contents. Other specimens illustrated the fact that virus will not pass from one part of a tomato plant to another through a length of stem which had been killed, though water and such dyes as eosin readily do so. There is, in fact, no evidence that the movement of virus within a plant takes place in the water or transpiration stream. This raises something of a mystery, for in general any infected plant contains the virus throughout and it spreads quite quickly

¹ Diagnostica e tecnica di laboratorio. Rivista mensile. Vol. I., No. 1. January, 1930.

from the locus of an artificial inoculation. Those who are inclined for further information will find a useful survey by Dr. Henderson Smith in the current number of *Biological Reviews*.

LEAGUE OF NATIONS HEALTH COMMITTEE.

At the recent session of the council of the League of Nations the Health Committee of the League was reconstituted for a period of three years from July 1st. The new members of the Health Committee appointed by the council after consultation with the outgoing committee include Dame Janet Campbell, Senior Medical Officer for Maternity and Child Welfare, Ministry of Health, who is chairman of the committee of health experts on infant welfare of the Health Organisation of the League. Sir George Buchanan, Senior Medical Officer, Ministry of Health, has been reappointed a member of the Health Committee on the nomination of the governing body of the Office International d'Hygiène publique in Paris.

POLLUTED STREAMS.

THE report¹ of the Water Pollution Research Board for the year ended last June is not so much a record of progress as evidence of co-operation between industry and the administrative authorities. The report points out that water for industrial purposes is often spoilt for industry by industry and that the growing population needs more and more to have recourse to rivers for domestic supplies. If we use the headwaters of a river for drinking purposes and if our factories use water from the lower reaches for industrial purposes, in each case we ought to return the effluent in such condition as to allow of a successful process of self-purification by the river. There is last but not least the æsthetic point of view. What a transformation in the countryside would be effected if all our streams and rivers were clean and fit to support fish-life. Further, we cannot cultivate respect for a stream which is used as a sewer or a conduit for unpurified trade effluents, or greatly blame those who throw litter or refuse into it. In recent years new processes dealing with artificial silk and the waste from milk and beet sugar factories have added to the problem, but science has not even solved the difficulties of sewage effluents and the waste waters from collieries and gasworks. Since its formation in 1927 the Board has co-operated in research with managers of sewage disposal works, the institution of gas engineers, the beet sugar factories' committee of Great Britain, and a committee of the Royal Sanitary Institute. The Tees may be taken as typical of a polluted river flowing through an industrial area, and a comprehensive biological, chemical, and hydrographical survey of this river has been undertaken by the Board. A summary of existing knowledge on the base-exchange or zeolite process of water softening has been issued, and further investigations are in progress from the physico-chemical point of view at the chemical research laboratory at Teddington and from the bacteriological point of view by Sir Alexander Houston. An investigation of the activated sludge process is being conducted by Prof. W. W. C. Topley at the London School of Hygiene. Another matter receiving attention is the gauging of rivers and streams for the purpose of obtaining exact knowledge of the flow of rivers and the effects of tidal flows. The special report of the Director of Research, Dr. H. T. Calvert, deals largely with beet sugar factories. He describes the operations at such a factory, which if it handles 1000 tons of beet may use three to four million gallons of water per day. Work at the experimental plant, Colwick, facilities for which were provided by the Anglo-Scottish Beet Sugar Corporation, Ltd., has already given hopes of so treating the waste waters that they may be re-used in the various operations.

¹ Obtainable from H.M. Stationery Office. A complete list showing prices may be had on application to the Department of Scientific and Industrial Research, 16, Old Queen-street, London, S.W.1.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles Contributed by Invitation.

LXXIV.

THE SIGNIFICANCE OF IDIOPATHIC SKIN REACTIONS.

PART II.*

WHAT DISEASES TO TEST FOR.

IN PART I. of this article it was made clear that we can produce a long list of symptoms by applying grass pollen to the hay-fever subject in various ways. From another point of view, it is useful to consider what disorders can be tested for by skin reactions.

The list includes:—

1. *Conjunctivitis*, the sufferer is sensitive to some foreign protein substance in the atmospheric dust.

2. *Paroxysmal rhinorrhœa*, or *vasomotor rhinitis* (of which hay-fever is but an example). The mucous membrane or, as the case may be, the modified epithelium of the respiratory passages is sensitive to, and therefore reacts to, some foreign protein particles in the inbreathed air; possibly the irritant may be circulating in the blood.

3. *Asthma*: the foreign protein is either in the inspired air or, more probably, is circulating in the blood—a toxæmia in fact. It may be difficult to guess what are the irritants in question.

4. *Urticaria*, *eczema*, *ichthyosis*, or any mixture of or intermediate stages between these three; the poison is probably circulating in the blood, but it may have gained adventitious entrance to the skin—e.g., by a prick or midge-bite.

5. *Angioneurotic œdema*, which is a subcutaneous accumulation of urticaria.

6. *Functional albuminuria*, which is a serous exudation or urticaria of the kidney: if this disorder arises from a protein sensitisation the protein must arrive as a toxæmia.

7. *Paroxysmal mydriarthrosis*, which is a similar serous effusion into a joint.

8. *Migraine*, if from the history of the case or the familial history it is suspected that some foreign substance is causing the trouble through a sensitisation: if a sensitisation is suspected it must be to a toxæmia.

9. *Epilepsy*, if a sensitisation is suspected; a toxæmia.

10. *Food idiosyncrasy*—i.e., nausea, vomiting, and diarrhœa as a local reaction to the food itself: the irritant is clearly some ingredient in the ingested food.

11. *Dysenteric symptoms*, *lœuœmus*, possibly such conditions as *cyclic vomiting*, may be due to a sensitisation: the irritant is not necessarily a foodstuff; more probably it is bacterial, or some product of digestion, and it may, of course, be present as a toxæmia.

It is noteworthy that the sensitisation of the patient to a foreign protein may give rise to a number of these disorders simultaneously; or these disorders may alternate or change from one to another—e.g., first migraine, then asthma, then urticaria, then back to migraine. Or the eczema which a child suffers from in babyhood may change to asthma after whooping-cough or pneumonia. In such a case one is searching for the ætiological agent for several "diseases" at once. Also (and this leads to much complication of testing) there may be with one patient a number, often a large number, of foreign substances each capable of producing any of these disorders.

The "Protein Irritant": Allergens.

The substance to which the sufferer is hypothetically sensitive has been spoken of as the "foreign protein"; this terminology may be questioned, since occasionally patients are demonstrably sensitive to such substances as morphine—or even such chemically simple substances as potassium iodide (see below). Another objection is that the active agent may not be a protein, but a much simpler substance, perhaps attached

* Part I. appeared last week.

to the protein molecule, which causes the disorder and also causes the skin reaction. This may be so, but since the reacting substance (in pollen or horse dandruff or fish myoplasm) will not go through a dialysing membrane, it seems justifiable when dealing with immunity phenomena to speak of them as protein substances. Making use of von Pirquet's term "allergy" which he coined for his tuberculin reaction, it has been the custom, especially in America, to label all the toxic idiopathies, all the diseases of the asthma group, as "allergy" or "allergic phenomena," although there seems to be an inherent difference between asthma, for example, and tuberculosis in the mechanism of the skin tests. If we accept this extension of the meaning, then the reacting substance, causing the disorder or the skin reaction may aptly be called the "allergen."

What Substances may Function as Allergens.

An infinity of substances may cause the asthma group phenomena—any particular animal or vegetable protein (including all the unclassified moulds and bacteria), or any product of any of these proteins when denatured by heat or chemicals. Even our own tissues when denatured by trauma or chemicals such as morphine or potassium iodide are capable of acting as the "foreign protein." This gives an impossibly unwieldy list and means that skin tests must be embarked on with discriminating intelligence; they should never be ordered at random by the physician or carried out blindly by the pathologist. Experience shows us that random tests seldom give much help because of the difficulty of knowing what to suspect.

Another great difficulty is that these allergens do not react equally on the skin; one type, grass pollen, is unusually good, so are the scurfs of animals—e.g., horse. Food substances are weaker in their action; and that important group, the fungi, including all the pathogenic bacteria and the enormous numbers of unclassified moulds, not only tend to give indeterminate reactions, but also delayed reactions (comparable to Pirquet's tuberculin reaction).

The useful application of skin tests, if we exclude those which are merely confirming a diagnosis brought by the patient, depends largely on whether we can pick up useful hints about possible allergens from a questionnaire.

What Proteins Should we Test: A Questionnaire.

Before deciding what skin tests to make, or even if such tests are worth making, the patient should be closely cross-questioned with allergens in view. The following suggested questions are not universally applicable—one cannot, for example, reasonably ask at what hour an attack of eczema started. Also, these patients are so suggestible that it is better to reach, say, the "horsehair mattress" indirectly. It is amusing to hear a woman explain that a feather pillow instantly gives her asthma when she is at that moment lolling on sofa cushions from which a few small white feathers are protruding.

How long has the patient had the disorder, continuously or off and on? What seasons of the year are worst, what are the least troublesome?

On what days of the week are the attacks worst? Very often patients will incriminate the week-ends—an interesting point, though it is not always easy to see its bearing.

At what hours are the attacks worst, or when do they usually start? The answer is often: "Usually at night, and very frequently at 6 A.M. or when I begin to get up." This answer bears on the psychological factor in asthma, &c.; it is only significant for us here as showing indirectly that the proteins of food are playing little or no causal part in the illness.

Does food affect them? The evidence is slight or overwhelming. Usually, food does not affect them as a specific protein, though they have probably been told that it does. Food affects the asthmatic, &c., in at least four ways:

(1) By introducing proteins to which the patient is sensitive (reaction in 20 minutes to 1 hour). (2) By causing bacterial fermentation in the gut; to these bacteria the patient may be sensitive (reaction in 24 hours approximately).

They will probably blame "rich" food and sugar. (3) By overloading the stomach and thus setting up disturbing nerve reactions (1 hour to 6 hours). (4) By suggestion, through remarks they have heard from others (reaction in any time, according to gossip, but usually within half an hour). The first of these is the one most talked about but is the least frequent; it alone can give positive skin reactions to specific food proteins.

What preceded the first attack? Bacterial sepsis is often implicated here, and anyway should be studied as carefully as the septic foci in a rheumatism case are investigated—how any suspected cultures are to be used will be described later.

Do places make a difference? Here one must guide the patient in discriminating between different localities and different houses or even rooms. The presence of mould spores in the dust of rooms is an important point. They had better be tested for by means of an extract made from the dust—to be described later. Trouble from the water-supply must be kept in mind, and if necessary, an extract made.

What are the home and what are the work-place surroundings? Does the patient see much of animals, birds, or horses? Does he work in a dusty atmosphere—e.g., flour or sawdust?

What is the toxic idiopathic history of this patient and of his blood relations? A line on probable directions for investigation may often be gained from this inquiry; one of a group of these diseases tends to run in a family.

How to Obtain Protein Reagents for Testing.

Reagents should approximate as closely as possible (chemically speaking) to the protein irritant suspected of causing the trouble; if practicable they should be the identical substance. Thus, if a man is egg sensitive a trace of white of egg will serve for the testing; hay-fever can be detected through any grass pollen; the pollen of any suspected flower can be dusted on to a scratch on the forearm, but any such sensitisation is merely accessory to true hay-fever and comparatively unimportant. An animal sensitisation can be diagnosed by means of a few hairs from the animal. A set of protein reagents, if they have been much "prepared" may easily have become denatured and so give only a poor reaction or none at all. I myself have failed to get reactions on horse asthma patients with the horse dandruff reagent supplied by several first-class firms, but have got it at once on getting some fresh curry comings from the nearest stable. It is, therefore, suggested that the practitioner should examine his case first by some such questionnaire as is given above and make a list of the proteins he wishes to test; he should postpone the actual testing till the next session. He will probably be able to extemporise from his kitchen or his garden the substances he requires. If necessary, the juice of a vegetable or of plasma from meat or fish can be expressed, but as a rule the unaltered material will do perfectly well. Such material as animal scurf and animal hairs can be used unaltered, or if preferred an extract can be made in normal saline and 0.03 per cent. sodium carbonate. The best way of sterilising such extracts or fluids is to put them through bacterial filters; but heavy centrifugalising will remove solid particles.

If this is deemed unprofessional or if a diagnosis has to be attempted out of hand, then recourse must be had to the sets of proteins on the market, and there are several to choose from. Or the practitioner may wish to make his own supply—particularly where, as with grass pollen, the material cannot be obtained all the year round.

There is one alleged advantage of the sets of reagents—one may have a group test—i.e., a mixture of all the members of the group: thus, a fish group, a nut group, a shell-fish group, an animal hair group, a stone-fruit group, a meat group, and so on. But if a single protein may fail to react if too much prepared, then still more easily may a single ingredient in a group mixture fail. Besides, preliminary testing with group reagents means blindfold testing—which should never be necessary, and is of doubtful utility. The home-made reagent is the best.

I spoke in a preceding section of cultures of bacteria, suspected of causing trouble by sensitisation. Though these are to be had in the sets of reagents, it is clearly

better to work with the patient's own cultures. A thick emulsion of the bacteria should be allowed to autolyse so far as they will, and then be centrifuged heavily to get rid of solid particles. I also spoke of dust, particularly fine house dust from the top of cupboards; this should be extracted in saline with a trace of sodium carbonate in it (0.03 per cent.). After extraction in the ice-chest for several days it should be put through a bacterial filter. Drinking water may be evaporated down at 45° C. under a vacuum. When it is reduced to a small bulk the concentrated salts are dialysed out.

If the particular protein is quite new to the investigator it would be wise to make a test on a normal skin (e.g., on his own) to make sure that the substance is not a universal irritant.

Routine Technique for Skin Tests.

A convenient site for testing is the flexor surface of the forearm; but if there is to be any scarring then the upper surface of the thigh, just above the knee, is preferable for women and convenient for children. Preliminary cleansing of the skin is probably quite unnecessary, but if thought desirable soap and water are the best.

A number of small areas, say 3 mm. in diameter, are scratched through the skin till the pink cutis vera is laid bare but without the drawing of blood. One such scratched area should be reserved as the control. On the other areas the various protein reagents are placed and gently rubbed in with a small glass rod or the wrong end of a wooden match in order to make intimate contact between the foreign protein and the living cells of the skin. After a minute or two any debris or blood can be cleared off the scratched areas with saline and cotton-wool so that the wealing, &c., can be clearly observed. A reaction will be precisely like that described above for hay-fever. It will begin in 7 minutes, and be fading in 20 minutes, reaching its height in 10 to 15 minutes. A positive reaction should show an urticarial weal not only over the scratched area, but extending beyond this with irregular edges, around the weal will develop the erythematous blush. This may be a scarcely perceptible pink rim round the weal or may extend beyond it for 2 or more inches; in any event, to be positive both must be definitely bigger than anything appearing on the control site. Such a method as this is very convenient for the rubbing on of solid substances, such as a piece of Brazil nut or a piece of carrot, and it can quite easily be used for fluids—e.g., cow's milk or horse's serum—it is, in fact, universally applicable.

Another method is to place a drop of fluid containing the test protein onto the skin and then to prick with a sharp puncturing through the drop vertically into the skin, only puncturing the skin to the depth of half to one millimetre. This puncture injects a minimal quantity intradermally, and is easy to make comparable from protein to protein and from day to day. For purposes of record it is convenient to trace on an ordinary microscope slide the central prick, the weal, and the surrounding erythema, or such of it as will go on to a slide. (If a wash of dilute egg white is smeared over the slide and allowed to dry this will facilitate the inking-in but is hardly necessary.) With this prick method a control prick should always be made through saline, and any reaction judged to be positive must be definitely larger both in the weal and in the erythema than anything shown round the control prick.

A special word must be said of extracts prepared from bacteria, moulds, or other fungi—frequently a dust extract comes under this head. These reactions are rather indefinite and tend to be delayed; sometimes they are at the height of their reaction an hour or two afterwards and sometimes even next day. Indeed, the condition begins to approximate to a von Pirquet reaction. It cannot be denied that it is a great disadvantage that two such important groups as the bacteria and the moulds give such comparatively unsatisfactory reactions. Perhaps it is better with them to make a filtered extract and then an intradermal injection can be given.

Conclusion.

If the application of a protein reagent produces no reaction this may mean that the preparation used for the test (1) does not tally quite with the protein suspected as the cause of the disease—it may, for instance, have got denatured in the process of preparation;

(2) it may be of a type (e.g., bacteria) which at best only gives a poor reaction; or (3) the failure may really mean that the patient is not sensitive to that particular substance.

If the reagent produces a definite reaction under suitable controls then the patient is sensitive to that particular reagent. But this sensitisation may not be causing all the mischief—or, indeed, any part of it. For example, a man who has been careful to avoid lobsters for years will not think one has got to the bottom of his trouble if the flesh of one gives a positive reaction, and he is merely told to avoid them in future. However many positive reactions one may get it is always possible that the chief "asthmatic" factor has not yet been detected; in fact, any degree of confidence on this point can only be gained by a really painstaking questionnaire as detailed in a previous paragraph.

Any positive skin reactions must have this significance at any rate; a patient's tendency to react puts him definitely into the sensitisation class and he is a candidate for all or any of the toxic idiopathies—even if the causal protein irritant has not yet been detected.

JOHN FREEMAN, D.M., B.Ch. Oxf.,
Director of the Department of Clinical Bacteriology,
St. Mary's Hospital.

The Services.

ROYAL NAVAL VOLUNTEER RESERVE.
Surg. Sub-Lt. J. D. J. Freeman to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. G. H. J. Brown, having attained the age for compulsory retirement, is placed on ret'd. pay.
Maj. and Bt. Lt.-Col. (temp. Lt.-Col.) F. A. McCammon to be Lt.-Col. vice Lt.-Col. G. H. J. Brown.
Maj. and Bt. Lt.-Col. R. E. U. Newman to be temp. Lt.-Col.

Maj. R. B. Myles retires, receiving a gratuity.
The undermentioned Capt's. to be Maj's. (substituted notifications): E. Percival, Lt. D. Cameron, H. M. Alexander, A. G. Harsant, J. K. Holland, and M. C. Paterson.
The undermentioned Lt's. (on prob.) are confirmed in their rank: G. F. Harrison, A. N. T. Menecese, E. F. Curran, and F. E. Gedye.

ARMY DENTAL CORPS.

Capt. B. E. Gentleman to be Maj.

ARMY RESERVE OF OFFICERS.

Lt.-Col. J. H. Fletcher to be Lt.-Col.

MILITIA.

"ON SIGNING YOUR NAME."

*A Clinical Lecture delivered at Guy's Hospital on
May 19th, 1930,*

By T. B. LAYTON, D.S.O., M.S.LOND.,
F.R.C.S. ENG.,

THROAT AND EAR SURGEON TO GUY'S HOSPITAL; CHAIRMAN
OF THE LONDON INSURANCE COMMITTEE.

As members of the medical profession we often have to sign our names to documents which appear at first to be of small importance but which may under certain circumstances have far-reaching effects. These documents fall under two heads, those which are signed by us as a part of our medical work and which contain some professional opinion, and those which we sign because the right or privilege has been given to us by the nation or otherwise as a mark of the confidence in which we are held. This power to sign our name should be held by us to be a sacred duty that we should at all times carry out with all the care that is within our power, and I want to discuss with you to-day some principles that should guide us in doing this duty.

Carelessness and Neglect.

I may start by giving two examples that have come within my experience where there has been a failure to perform it, in the one due to gross carelessness, and in the other to criminal neglect.

CASE 1.—Some 22 years ago I was a medical officer in a large poor-law infirmary, and one day did a round for a colleague off duty. As I finished the sister said: "There is Daddy Twenty's pension paper to sign." I looked at it and said, "Where is his discharge certificate?" Although the patient had been under her charge for over two years, the sister had never heard of this. Each week the doctor had signed the paper without seeing this document, although by his signature he said that he had that day seen the certificate and the pensioner, and that he believed him to be the person described thereon. The sister was a bit indignant that I would not sign. The young woman who had come to fetch it was more so, saying she wanted the money that day, and had to return to work by 2 o'clock. I pointed out that it was then 12, that she had plenty of time to go home and fetch the document, and that if she wanted the money so badly it was worth this effort to obtain it. She went away, and no question of a pension to be drawn by that patient was ever raised again.

I have but little doubt that certain persons had been causing this old man to impersonate some dead pensioner over a period of two years or more. This could only have been rendered possible by the false certificate signed weekly by my friend.

CASE 2.—At Christmastime, 1916, I was the senior medical officer of a small detached force of 7000 men in Northern Greece. The O.C. the R.E. Coy. came to me saying that as things were quiet it would be a convenient time to get his men inoculated. I was surprised that he had any appreciable number of men uninoculated, for we had left England but six months; and great efforts had been made to get everyone in the division injected before we left. I, therefore, sent a sergeant over to his orderly room to examine the pay-books of his men. In the last page of this a medical officer entered every inoculation as he did it, dating and initialing his entry. My sergeant brought back a report that all the pay-books were entered up as though the men had been inoculated immediately before we had left this country. I told the O.C. this, and he then informed me he had reason to believe that all these entries were false. He had only taken over the command a day or so before we had left, but he had learnt that actually hardly any of the men had been done. We inquired further of the N.C.O.'s of the Company, and learnt that the M.O. in charge had let time so slip by that there were no longer the necessary number of days before embarkation for the inoculation to be done, and that, finding himself in this fix, he had made entries in all their pay-books as though he had inoculated them, whereas in fact he had only done two or three. This officer was not with our small force, but he

was still with the Division some 100 miles away, and I reported the matter to the A.D.M.S., saying that I thought there was no doubt there was evidence enough to obtain a conviction on court-martial. I was informed that no action would be taken, that the Divisional Commander did not want a scandal in the Division, especially in reference to an officer of the R.A.M.C., for fear it would weaken the confidence in which the medical officers were held.

Let me at the outset lay stress upon the different view the doctor and the layman takes in these matters. I think we should all agree that the second of these two cases was the more serious. That the medical officer there had no sense whatever of professional honour when he definitely endangered these men's lives by making false entries in their pay-books to cover his own slackness. Yet here was a Divisional Commander, himself the very soul of honour, who would take no action in the matter. This was not weakness on his part; he was ruthless in following up any suspicion of neglect of a sick or wounded man on the part of any member of the R.A.M.C. I have no doubt he would have taken a most serious view of Case 1, and in this he would have the support of every lawyer, financier, or administrator who would feel that the very system upon which our complicated finance is based was being undermined by the doctor's neglect. Understand that it is impossible to defend that action to laymen or even to plead mitigation of the offence.

Pressure from Without.

In neither of these cases was there any pressure from without, yet in many there is and the doctor places his signature against his better judgment. Such pressure may be a fear of social opprobrium or of financial loss. To give in to it is weakness, a weakness with which we may condole, but which we must not condone, for when it brings its owner in trouble and he is faced with his signature on the document anything said in extenuation appears but as a specious argument.

CASE 3.—One evening a neighbour dropped in upon a doctor, asking him to sign a passport paper for her brother-in-law. He replied that he would be delighted but, on looking at the document, added that he could not, as it stated that he knew the applicant personally. The lady indignantly suggested that surely he could trust her, adding that if he did not sign they could not go on their trip, as the paper must go in next morning and there was no time to get any other eligible person to sign. The doctor's wife supported her, not wishing to have any unpleasantness in a new neighbourhood to which they had recently moved.

I am glad to say I know of no case of improper signing of a passport paper by a doctor; but this case shows the pressure that may be put up by unthinking people, who have no idea that they are doing dishonourable deeds. Such pressure must always be resisted. The right to sign a passport paper is one of the things that puts us above the common herd. It is the recognition by the State that the code under which we live and work is a higher one than the average of the community.

CASE 4.—A doctor working at the Ministry of Pensions was asked by the head clerk to sign his paper for a weekly pension. He looked at it, and pointed out that the signature involved his saying he had that day seen the pensioner's children alive. In an unpleasant tone the clerk said, "The children are at school, I can't bring them here." The doctor suggested he could between 12.30 and 2, and offered to wait during that period to see them. In a huff the clerk removed the paper, saying, "I can easily get someone else to sign it. I have never been asked to bring the children before." For several weeks after this the number of sessions that the doctor was called up for attendance at the boards showed a diminution.

The importance of this case shows that there must be a number of medical men prepared to sign a document without reading it or else without a due appreciation of their responsibility when signing. This clerk had been drawing his pension for over two years and apparently he had no difficulty in getting some medical man every week to sign a false statement on his pension paper. The men working there were all from the consultant branch of the profession.

There is another very common reason given for asking a doctor to sign a certificate wrongly. It is that unless he does so some poor person cannot draw the weekly money and the invalid, his wife and child must go starving without it. Against such suggestion you must rigidly set your face. Either the regulations for drawing the money are bad and should be amended, or the person bringing the certificate for signature has let time slip by, so that he or she is faced with the difficulty out of which you are asked to get him. In neither case is there any reason why you should put your signature to a false statement and risk the whole of your career thereby. Let there be no doubt about this. When you are faced with that document and its misstatement no arguments about doing it out of kindness to the sick will protect you. The case is bound to go against you and no one can save you.

If you are brought up before the General Medical Council you are liable to be struck off the rolls. If the case comes up in a civil or other court you will break down in cross-examination; and if it is a case under the National Insurance Act you will, as we shall see later, get into serious trouble.

Signing an Unfinished Document.

In association with this never sign a form in blank and leave it for someone else to fill in. Some years ago, as we were going out of the ward, the sister asked my house surgeon to leave her some certificates and he turned round and signed in blank some half a dozen that she had ready for him. I was aghast at this and spoke most severely to both. The sister produced the usual arguments. That the house officer was out during the visiting hours when the relatives asked for the certificates and they, poor things, would have to come up again if these were not ready. I pointed out to her that with a little forethought on her or the patient's part the certificates could be got ready for the house surgeon to sign on his morning round. Then her arguments changed. Surely I could trust her to fill them in properly. This is a most dreadful argument to put forward. It is so difficult for a young man to controvert, especially when morning and evening he has to go round with the woman who puts it forward. The answer, of course, is that to sign a blank certificate is the same as signing a blank cheque for that, in effect, is what it is, the only difference being that it is a cheque on someone else's money. A house surgeon who gave the sister of his ward half a dozen blank cheques would be looked upon as a fool, but it is only his own money that can be drawn on them; to do so with documents on which someone can draw another person's money does not far remove him from being a knave.

Nor can any sister who is an accessory to this practice be considered free from blame. I do not know whether the General Nursing Council has any disciplinary control in the way our Council have; but in the event of such a certificate causing the doctor to be brought before the Medical Council the member of the nursing profession should be brought before her council. It should be considered as "infamous conduct in a professional respect" for a nurse to use her position in relation to a patient to influence the doctor treating that patient to do anything that can be so considered in respect to his profession. To my mind the only thing to do is to refuse ever to sign any document, even an admission slip to the hospital, unless and until it is completely filled in. You will thereby educate yourself not to sign any document till you have read it; and it will soon be known that it is useless to put an unfinished document before you and people will cease to do so.

A few days after I found the sister of my ward asking for blank signatures from my house surgeon. I saw the physician in Clinical sign such a form and leave it for the clinical assistant to fill in. I remonstrated with him and he responded with the same high sounding rhetorical question: "Do you mean to infer I cannot trust Mr. X?" He failed to see

that he was educating Mr. X in slipshod ways which he would carry out into the world with him. Your teachers are so busy trying to instil into you pathology and diagnosis with some smattering of treatment that they omit to teach you anything about the conduct of practice.

I find that leading members of our profession are not particular enough upon these points. They seem to think it undignified to do anything that they do not consider to be real medicine, and under this they do not include the signing of a document. Yet if they teach you nothing of the conduct of practice they should at least abstain from educating you by example in bad methods.

Do not for a moment think that these same physicians and surgeons will defend you when having risen to the top of the profession they come to sit upon the General Medical Council. They will not; nor if they would, can they protect you from the consequences of your action if you are brought before them with a certificate signed by you, the falsity of which has been proven before them. The Council has made this quite clear in the Warning Notice which they have issued to the profession and which contains the following:—

Registered medical practitioners are in certain cases bound by law to give, or may be from time to time called upon or requested to give, certificates, notifications, reports, and other documents of a kindred character, signed by them in their professional capacity, for subsequent use either in Courts of Justice or for administrative purposes. (Here follows a list of documents, &c.) Any registered practitioner who shall be shown to have signed or given under his name and authority any such certificate, notification, report, or document of a kindred character, which is untrue, misleading, or improper, whether relating to the several matters above specified or otherwise, is liable to have his name erased from the Medical Register.

Certification for National Insurance.

Of the documents in this list, the most numerous, and from the national point of view, probably the most important, are those "under the National Insurance Acts and the Regulations made thereunder." Many, and perhaps most, of you will spend your lives by taking service under these Acts, and under Your Terms of Service you will agree to take on certain duties in the way of signing certificates. In the complicated state of our society we cannot exist side by side without the use of forms and documents; and upon the confidence that can be put in them must depend to some extent the stability of our social order. But I hope to show that a meticulous accuracy in such matters is nowadays also necessary for the proper treatment of our patients and is, therefore, as essential a part of medicine as is the ordering of an appliance or the writing of a prescription.

In the certificates that you will have to sign under this service there are two parts. The first involves a statement of fact, the second involves your medical opinion. The statement of fact which is included in every certificate is that you have that day examined the patient, and you have no right under any circumstances to sign this statement if you have not seen the patient on that day. Let us consider some cases which have been considered by the London Insurance Committee and where a doctor has done so.

CASE 5 (M. 29/11).—The facts of the case are as follows: The insured person was admitted to a hospital on Jan. 4th, 1920, and the society were furnished with a certificate of admission issued on that day. Certificates on Form Med. 40 were furnished, however, by the practitioner on Jan. 11th, 18th, and 25th, and each of those certificates indicated that the insured person had been examined by the practitioner on the dates appended respectively thereto. The first of this series of certificates—i.e., that dated Jan. 11th—contained a note made by the practitioner to the effect that the patient was in hospital.

CASE 6 (M. 29/21).—From the statements submitted to us by the society and the practitioner, we find the following facts to have been established: The insured person was first certified by the practitioner to be incapable of work on Dec. 11th, 1923, a First Certificate having been issued on that day indicating that the patient had been duly examined

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

A Hospital for Convalescence.

THE Astley Ainslie Institution was formally opened by the Lord High Commissioner on May 22nd, but has actually been in partial use for over a year. The buildings now standing in the splendid park, facing south, include the old house of Millbank, which was formerly the home of James Syme, the famous Edinburgh surgeon. Joseph Lister married Syme's daughter in 1856 and the marriage took place in the drawing-room of the mansion house. There are also two other properties—Canaan Lodge and Canaan Park. These three, and the ground attached, form the superb site for the new convalescent establishment. This contains a kitchen department, nurses' home, scientific department for treatment and research, and two special pavilions. The plans provide for the accommodation of 150 patients, with a staff of 42. The scientific department contains research laboratory, radiographic and radiotherapeutic installations, a gymnasium for remedial exercises, a dental room, a dispensary, and other offices. There will also be open-air shelters, sun-baths, and recreation grounds for patients.

This splendid endowment was left by Mr. David Ainslie of Casterton, who died in 1900, and directed his trustees to apply the residue of his estate to "the purpose of erecting, endowing and maintaining a hospital or institution for the relief and behoof of the convalescents in the Royal Infirmary of Edinburgh." The name "Astley" has reference to Mr. Ainslie's nephew and heir, John Astley Ainslie, who predeceased him. The Board of Governors represent the Royal Infirmary, the College of Justice, the Royal Colleges, the Edinburgh Merchant Company, the Chamber of Commerce, Society of Accountants, the Presbytery of Edinburgh, and the Corporation of Edinburgh, along with the only surviving trustee, Mr. Scott.

The site of the institution, which commands a full view of Blackford Hill, the Braid Hills and the Pentlands, formed at one time a part of the Borough Muir, which played a great part in the history of Scotland in the sixteenth century. This was the mustering ground for the march to Flodden. In earlier days, too, it is said that the ancient chapel of St. Roque stood here, a resort for victims of the plague.

The new departure in the history of the site will not be the least important, for the institution means a very material expansion of the Edinburgh medical school. Although associated with the Royal Infirmary, it will be independent. It opens a definite prospect of detailed study of the processes of convalescence.

Infectious Disease in Glasgow.

Dr. A. S. M. Macgregor's latest report shows that the infectious diseases death-rates in Glasgow for March and April were 1.2 and 1.1 against 0.9 and 0.7 a year ago. This is mainly due to measles, the number of cases recorded for the nine months being 5020. The percentage death-rate from measles is, however, only about 2.2, which reflects the mildness of this year's epidemic. In the epidemic of 1927-28, the percentage death-rate was 3.6. For the six months ending March, 1930, the number of cases was 13,988 as against 15,802 in the previous epidemic for a similar period.

Dr. Macgregor has an interesting note on cases of acute sore-throat followed by nephritis, with two deaths. Within the last few weeks a small group of cases have been reported. "The early symptoms are severe, with fever, and there is no evidence that the condition is due to scarlet fever; swabs from the throat are negative for the hæmolytic streptococcus, although this organism was recovered in one instance where three members of a family had nephritis following acute sore-throat, and in one or two of the other sporadic cases. The general hospitals report no increase in admissions for nephritis during the past three months, but, in view of the possibility of the presence of a throat infection followed by this complication, I shall be glad to receive information from

medical practitioners who may have had recent experience of illness of this nature."

The late Dr. Robert Robertson.

Dr. Robert Robertson, who died on May 18th, was one of the best-known general practitioners in Edinburgh. He graduated in medicine at Edinburgh University in 1888 and took the B.Sc. in public health a year later. In his early days he developed a large practice and it was a pleasure to discuss medical problems with him, partly because of his very wide experience as a general practitioner and partly because of his freshness and originality. He was practical and at the same time critical. He had a very alert, speculative mind and took a keen interest in all current public health problems, serving for a considerable period as an active member of the Edinburgh Town Council. He was a competent critic of hospital conditions and he did not hesitate to express his views; but he was always fair and considerate both of the medical officials and of any lay opponents. In personal conversation one was always struck with his grasp of general principles and his quiet but broad humanism. His mother is now 104, and it is said that he paid her a visit every day of his life. It was precisely what one would expect of his sympathetic and understanding temperament.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Medical Benefits for Northern Ireland.

THE Northern Ireland National Health Insurance (Medical Benefit) Bill was issued on May 14th. There was also issued a White Paper explaining the measure, and it sets out the main objects of the Bill as follows: (1) to include in the National Health Insurance Scheme a system of medical benefit; (2) to provide for an increase in the contributions payable under the National Health Insurance Acts; (3) to provide for the administration thereof; (4) to give effect to an agreement entered into with dispensary doctors with regard to the terms of insurance practice; and (5) to make alterations for the treatment of tuberculous insured persons. Since the commencement of the National Health Insurance Scheme in 1912 medical benefit has formed an integral part of the scheme in Great Britain, but Ireland was excluded so far as these provisions were concerned. The Bill proposes to extend the provisions of the National Health Insurance Act to insured persons in Northern Ireland so as to make them entitled to medical benefit on the same lines as insured persons in Great Britain. The Ministry of Labour is to be responsible for the administration of medical benefit with the assistance of a medical benefit council to act in an advisory capacity and certain local committees to deal with local problems. These bodies will replace the existing insurance committees. The medical benefit council will be representative of insured persons, employers, medical men, chemists, and certain members nominated by the Ministry of Labour. It will confer with and advise the Ministry on administrative questions, and will inquire into complaints referred to it by the local committees. These local committees will be representative of doctors, chemists, and insured persons, and will deal with the provision of medical benefits for persons failing to secure acceptance by doctors, and with complaints about treatment and supply and quality of medicines. In addition, committees will be established composed of representatives of the panel doctors and of chemists for questions of exclusive concern to both. One of the most important points in the Bill deals with the present dispensary system. Many persons who at present attend dispensaries for medical treatment are insured persons. Under the new scheme these will be entitled to treatment from a

panel doctor who in many cases will be the local dispensary doctor. It becomes necessary then to effect an adjustment in the remuneration payable to these medical officers, and they have agreed to undertake insurance practice subject to a reduction of 1s. 6d. in the rate per head ordinarily payable to insurance doctors for insured persons (9s.). Their present rate of pay as dispensary doctors will be unaltered. For the effective administration of the National Health Insurance scheme it is desirable that those in receipt of benefit should be visited at regular intervals, but as the insured population is scattered widely over Northern Ireland and is distributed over a large number of societies, it is not possible to do this fairly and effectively without some form of unified scheme available to all societies. The Bill provides that such a scheme be set up and controlled by the societies themselves, but should they be unable to do so before Jan. 5th, 1931, the Ministry may take the necessary steps to provide such a scheme. The domiciliary treatment of tuberculosis in insured persons will become part of the duty of the panel doctor under the medical benefit scheme. As regards the institutional treatment, this will be carried out by the county tuberculosis committees.

Introduction of the Bill.

The Minister of Labour, in introducing his Bill, stated that the death-rate in Northern Ireland was 3 per 1000 higher than in England. This had been attributed to climate and to factory life, but the climate in Northern Ireland and factory conditions were as good as in the North of England. The approved societies considered the high death-rate was due to the non-adoption of medical benefits. Some of the members criticised this, stating that the high rate of emigration left Northern Ireland with a large percentage of old and frail inhabitants; also, that if the inspection of school-children were more generally adopted the death-rate would be lower. Prof. R. J. Johnstone, M.P., who acted as chairman of the Local Government Commission which sat for three years to consider the whole question of the poor-law, summed up the feelings of the majority of medical men and social workers in Northern Ireland when he said in the debate on the Second Reading: "The lack of opposition to the Bill shows that at last public opinion in Northern Ireland is beginning to have a conscience in regard to public health. I am perfectly certain that this measure of public health will be only the forerunner of others that will remove the reproach that we are less interested in public health than the people of other civilised nations. I should have liked to see the recommendations of the Local Government Commission put into effect, with a revision of the entire administration of the public health and medical supply services. It is bound to come and I am sorry it has not come now."

Grants in Aid of Scientific Research.

For the purpose of encouraging and assisting scientific research the Ministry of Education for Northern Ireland is prepared to make grants to a limited number of research workers and students of approved qualifications. The grants, which will be made on the recommendation of the Advisory Board, will be of two kinds: (1) maintenance allowances to enable students to undergo training in research, and (2) senior research awards to enable young investigators of exceptional promise and proved capacity to devote their whole time to original research. Maintenance allowances, which will not exceed £100 and will not be tenable for more than two years, are for students recommended by the professor as able to take full advantage of the facilities for training in fundamental scientific research and who intend to take up a career in which they will devote the whole or part of their time to research work. The senior research awards will not exceed £250 per annum or be tenable for more than three years. The awards will be open to candidates who are not more than 27 years of age and who are recommended by the head of the

laboratory or department in which they have been working. The investigators will be expected to publish the results of their research and will not be permitted to make commercial use of them without the previous consent of the Ministry of Education.

Dublin Hospitals and Religious Tests.

In the last week, in the course of a discussion on certain Government grants which are paid to a few of the Dublin hospitals, it was stated by a deputy that the charter of one of the hospitals concerned—namely, the Rotunda Hospital—made it a condition of the appointment of its Master that he should be a Protestant. A suggestion was also made that the present Master had been induced to change his religion in order to render himself eligible for the post. On the following day Deputy Sir James Craig, on the authority of the Master of the Rotunda, gave an unqualified contradiction of both suggestions, and the deputy responsible for them expressed his regret for having made a statement on misleading information. It is, perhaps, just as well that the opportunity arose for giving a public denial to the widespread rumour that a religious test is a qualification for the Masterhip of the Rotunda. In only one of the Dublin Hospitals, as far as is known, is the profession of any particular form of religious belief a necessary condition for appointment to the staff. It is true, however, that some of the hospitals, having close association with particular churches or religious orders, are likely to have the majority of the members of the staffs in religious sympathy with such churches or orders.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Lübeck Disaster.

THE Lübeck disaster has caused much public alarm, for the number of deaths has risen to 21, and more of the children will probably die. A provisional report has been issued by Prof. Ludwig Lange, of the German Health Office, who was sent to Lübeck by the Government to make an inquiry. He stated that the infection was probably due to the administration of tuberculous material. It has not yet been ascertained for certain, he says, how the tubercle bacilli were introduced into the vaccine, but they were obviously already present at the beginning of the treatment. According to observations in various countries, a return of BCG bacilli to virulence has never occurred. It is thus probable either that tubercle bacilli were present in the cultures sent from Paris or that they were introduced into later cultures. It had not been proved that the cultures were adulterated by negligence in the Lübeck laboratory, but a final explanation can only be given after thorough investigation in the laboratory, which will take several weeks. Replying to a question in the Reichstag, the Minister of the Interior said he had instructed the governments of the individual States of Germany to abstain from using Calmette's method until the facts have been cleared up. A medical member, Dr. Moses, said that the Lübeck authorities had acted with great negligence in distributing a remedy which even in France was not quite established. They had informed the Health Office only 20 days after the first cases of infection were observed.

Prof. Calmette has stated in an interview that it is only to French hospitals that the Pasteur Institute supplies vaccine ready for use. To hospitals abroad the Institute does no more than send cultures from which vaccines can be prepared. Those sent to Lübeck were examined before dispatch and were found innocuous, and the Pasteur Institute is therefore not responsible for the disaster. In France, said Prof. Calmette, 225,000 children were treated by his method between July, 1924, to April, 1930, and no harm was done to any of them.

The German Surgical Congress.

The German Surgical Association held their annual meeting in Berlin from April 23rd to 26th, with Prof. W. Anschütz, of Kiel, in the chair. The first official subject of discussion concerned hæmorrhage and styptics and was introduced by Prof. R. Stich, of Göttingen, who said that high-frequency currents had proved useful as a hæmostatic. The second theme was operation on the vertebral column introduced by Prof. V. Schmieden, of Frankfurt. For vertebral tuberculosis he recommended conservative treatment, but if a cervical vertebra is dislocated Albee's operation is useful. He uttered a warning against opening the dura mater, because of the possibility of infection. In the discussion the majority spoke against Albee's operation. Prof. Rein, of Freiburg, reported that it has been observed that the circulatory organs of surgeons show signs of strain on days of over-exertion after severe operations. The mortality of surgeons is high, and circulatory troubles are the commonest cause of death among them, which occurs on the average ten years earlier than among other people. Operations for gastric ulcer were reported on by Dr. Starlinger, of Vienna, whose records covered 25,600 operations in 85 hospitals. In 14,270 cases Billroth's method with retrocolic gastro-jejunostomy was performed. Relapse was observed in only 0.7 per cent. of the cases and was usually in the anastomosis. To avoid relapse he recommended total removal of the ulcer, the pylorus, and the antrum. A discussion on the dietetic treatment of tuberculosis was introduced by Prof. F. Sauerbruch and Dr. A. Hermannsdorfer who showed numerous patients. It was attested that even desperate cases of tuberculosis were saved by the treatment. Prof. P. Clairmont, of Zürich, confirmed these observations, and there was also a demonstration of cases of lupus successfully treated by the method.

Six Days' Bicycle Race.

Dr. Conrad lately read a paper before the Berlin Medical Society on medical observations during a six days' bicycle race. He said that injuries produced by a fall when travelling at a speed of 60 km. per hour are often less dangerous than those in cyclists going slowly. At high speeds the muscles are keyed up and the possibility of a fall is provided against subconsciously. Among surgical sequels fracture of the articular fossa of the scapula is especially frequent. Constipation is a characteristic feature, and is caused by excessive perspiration producing inspissation of the feces. Infection of the gluteal skin by friction of the saddle is a common result of prolonged cycling. The heart of professional cyclists is, as a rule, much enlarged.

Constipation in School-children.

Dr. Hinsche, a school medical officer, writing to the *Zeitschrift für Schulgesundheitspflege*, is of opinion that constipation is due less to sedentary occupation than to the impossibility of evacuating the bowels at the usual time and of taking long enough over it. This is especially the case with the children who get up too late in the morning and eat their breakfast in haste so that they have no time for defæcation. The early hour at which school begins in Germany contributes to the rush. In the schools children are generally not allowed to visit the w.c. during the lessons and the condition of the privies, which are sometimes dirty and cold, may discourage their use at other times. Constipation in school-children is not a morbid condition, but is caused by external causes which might easily be removed.

Treatment of Diseases of the Adnexa.

Dr. Loeser reports in the *Centrablatt für Gynäkologie* on his experiences with subcutaneous injections of living gonococci. He has performed 1600 injections in women suffering from chronic gonorrhœa of the

cervix and the adnexa, and he says that 76 per cent. were cured within two to six weeks. The chances, he claims, are still better if, during the two first weeks, a small rod of Parthagon or some other silver preparation is introduced into the cervix. This therapy is a specific one, unlike the injections with the vaccines on the market, and it is often useful when other therapeutic measures have proved ineffective. The gonococci used by Loeser came from cases of florid gonorrhœa, and were cultivated in ascites agar.

Dr. Bauer has used fibrolysin in chronic diseases of the adnexa and in post-operative infiltration of the pelvis. It is contra-indicated in acute and subacute inflammation of the true pelvis and in specific inflammation caused by gonorrhœa, tuberculosis, and actinomycosis. Injections of 0.1 g. are made into the muscles every four to ten days, the number of injections being, as a rule, four to ten. He says that in 65 out of 250 cases where the usual treatment had been unsuccessful the infiltration so much decreased under this treatment that the patients no longer complained; in 30 per cent. a considerable improvement was obtained, and in only 5 per cent. did the condition remain unchanged.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 17TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 324 (last week 462); scarlet fever, 1927; diphtheria, 1210; enteric fever, 65; pneumonia, 919; puerperal fever, 60; puerperal pyrexia, 110; cerebro-spinal fever, 16; acute poliomyelitis, 3; encephalitis lethargica, 10; dysentery, 2; ophthalmia neonatorum, 117. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 20th-21st was as follows:—Small-pox, 513 under treatment, 22 under observation (last week 568 and 22 respectively); scarlet fever, 2016; diphtheria, 2414; enteric fever, 29; measles, 879; whooping-cough, 61; puerperal fever, 23 (plus 16 babies); encephalitis lethargica, 120; poliomyelitis, 1; "other diseases," 20. At St. Margaret's Hospital there were 19 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 96 (36) from measles, 8 (3) from scarlet fever, 27 (3) from whooping-cough, 37 (9) from diphtheria, 44 (10) from diarrhœa and enteritis under two years, and 37 (3) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Manchester and Newcastle-on-Tyne. Fatal cases of measles are still widely scattered; Darlington reported 7, Willesden, Warrington, and Middlesbrough each 4, Croydon, Tottenham, Plymouth, Liverpool, and Stockton-on-Tees each 3. Middlesbrough reported 3 fatal cases of whooping-cough. Seven deaths from diphtheria occurred at Liverpool, 3 at Plymouth. Diarrhœa was credited with 5 deaths at Birmingham, 4 at Liverpool.

The number of stillbirths notified during the week was 333 (corresponding to a rate of 46 per 1000 births), including 56 in London.

A SHROPSHIRE COTTAGE HOSPITAL.—Lord Bridgeman recently performed the opening ceremony of the Annabelle, Lady Boughey Hospital at Newport, Salop. The lady whom it commemorates, and who died in 1914, was the wife of Sir Thomas Fletcher Boughey, of Aqualate Hill, Newport, the eldest of five brothers who held the baronetcy in succession between 1880 and 1921. She bequeathed a sum of £15,000 for the establishment of the hospital, which has been increased by accumulations of £27,000. The building, which has cost £15,000, consists of two blocks, a fully equipped theatre, and an X-ray department.

GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

At the opening of the one hundred and thirty-first session of the Council on May 27th, Sir Donald MacAlister, the President, referred to the death, since their last meeting, of Principal John Yule Mackay, for many years chairman of the Education Committee. "His eminence as a scientific anatomist," he said, "and his experienced capacity as an educational administrator, gave weight and distinction to his often laborious contributions to our proceedings." Mr. Samuel Osborn had resigned his membership after five years' tenure as the representative of the Apothecaries' Society of London, his place being taken by Lieut.-Colonel Charles Thomas Samman.

Indian Medical Degrees.

"The position," said [Sir Donald], "which I outlined in my address last November, with regard to Indian qualifications, was not modified by any action taken by the authorities prior to Feb. 24th of this year. The Executive Committee, to whom by the standing orders is delegated the statutory responsibility of recognising overseas diplomas, and so of guaranteeing that every holder thereof possesses the requisite knowledge and skill for the efficient practice of medicine, surgery, and midwifery in this country, felt that the authoritative information placed at its disposal by the Indian authorities was inadequate and defective. The Committee was, in fact, no longer in a position to give this country the guarantee of sufficiency required by law. Accordingly, the conditional recognition which since 1922 had been granted until February, 1930, to certain Indian medical degrees, in the hope that a satisfactory method of official standardisation and guarantee might in the meantime be brought into operation, lapsed on non-fulfilment of the conditions laid down. Until, therefore, a central body, such as the proposed All-India Medical Council, is established by Indian legislation, and is empowered to control and pronounce upon provincial medical qualifications and standards in India, the diplomas referred to, while they may be held to meet the local needs of India itself, will not be registrable here as conforming with the requirements of practice at home.

This decision was reluctantly but inevitably arrived at, after much patient and sympathetic consideration of present difficulties in India. It was duly transmitted to the Secretary of State for India and the Indian Government; but no further official communication on the subject has been received. It is, however, understood that steps towards central legislation will not be undertaken before, at earliest, the session of Assembly in the autumn.

"The Registrar," he added, "has drawn up, from the minutes of the Council since 1921, a memorandum setting forth the successive steps in the long-drawn-out negotiations with the Indian authorities that have led up to the present position."

Privileges of Foreign Practitioners.

The Council had been asked by the Foreign Office, through the Privy Council, for information regarding the rules governing the privileges of foreign practitioners, not registered in our register, in respect of practice among patients in hospitals established for the treatment of foreigners in this country. The question had arisen whether any such privileges might be extended to British practitioners practising in hospitals established in France for the treatment of British subjects. The law, said the President, is contained in Section 6 of the amending Medical Act, 1859, and is as follows:—

Nothing in the said Act (Medical Act, 1858) contained shall prevent any person not a British subject who shall have obtained from any foreign university a degree or diploma of doctor in medicine, and who shall have passed the regular

examinations entitling him to practise medicine in his own country, from being and acting as the resident physician or medical officer of any hospital established exclusively for the relief of foreigners in sickness: provided always, that such person is engaged in no medical practice except as such resident physician or medical officer.

The French authorities, it is understood, are considering the subject, with a view to an agreement to confer corresponding privileges on British practitioners in relation to hospitals for the treatment of British subjects in France. The terms of such an agreement have been drafted with the assistance of the officers of the Council.

Pharmacopœia.

The Pharmacopœia Committee would report on the progress of the work of revision undertaken by the Pharmacopœia Commission. The preparation of a revised text was in an advanced state; but in view of the considerable amount of new matter, in relation, for example, to biological methods of testing under the Therapeutic Substances Act, and otherwise, it appeared unlikely that the new Pharmacopœia would be ready for publication before the end of this year. The Commission and its Committees are, said the President, diligent in their devotion to the tasks assigned to them, and with their chairman, Dr. Beddard, deserve the grateful acknowledgments of the Council. The Privy Council have forwarded the text of the International Agreement respecting the pharmacopœial unification of potent remedies, drafted by the Brussels Conference of 1925, and approved by the Council subject to certain reserves. The text has been communicated to the Pharmacopœia Commission for its guidance.

Examinations.

The cycle of inspections of final examinations was now being carried out continuously by Dr. Wardrop Griffith, Mr. Farquhar MacRae, and Dr. Fairbairn. Reports on a number of licensing bodies had already been received by the Examination Committee, and would in due course be submitted to the Council for transmission to the Privy Council. Visitations of particular professional examinations by members of the Council had taken place, and the visitors' reports were under consideration by the Examination Committee. It appeared that the complex subject comprehending materia medica, pharmacy, pharmacology, and therapeutics, was very variously dealt with by different licensing bodies. "The time seems to have come for considering," said Sir Donald, "whether greater uniformity in the systematic instruction in methods of treatment, medicinal and other, has not become desirable and practicable." A report on the subject was to be presented at the present session.

Preventive medicine as a part of the medical curriculum had been occupying the attention of the Committee, and much valuable information on the place given to it by the medical schools and licensing bodies had been gathered from the visitors' reports. Here, also, the great variety of emphasis assigned to the subject in different quarters seemed to call for serious consideration. The Council of the Society of Medical Officers of Health had presented to the Council a careful and detailed report on the matter from an influential committee appointed by them, and this had been referred to the Education and Examination Committees, in the expectation that they would find it of assistance in framing conclusions, for submission to the Council.

The Education Committee had further considered the question of the methods in use for the teaching of the applications of the pre-clinical subjects, chemistry, physics, biology, &c., during the later (clinical) years of the curriculum. Fuller and more detailed information than was available last November had been gathered, and their conclusions would be reported pending the completion of the cycle of inspections.

illustrative example has come to my notice. On p. 149 of "All Quiet on the Western Front," describing an event from the German side in the recent war, it is stated "Westhus drags off with a great wound in his back through which the lung pulses at every breath." I should be grateful if any of your readers could cite, from their own experience, similar cases showing that the freely exposed lung remains distended and does not collapse.

I am, Sir, yours faithfully,

P. WATSON-WILLIAMS.

Clifton, Bristol, May 21st, 1930.

THE STERILISATION OF HYPODERMIC NEEDLES.

To the Editor of THE LANCET.

SIR,—The annotation on broken hypodermic needles in your issue of May 17th opens up the unsatisfactory question of the sterilisation and storage of hypodermic outfits in general. Correspondence on this subject would probably be both interesting and instructive.

If steel hypodermic needles are sterilised in olive oil at its boiling point, and, after use, washed through with two changes each of distilled water, surgical spirit and ether, impelled in an outward direction by means of the syringe, being subsequently dried by air similarly impelled, they will not rust or block, nor, barring accidents, do they seem to get blunt, whilst the ease and painlessness of the injection, owing to the lubrication in itself repays any possible extra trouble.

Such needles can either be stored in the oil or lightly oiled and stored dry. I have in my possession needles treated in this manner which, although at a mild estimate used more than 50 times each, appear as good and bright as ever, the only part showing wear being the plating of the holder, scratched from frequent manipulation with forceps. It is of interest to note that the tedious process of searching for, picking up, and inserting the tiny wire stilette appears unnecessary in this method. For obvious reasons the oil-sterilised needles should not be used for drawing the solution into the syringe, this duty being best performed by a platinum-iridium needle of fairly wide bore, kept for the purpose only and sterilised by flaming. A substitute which does not possess the unpleasant smell of boiling olive oil would be welcome.

The advice that a fresh needle should be used for each injection is a counsel of perfection, but in a course of 12 injections it would involve an extra cost of from three to nine shillings, or more than twice this sum if stainless steel were used, though prices as quoted in different catalogues vary widely. This is a consideration, in view of the increasing use of hypodermic, intramuscular, and intravenous therapy. Needles showing any discoloration, roughness, or rusting should be discarded forthwith. Breakages usually occur from erosion at the junction of needle and holder, and it is therefore wise to keep the proximal one-eighth of an inch of the needle in view during the process of injection, especially in intramuscular cases, so that extraction with forceps can be carried out in case of accident.

Whatever method is adopted in sterilising syringes and needles, provided sterilisation is effective, and the comfort of the patient and welfare of the outfit taken into consideration, a period of time measured in minutes is necessary. If there is real necessity for extra haste, or circumstances are unfavourable for routine procedures as, for instance, in road or rail accidents, recourse can be had to the Tubunic ampoule syringe (Hoffmann la Roche) or similar principle in which solution, syringe, and needle in sterile condition are so arranged as to be ready for instant use.

I am, Sir, yours faithfully,

Rustington, Sussex, May 23rd, 1930. W. E. WALLER.

TREATMENT OF G.P.I. BY INJECTION OF SULPHUR.

To the Editor of THE LANCET.

SIR,—Dr. Noel G. Harris, in the paper published on p. 1068 of your issue of May 17th, gives a preliminary report on his results with the treatment of general paralysis by injection of sulphur. On the whole, this report is confirmatory of my paper¹ on the therapeutic effect of sulfosin, but I would like to make a couple of comments upon it. Harris prefers to give the injection at about 7 P.M., instead of giving it in the morning as suggested by me. Whether the injection is given in the morning or in the evening makes no difference in its therapeutic effect; so the time of injection is mostly a matter of convenience. I heartily agree with him in emphasising that each patient should be studied as to his individual capacity for responding to the injection pyrexia. I myself have never employed any fixed increase of dosage. I also agree with his statement that the earlier the pyrexial treatment is instituted in cases of general paralysis, the greater is the chance of recovery. The great advantages of sulfosin therapy are that the treatment may be instituted at once and anywhere, since one may always have it at hand ready for use without any preparations—and that it may be given unhesitatingly, because, unlike malaria therapy, it is perfectly safe.

I am, Sir, yours faithfully,

Odense, Denmark, May 22nd, 1930. KNUD SCHROEDER.

BLOOD-PLATELET COUNTS.

To the Editor of THE LANCET.

SIR,—Dr. Willinsky's very interesting researches on the variation of blood-platelet counts, published in your last issue (p. 1126), do not provide any direct evidence in support of Howel Evans's theory of post-operative thrombosis as, unfortunately for his investigations, no case of thrombosis occurred in his series, although the count reached over a million in three of the recorded cases. A. Kristenson, who uses a direct method for counting blood-platelets (*Act. Med. Scand.*, 1928, lxi., 227), reports that in a series of spontaneous venous thrombosis, not associated with operation, clinical signs of thrombosis were preceded by a fall in the count. He refers to the work of E. Normann (*Act. Med. Scand.*, *ibid.*, p. 479), who confirms this fall in the blood-platelet count in post-operative thrombosis. E. Koloze has pointed out (*Wien. klin. Woch.*, 1928, xli., 1342) that the great difficulty in investigating blood-platelets lies in their easily altered form and structure. Her technique for counts is an indirect method which gives results from 600,000 to 900,000 as normal. She argues that the "fragility" of the blood-platelets is a very variable factor in different diseases, and explains the discrepancy between different methods of counting.

I am, Sir, yours faithfully,

Bristol, May 24th, 1930.

FRANK BODMAN.

BACTERIAL BLOOD CULTURES.

To the Editor of THE LANCET.

SIR,—In your issue of April 12th (p. 821) Dr. R. J. V. Pulvertaft condemns the use of sodium citrate and solid media in blood culture work. I have had considerable experience in the Caribbean in culturing the blood of patients suffering from infections with the beta-hemolytic streptococcus and find both of these agents to be of great value. It has been my custom to take 15 c.cm. of blood into 1.5 c.cm. of 10 per cent. sodium citrate (Merck), and to place 0.5 c.cm., 1.0 c.cm., and 2.0 c.cm. into three

bottles each containing 40 c.cm. of phosphate glucose broth. The same quantities of blood were mixed with 10 c.cm. of ox heart agar and three plates poured therefrom. The advantage of the solid medium is that it enables one to identify hemolytic colonies at once, to determine the degree of hemolysis in the weakest dilution, and to detect contaminating organisms. The use of liquid medium alone increases the time taken to isolate a strain of beta-hemolytic streptococcus, owing to the fact that the original liquid culture has to be streaked on a blood-agar plate to detect the hemolytic colonies. It also increases the risk of losing the strain altogether for, if contamination has occurred, the contaminating organism usually outgrows the streptococcus overnight, and the strain can only be saved by the expenditure of considerable time upon the pouring of plates and subsequent fishing of colonies.

I am, Sir, yours faithfully,
ARTHUR W. GRACE.

Pathological Laboratory, Public Hospital, Kingston,
Jamaica, B.W.I., May 13th, 1930.

SANATORIUM AND AFTER.

To the Editor of THE LANCET.

SIR,—Reflection on the work done at Papworth, Preston Hall, and other settlements, and on your leader and special article of May 24th, suggests the question: Can nothing further be done for the much greater number of the tuberculous who are, physically or otherwise, unsuitable for such settlements, and who are probably still more unsuitable for life in an ordinary community? Keeping in view the object, as stated by Dr. P. C. Varrier-Jones, "to stamp out tuberculosis," it would seem that to prevent highly infective persons, who are unfit for any employment, and who must be maintained, from returning to their families, to the common lodging-house, or to other unsuitable houses, must be worth a great amount to any population. Any capital invested in such an undertaking, which I believe is quite feasible, would be returned many times over in the saving on treatment, as the numbers infected by exposure would certainly be much diminished. Under any scheme adopted, those segregated would be made reasonably comfortable and content, and the measure of its success would be the extent to which it was able to prevent the return of those who were most dangerous, from the public health point of view, to their old mode of life.

I am, Sir, yours faithfully,

WALTER CRANE,

Principal Resident Medical Officer,
Fazakerley Sanatorium, Liverpool.

May 27th, 1930.

ROYAL MEDICAL BENEVOLENT FUND.—At a recent meeting of the committee 40 grants were voted amounting to £1025. The following were some of the cases helped:—

Widow, aged 47, of M.R.C.S., who died in February, at the age of 46 leaving his widow and two boys, aged 16 and 13. The widow expects to have an income of £100 a year. The Fund has undertaken to pay the school fees and maintenance of the two boys for this year; this will mean an expenditure of £42. This grant will relieve the widow from immediate anxiety and give her time to look for employment herself, which she hopes to find, for she is a fully trained nurse. The elder boy of 16 will leave school at the end of this term and find employment.

M.R.C.S., aged 75; widower; has been an assistant for the last eleven years, but has recently had to retire owing to defective hearing and impaired eyesight. He is now living with his step-son, upon whom he has no direct claim. The step-son is a country clergyman and without means. Applicant's only income is the old age pension. Voted £40.

M.R.C.S., aged 60, with wife and child aged 6. Had to give up practice in 1925 owing to paralysis. He has a pension for incurables of £20 which is his only income; his wife has £130 a year. Voted £10.

Widow of L.R.C.P. & S., aged 76. Has an Epsom pension of £10 and old age pension of £26. Fund voted £25 to bring the total income to £41 a year.

Subscriptions and donations should be sent to the Hon Treasurer, 11, Chandos-street, Cavendish-square, London, W.

Obituary.

FRANK RICHARDSON BLAXALL, M.D. LOND.,
D.P.H. CAMB.,

DIRECTOR OF THE GOVERNMENT LYMPH DEPARTMENT.

WE much regret to record the death on May 24th of Dr. F. R. Blaxall, the head of the Government Lymph Department at Hendon, which occurred in his sixty-fourth year at his residence, Brantwood, Edgware.

Frank Richardson Blaxall studied at University College, London, taking the English conjoint diploma in 1888, and in the same year graduating in medicine in the University of London with honours. Having held the resident posts at the hospital as house physician and obstetric assistant, he became assistant medical superintendent at St. Pancras Infirmary, and for a time held a post with the Ocean Steamship Company. In 1890 he proceeded to the M.D. Lond., he shortly afterwards took the diploma of D.P.H. Cambridge, and in 1893 commenced his real life-work with his appointment as lecturer in bacteriology at the Westminster Hospital medical school. Here he did some work on ringworm in collaboration with Dr. Colcott Fox, then physician to the skin department of the hospital, and this was followed by association with Prof. Allan Macfadyen at the Lister Institute of Preventive Medicine, a paper on Thermophilic Bacteria being published by them in the *Journal of Pathology and Bacteriology* in 1894. Sir Richard Thorne Thorne, then principal medical officer to the Local Government Board, appointed Blaxall as bacteriologist to the Government Vaccine Laboratories while the Royal Commission on Vaccination, appointed in 1889, with Lord Herschell as president, was still sitting. The evidence given before this Commission was issued from time to time in interim reports, and Dr. S. M. Copeman, who had already been working for some three years on the employment of glycerin for the preservation of vaccine lymph, gave evidence before the Commission and was instructed by the Local Government Board to make arrangements with Blaxall to carry out a further series of experiments on the lines indicated in the evidence. At the instance of the Local Government Board, however, before taking up his official duties, Blaxall made an extended tour of the continent with a view to inquiring into the whole subject of vaccination as understood in the various vaccine institutions of other countries, and when he commenced in 1893 what proved to be his official work for the next 32 years of his life he was thoroughly well equipped both in principle and in detail for dealing with the many problems presented by the subject. How faithfully he had dealt with them is well illustrated by the following which we have received from one of his senior colleagues at the Ministry of Health:—

Sir George Buchanan writes: "Combining Local Government Board and Ministry of Health services, Blaxall had for several years been the senior of the medical officers of the central public health department. On the usual official reckoning we should at least have had another year of active work from him, and have found it as invaluable as ever. His was one of the expert posts in the civil service of which little or nothing is heard so long as, and because, it is quietly and efficiently run. When this has been said of Blaxall over duties so liable to meticulous criticism as the supply of vaccine lymph, there can be no higher tribute to his work. The distressing news of his death reaches me abroad and away from references, or I would turn to and quote from records which show how, since the vaccination legislation of 1898, he successfully established the Government Lymph Establishment at Hendon on a system which has given us continuously a supply of vaccine for the public vaccination of the country that can confidently challenge comparisons with any other system in the

recognition to the Indian medical degrees. That something might be arranged at the earliest possible moment was in the interests of both India and this country alike.

HOUSE OF COMMONS.

WEDNESDAY, MAY 21ST.

Cargo of Narcotics for the Far East.

Mr. D. G. SOMERVILLE asked the Secretary of State for Foreign Affairs whether he could make any further statement as to the ownership, destination, and contents of the ship which recently sailed from the Persian Gulf for the Far East with a large cargo of narcotics.—Mr. A. HENDERSON replied: The ship in question is reported to be a Chinese vessel and to have sailed from Bushire on April 27th with a cargo of 2308 cases of unlicensed opium declared for Vladivostok.

THURSDAY, MAY 22ND.

Improvements at Bracebridge Mental Hospital.

Lieut.-Colonel HENEGE asked the Minister of Health whether his attention had been called to the delay in authorising the alterations and improvements required by the visiting committee to the Bracebridge Mental Hospital; whether he was aware that the committee was being constantly referred from one Government department to another; and whether he could see his way to obviate the present delay in the interests of patients.—Mr. GREENWOOD replied: The proposals have required the consideration of the Ministry of Health and the Electricity Commissioners as to the power plant at the hospital. I will endeavour to ensure that an early decision is given.

Sewage Works Nuisance at Hanwell.

Major SALMON asked the Minister of Health if he was aware that the residents in some 300 houses on the Elthorne Heights Estate, Hanwell, Middlesex, suffered inconvenience from the odours which emanated from the sewage disposal works in the vicinity; whether his attention had been called to the proposal of the Corporation of Ealing to expend the sum of £11,500 on the enlargement of such sewage disposal works; and what steps, if any, he proposed to take to ensure that the nuisance at present arising from the works should be permanently eliminated in the interests of the health of the residents.—Mr. GREENWOOD replied: I have received complaints. The town council have applied for sanction to a loan for the improvement of the works, and inquiry into the application was recently held by one of my inspectors. On receipt of his report I will consider the appropriate steps to be taken.

Mental Treatment Bill.

Mr. WINTERTON asked the Minister of Health whether with regard to the two medical commissioners to be appointed under the terms of the Mental Treatment Bill he would favourably consider the suggestion that one of them should be a woman.—Mr. GREENWOOD replied: The Mental Treatment Bill proposes that of the five senior commissioners who are to compose the Board of Control, one shall be a woman. In the appointment of the two medical senior commissioners, it will be necessary to have regard primarily to their qualifications for advising upon the treatment of mental disorders; and I cannot give any undertaking that one of the medical commissioners shall be a woman.

Home Office and Anthracosis.

Dr. JOHN WILLIAMS asked the Home Secretary (1) whether his department had published reports of cases of anthracosis; and whether a list of persons declared to have suffered from this complaint was available at the Home Office; and (2) whether he had any evidence that anthracosis was due to special conditions obtaining in the anthracite coal-field; and whether he was prepared to include it in the list of occupational diseases which could be scheduled for the purposes of the Workmen's Compensation Act.—Mr. SHORR (Under Secretary for the Home Office) replied: The reply to both parts of my hon. friend's first question is in the negative. The investigation of the effects of coal dust on the lungs has been referred to the expert Committee on the Industrial Pulmonary Diseases, which was recently set up at my right hon. friend's request by the Medical Research Council, but it has yet to be established that the condition of the lungs described as anthracosis is the cause of disablement, and meanwhile it would not be possible to bring it within the scope of the Workmen's Compensation Act. I am advised that there is some evidence of special changes in the lungs due to the conditions in the anthracite coal field, but this is a point which will need further investigation.

Home Office and Anthrax.

Mr. DUKES asked the Home Secretary if his attention had been directed to the following fatal cases of anthrax

in the Liverpool, Runcorn, and Warrington district: Walter Pritchard, 16, Ellesmere-street, Warrington, January, 1920; William Ronald Williamson, Runcorn, February, 1920; Thomas Burden, July, 1920; Ernest Hindley, Runcorn, March, 1930; Richard Andrews, 35, Fothergill-street, Warrington, April 12th, 1930; and Mary Dawbarn, 3, Glazebrook-street, Warrington, April 20th, 1930; and whether, in view of the frequency of these cases, he would set up a committee of inquiry with a view to having this disease treated more expeditiously than at present.—Mr. SHORR replied: The cases mentioned in the question were all reported to the Factory Department and carefully examined, and my right hon. friend is advised that, while in some of them the seriousness of the case may have been aggravated by some delay in recognising the disease, treatment was given without delay in every case as soon as it was recognised to be anthrax. It is, of course, most important that cases of anthrax should be recognised as well as treated without delay, and various steps have been taken by the Factory Department from time to time with this object. For example, a large placard indicating symptoms and precautions and the urgency of medical examination where infection is suspected has been prescribed for exhibition at the places of work; and a small card on similar lines is now being prepared, which the workman can keep by him and show to the doctor or hospital authorities, to indicate that his employment involves risk of anthrax. Further, special steps have recently been taken as regards the tanning industry in which my right hon. friend understands all but one of the cases referred to in the question occurred. The senior medical inspector recently addressed a circular to the hospitals in districts where cases have occurred drawing attention to the risk among persons handling hides and skins, and the importance of being on the look-out for possible cases among patients presenting themselves at the institution. Again, in a recent Home Office circular to tannery occupiers the importance of prompt diagnosis and treatment was specially mentioned, and they were urged to review their arrangements for securing this and to get into touch with local hospitals where necessary. My right hon. friend does not think that the appointment of a committee of inquiry would be likely to carry matters any further, but the subject will continue to receive close attention, and if my hon. friend has any particular suggestion to make my right hon. friend will be very glad to consider it.

MONDAY, MAY 26TH.

Cattle and Tuberculosis.

Dr. HASTINGS asked the Minister of Agriculture if he could say, having regard to the fact that of the 241,000 bovine animals examined during 1929 under the Tuberculosis Order, 1925, 2.8 per cent. only were condemned to be slaughtered, whether all the remaining 97.2 per cent. were entirely free from tuberculosis; and, if not, whether he could give any estimate of the probable number infected.—Mr. BUXTON replied: The total number of animals on premises, on which cases of tuberculosis were reported under the Tuberculosis Order, 1925, during 1929, was 621,396. Of this total 241,262 animals were examined by veterinary inspectors. Of these, 15,732 animals were condemned and slaughtered, representing 2.8 per cent. of the total number of animals on the premises, or 6.5 per cent. of the total number examined. The remainder were not necessarily entirely free from tuberculosis, but they presented no symptoms of a nature to bring them within the scope of the Tuberculosis Order as to compulsory slaughter. As regards the last part of the question there is no information upon which an estimate could be based of the proportion which might be infected.

Pensioners and Sickness Benefit.

Captain CAZALET asked the Minister of Health whether, in view of the fact that men drawing disability pensions and who were members of the National Health Insurance Fund only drew part benefit for sickness, he would take action either by legislation or administration to see that they drew full benefit.—Miss SUSAN LAWRENCE replied: Under the Act, benefit is only reduced in the case of men who are in receipt of a pension from the State at the total disablement rate. The reduction ceases to operate when a man has resumed work, and contributions have been paid for a certain number of weeks. My right hon. friend does not propose to introduce any amending legislation on the subject.

International Congress on Mental Hygiene.

Mr. MANDER asked the Minister of Health whether the Government were officially represented at the International Congress on Mental Hygiene recently held in Washington; if so, by whom; and what report had been received of the proceedings.—Mr. GREENWOOD replied: His Majesty's Government were represented at this congress by Sir Hubert

Bond, a medical commissioner of the Board of Control. Sir Hubert Bond has not yet returned to this country, and no report has yet been received.

Small-pox and Vaccination.

Mr. GROVES asked the Minister of Health which county of England and Wales had the lowest and which the highest percentage of primary vaccinations to births during the past ten years; and how many cases of small-pox per 1000 of the population had been reported in the counties in question during the same period.—Mr. GREENWOOD replied: During the years 1919 to 1928 inclusive, the counties in England and Wales with the lowest and highest percentage of primary vaccinations to births were Leicestershire and Anglesey respectively. The total number of cases of small-pox notified during the same ten years per 1000 of the average population was 0.03 in Leicestershire (including the county borough of Leicester) and 0.02 in Anglesey.

Remuneration of Public Vaccinators.

Mr. GROVES asked the Minister of Health how many public vaccinators were now paid by salary and how many by fees.—Mr. GREENWOOD replied: On March 31st last, which is the latest date for which complete particulars are at present available, 28 public vaccinators had contracts which provided for payment by salary, and 4293 had contracts which provided for payment by fees.

TUESDAY, MAY 27TH.

Increase in the Population.

Mr. DAY asked the Minister of Health the average annual increase of the population of England and Wales for the years 1927-1928 and 1929.—Mr. GREENWOOD replied: The increase of the population of England and Wales between mid-1927 and mid-1929 is estimated at approximately 317,000, corresponding to an average annual increase of 168,500.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful:—

Surgery.—E. C. Dymond, St. Mary's Hosp.; R. F. T. Flann, St. Bart's Hosp.; E. A. Froywirth, Heidelberg; H. G. Hind and J. H. Johnston, St. Bart's Hosp.; E. Letham, Guy's Hosp.; A. Liberis, St. Bart's Hosp.; and J. Ross, Toronto and Charing Cross Hosp.

Medicine.—G. P. Charles, Sydney and Westminster Hosp.; A. R. Edwards, Liverpool; J. D. B. Games, St. Bart's Hosp.; J. Ross, Toronto and Charing Cross Hosp.; E. M. M. Shaw, Westminster Hosp.; W. H. Willis, Western Reserve University, U.S.A.

Forensic Medicine.—A. Buch, St. Mary's Hosp.; G. T. W. Caswell, King's College Hosp.; T. C. Koble, St. Mary's Hosp.; E. H. W. Lyle, King's College Hosp.; C. G. Nicol, St. Mary's Hosp.; J. Ross, Toronto and Charing Cross Hosp.; C. M. Smith, Edinburgh; A. L. Thomas, Guy's Hosp.; and W. H. Willis, Western Reserve University, U.S.A.

Midwifery.—G. T. W. Caswell, King's College Hosp.; Y. Haig, Paris; J. Ross, Toronto and Charing Cross Hosp.; A. L. Thomas, Guy's Hosp.; and W. H. Willis, Western Reserve University, U.S.A.

The diploma of the society was granted to the following candidates, entered them to practise medicine, surgery, and midwifery: A. R. Edwards; J. H. Johnston; A. Liberis; and J. Ross.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS.—The annual general meeting of this college, held at the Royal College of Nursing, London, on May 20th with Prof. W. Blair Bell, the President, in the chair, the result of the election of the council was announced. At the first meeting of the new council held in the afternoon of the same day the officers were elected, and the casual vacancies created by these elections were filled. Dame Louise McIlroy was co-opted for the special purpose of representing women Fellows and Members. The following are the officers and the full council elected:—President: Prof. W. Blair Bell. Vice-Presidents: Dr. J. S. Fairbairn and Prof. J. Munro Kerr. Hon. Treasurer: Mr. Eantley Holland. Hon. Secretary: Prof. W. Fletcher Shaw. Council.—London: Dr. H. Russell Andrews, Dr. T. Watts Eden, Dr. J. S. Fairbairn, Dame Louise McIlroy, and Mr. L. O. Rivett. England and Wales: Prof. A. Donald, Sir Ewen Maclean, Dr. H. Leith Murray, Prof. Miles Phillips, Prof. I. Beckwith Whitehouse, Dr. E. Farquhar Murray, and Dr. Eric Stacey. Scotland: Prof. R. W. Johnstone, Prof. Munro Kerr, Dr. R. A. Lennie, and Dr. W. P. T. Haultain. Ireland: Prof. C. G. Lowry, Dr. Bethel Solomons, and Dr. T. M. Healy.

UNIVERSITY OF LONDON.—At a meeting of the Senate on May 22nd the Dunn Exhibitions in anatomy and physiology for 1930 were awarded to Mr. Abraham Birnbaum, of the London Hospital Medical College.

The degree of D.Sc. in physiology has been conferred on Mr. A. S. J. M. Huggott, of St. Thomas's Hospital Medical School.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—Dr. S. A. Kinnier Wilson will deliver the Morison lectures at the College at 5 P.M. on Monday, Tuesday, and Wednesday, June 2nd to 4th. His subject will be Nervous Semiology.—The Dr. Alexander Black lecture will be given by Dr. David Morison at 5 P.M. on Friday, June 20th, and will be devoted to Folk Medicine in Scottish Ballad Literature.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—The biennial dinner of this Society was held at the May Fair Hotel, London, on May 22nd, when the President, Dr. G. Carmichael Low, welcomed a large company of members and guests; the latter included Lady Manson, Sir John Rose Bradford, Admiral Gaskell, Lieut.-General Fawcett, Sir Herbert Read, Sir Basil Blackett, Mr. Donald Armour, Col. T. R. St. Johnston, Major F. T. G. Hobday, Dr. N. G. Horner, and Sir Squire Sprigge. After the loyal toast it was announced from the chair that the Morison Reading, who had intended to propose the toast of the evening, was unable to be present, but Dr. Low took the opportunity to point out how extensive and valuable his work in connexion with tropical medicine in India had been during his Viceroyalty, and how enthusiastically that work had been seconded by the late Lady Reading.

Sir John Rose Bradford, who had consented to speak in Lord Reading's place, was, said Dr. Low, the author of researches to which tropical medicine owed a real debt, although his early and special studies might have been somewhat overshadowed by his great general and professional activities. He reminded the audience that Sir John had been until lately senior medical officer to the Colonial Office. Sir John Rose Bradford, in proposing the prosperity of the Society, gave a brief sketch of its progress enumerating the names of the highly distinguished presidents. He pointed out that what it existed to promote should have a peculiarly strong appeal because the study of tropical disease was above all things one where laboratory and clinical work proceeded hand-in-hand. While the objects of medicine were threefold—to cure, to relieve, and to prevent, in tropical medicine, through researches in the laboratory, we had the most direct examples of prevention. But the results of laboratory research, he said, must never blind the physicians of to-day to the extraordinary accuracy and success with which the old clinical workers, possessing none of the modern adjuncts to research, came to accurate conclusions. Speaking as a general physician he desired to regard medicine as a branch of natural history, and in no department of medicine was this fact displayed so accurately as in tropical medicine. Dr. Low in reply told how the Society had been formed at a meeting in the Colonial Office in 1907. In enumerating the presidents, he alluded to the wonderful work of Patrick Manson, Ronald Ross, Leishman, and Bruce, and pointed out that the number of Fellows of the Society had steadily increased as its objects became known and its doors had been thrown open to persons interested, whether medical men or not. But, he said, this success could never have been achieved save through the efforts of the Society's officials, and he described the heavy debt which the Society was under to Dr. C. M. Wenyon, the honorary secretary, and Miss M. Wenyon. He closed by bringing to the notice of the audience the recently issued appeal for subscriptions to take the form of a memorial to the Society of Tropical Medicine and Hygiene, which would also be a material memorial to Patrick Manson. Towards the object of this appeal the Fellows of the Society themselves had subscribed over £2000, but three times that sum was still required.

The toast of the Guests was proposed by Dr. Manson-Bahr in amusing terms, for he stated that there were 15 of them and although two of them had defaulted the other 13 represented a formidable combination, when he allotted places to them in accordance with football physiology. The toast was given in the name of Sir Herbert Read, who had been private secretary to Joseph Chamberlain when under that great Colonial Secretary the era of tropical medicine commenced, and Admiral Gaskell the medical director of the Navy. Sir Herbert Read, the Ex-Governor of Mauritius, testified, as a result of personal visits to many colonies, to the vital work carried on by the officers of the Colonial Service and workers in hygiene and science in all regions of the world. Admiral Gaskell, in his brief reply permitted himself one political allusion, when he said that a strong Navy was not required for attack but as an insurance against attack, while to be strong the Navy must be healthy. The toast of the Chairman was proposed by Col. W. P. MacArthur.

Notes, Comments, and Abstracts.

THE EFFECTS OF ELECTRIC SHOCK.

THE pathology of electric shock still needs elucidation, and research on animals; though its shortcomings are obvious, gives valuable information not otherwise obtainable. O. R. Langworthy and W. B. Kouwenhoven have recently published the results of a series of experiments on rats.¹ Their work was concerned primarily with injuries to the nervous system; rats do not die from auricular fibrillation, and the terms of the experiments eliminated the possibility of death through burning or failure of respiration.

The two questions which they tried to answer were whether it was possible to demonstrate definite lesions of the central nervous system in all cases of death by electricity with respiratory failure, and how many cases of delayed death were due to demonstrable lesions of the central nervous system. The current was applied from a metal cap on the head to a clip on the base of the tail. The results varied considerably with the intensity and nature of the current applied. It was found, contrary to the general belief that anaesthesia and sleep diminish the effects of an electric shock, that the mortality was definitely greater under deep anaesthesia. There was no noticeable sex difference, except that pregnant rats seldom recovered. Younger animals were less resistant than older ones. At 110 and 220 volts the alternating current was more destructive than the continuous, but at 1000 volts the continuous current did more harm. The duration of the contact proved more important than it had seemed to be in previous investigations; no rat survived after an exposure to a continuous current of 1000 volts for a second or more, although several survived exposure for a fraction of a second. The paralysis, however, depended less on the time element than on the initial shock.

The experiments provide an interesting commentary on the suggestion that it is possible by artificial respiration to save an animal whose nervous system has not been burnt. A large number of rats died at once after the shock without breathing again, and many of them were found to have developing hemorrhages in the nervous system. A continuous current left the chest completely collapsed, whereas the alternating current fixed it in maximal expansion, and the strong tonic contraction of the whole musculature persisted for several seconds after the current was interrupted. Manipulation of the chest then often initiated spontaneous breathing, and at the higher voltages artificial respiration was more successful after alternating currents than after continuous ones. It is, however, never very satisfactory in such small animals. No rat died from cardiac failure, and the heart beat strongly and regularly after the shock in nearly every case. Rats only breathed during the shock with the lowest voltage, that of the 110-volt continuous current, and the respiration stopped when the switch was opened. Breathing seldom began spontaneously and was usually abnormal for a period of varying length, a result which suggests an intense injury to the respiratory apparatus. The authors believe that few of these rats could have been saved by any method of artificial respiration, but nevertheless emphasise the importance in man of attempting rescue immediately after the shock.

Cerebral hemorrhage was commonest in the brain-stem. It was often found that some blood had escaped into the subarachnoid space, and rupture of the arteries of the choroid plexus produced the common picture of hemorrhage into the cerebral ventricles. Hemorrhage into the spinal cord, an injury of alternating currents, seemed to be due to a mechanism typical for all cases, chiefly the rupture of a small artery in the posterior septum in the lower thoracic region. The blood, it appears, escapes among the posterior column fibres of the cord, producing a good deal of damage and extending for a considerable distance in both rostral and caudal directions. Minor hemorrhage limited to the posterior columns produced little abnormality of behaviour, but in most cases the blood broke into the central canal and spread up and down, pressing on the ventral cells and injuring the tracts, and in some cases leading to a complete transverse necrosis of the cord. At autopsy the cord in the lower thoracic area of rats which had shown severe paralysis of the hinder parts was often completely disintegrated. These hemorrhages into the cord were much more commonly found after shocks with alternating currents than with direct; the time of exposure did not seem to be very important. R. W. Urquhart² showed that the blood pressure rose to twice its normal height when the current was switched off, and the present authors consider that this fact would account for all hemorrhages except, possibly,

those of the spinal cord. They point out that the latter seemed to occur always at the place of greatest curvature of the spinal column. The cord, however, lies so freely in the vertebral canal that it is hard to see how even a violent pull on the spine could injure its blood-vessels. The authors do not suggest an explanation. They promise a further contribution describing the injuries to the central nervous system in greater detail.

The important part of their work, practically speaking, is the doubt which it throws on Urquhart's statement that artificial respiration will revive any animal in which no cardiac damage has occurred. They have shown that hemorrhages incompatible with life can certainly occur in the central nervous system of rats. It would be valuable to know whether this is true for larger animals or man.

A MEDICINAL SPRING ON THE BEACH.

To the Editor of THE LANCET.

SIR,—I should like to bring to the notice of those of your readers who are interested in hydrology a flow of waters on the beach at Newtown, Porthcawl, Glam., which has a remarkable action on a limb immersed in it. Although the waters are much colder than the sea, they confer on the limb a ruddy appearance and a feeling of warmth. If immersed for some time in adjacent pools, though these feel much warmer, the part turns white and becomes numb. The well is mentioned by Camden in his "Britannia" and has a tradition of being efficacious in healing pain in old wounds and arthritic joints.

I am, Sir, yours faithfully,

W. HARTLAND, M.B., B.Ch. R.U.I.

The Poplars, Porthcawl, March 31st, 1930.

BRITISH EQUIPMENT FOR HOSPITALS.

To the Editor of THE LANCET.

SIR,—May I ask for the hospitality of your columns to emphasise how desirable it is that our large voluntary hospitals should be equipped with British instruments? Although it may be taken for granted that the members of our hospital committees and the subscribers to hospital funds are patriotic men who appreciate the dire need of our home industries in the present conditions of unemployment, it is a lamentable fact that foreign surgical and electro-medical instruments, &c., are still to be found in many of our institutions.

It is safe to say that in the majority of these cases the responsible authorities have no knowledge of the facts, as in too many instances in which foreign appliances are factored by British firms some pains are needed to elucidate the position.

I trust, however, that once this matter has been ventilated, our hospital committees will ask the firms who quote prices for their equipment to give full particulars in their tenders of the factories in which the work will be carried out, so that they can satisfy themselves that the goods they purchase are not only sold by British firms, but are indisputably manufactured in this country.

The leading British manufacturers can be trusted to produce the very best instruments, so that in the long run this should not involve any extra cost, and even if in some cases additional money has to be provided at the outset the purchasers will have the satisfaction of knowing that, by their patriotic action, they are helping the classes on whom they depend for the maintenance of the institutions they administer so faithfully.

I am, Sir, yours faithfully,

J. A. CORCORAN,
Director.

TUBERCULOSIS LEAFLETS.

THE National Association for the Prevention of Tuberculosis (Tavistock House North, Tavistock-square, London, W.C.) has issued revised editions of three leaflets: No. 3 dealing with milk and tuberculosis, No. 9, with hints on the management of children up to 5 years of age, and No. 10, with hints on the care of children of school age. Any of these may be obtained at one shilling a dozen or five shillings a hundred, post free. The practitioner will find these leaflets useful in saving his time when he has to give directions for prevention or treatment.

INFORMATION ON BIRTH CONTROL

OUR issue of April 12th contained an account of a recent conference on the giving of Information on Birth Control by Public Health Authorities. A full report of these meetings has now been published and may be had from the Conference Secretary, Parliament Mansions, London, S.W.1. (Price 6d.)

Lectisomian Lectures

ON

ENLARGED PROSTATE AND
PROSTATECTOMY.

Delivered before the Medical Society of London

By SIR JOHN THOMSON-WALKER, O.B.E.,

M.B. EDIN., F.R.C.S. ENG.,

CONSULTING UROLOGIST TO KING'S COLLEGE HOSPITAL; SURGEON
TO ST. PETER'S HOSPITAL.LECTURE II.—SELECTION OF CASES OF ENLARGED
PROSTATE FOR OPERATION.

(Delivered on Feb. 26th.)

THE cases on which McGill and his contemporaries operated were cases where catheter life had been tried and had failed. All other cases were treated by the regular passage of the catheter. At the present time catheter life, or permanent bladder drainage, is only used in cases that are unsuitable for operation. The conditions under which cases of enlarged prostate are selected for operation have therefore been reversed. When did this change take place? Undoubtedly at the time when the perineal method was simplified by the French surgeons and the suprapubic operation was popularised by Freyer. It was one of those changes that come about almost without comment and is accepted without being definitely stated. It would seem as strange now to put all cases of prostatic enlargement on the catheter as it would, in McGill's day, have seemed out of the question to submit all cases to operation. As late as 1901 Cabot of Boston¹ expressed his view that operation should only be done in carefully selected cases, and that the greater proportion of cases should be treated by the intelligent use of the catheter. Three years later (1904) I wrote, in a review on the "present status of suprapubic prostatectomy for enlarged prostate," as follows: "The question that presents itself to the surgeon in cases of enlarged prostate is not now whether catheter life, vasectomy, orchidectomy, ligation of the internal iliac arteries, permanent suprapubic bladder drainage or prostatectomy should be recommended, but whether the case is suitable for prostatectomy and, if so, what form of prostatectomy should be performed." In considering what cases are suitable for prostatectomy we have to consider: (1) the prostate; (2) the urinary organs; (3) the general condition of the patient.

It would be out of place here to discuss such elementary matters as the examination and diagnosis of enlargement of the prostate gland. I shall select two types of enlarged prostate for discussion—namely, the fibrous prostate and the malignant prostate.

The Fibrous Prostate.

The term "fibrous prostate" has crept into our surgical nomenclature without any very careful definition of its pathology. A surgeon will regard any prostate of small size which causes symptoms of chronic obstruction and irritation and which resists digital enucleation as a "fibrous prostate." It is not surprising, therefore, to find a number of different pathological conditions included under this clinical term.

From a series of 185 prostates in which full histological details were obtained, I have selected those weighing 20 grammes or under as representing prostates of this type. A prostate of 16 or 20 grammes after removal does not appear larger than one would judge the normal prostate to be. There were 44 prostates of 20 grammes or under (23.7 per cent.).

Microscopical examination of these specimens gave reports as shown in Table I.

TABLE I.

Adenocarcinoma	1
Adenoma with little change in stroma	14
Adenoma with amyloid bodies	5
Hyperplasia of the stroma	5
Chronic prostatitis and fibrosis of stroma	14
Multiple small calculi	7
	44

Clinical examination of these patients gave no indication as to the nature of the change. The prostate was usually regarded as slightly or moderately enlarged on rectal examination, and was elastic and movable. In one case of adenoma with multiple amyloid bodies it was noted as "granular." The calculi in these prostates were so small that they were not detected with the rectal finger. The cases of small adenoma varied in their ease of removal. Where there was an intravesical nodule the enucleation might be comparatively easy, but in some of these cases, and also in cases where no circumscribed intravesical projection existed, the enucleation was difficult and usually developed into a dissection of the prostate under the eye. In the cases of fibrosis and chronic prostatitis enucleation was easy in one case and moderately difficult in another. In the remaining cases clean enucleation was not possible and the gland was dissected out under the eye. Where calculi were present there was usually a good deal of difficulty in enucleation, and most of these cases required dissection. Two other glands, larger than the group of 20-gramme prostates, were diagnosed microscopically as chronic prostatitis. They weighed 23 and 27 grammes respectively. Both these prostates had a well-developed intravesical projection. They shelled out without difficulty.

There is another type of fibrous prostate that is not included in the foregoing list. In this type an adenomatous prostate has been subjected to treatment, such as deep X ray therapy, that has caused fibrosis of the stroma, and adhesion of the gland.

From the foregoing it would appear that the surgical term "fibrous prostate" covers a number of different pathological conditions—namely, early adenomatous enlargement, chronic prostatitis, fibrosis of the stroma, scattered prostatic calculi, with fibrosis, and a form of early malignant growth which develops round the internal meatus, all of which may produce similar clinical symptoms. The condition cannot be diagnosed with certainty before operation. At operation difficulty of enucleation is the principal feature, and it may be impossible to remove the gland by this method. By transvesical dissection under the eye these prostates can be cleanly and thoroughly removed.

The Malignant Prostate.

There are two distinct clinical forms of malignant growth of the prostate that may be termed primary and secondary. In the primary malignant prostate the change in the gland is, clinically at least, cancerous from the outset; in the secondary malignant prostate the gland has at first the character of the ordinary enlarged prostate and the malignant changes are engrafted upon this. The proportion of primary malignant prostates to simple is about 1 to 6. In 2496 cases of enlargement of the prostate examined by me in private practice, there were 347 cases of undoubted malignant growth and 2149 cases of simple enlargement. Thus the percentage of malignant growth was 13.50 and of simple enlargement 86.50.

The secondary malignant growth of the prostate is engrafted on a simple enlargement of the gland. These patients come to the surgeon with the symptoms of simple enlargement of the prostate gland, and rectal examination confirms the diagnosis. The malignant growth may develop in one of three localities. It may infiltrate the base of the prostate in the neighbourhood of the internal meatus and not

* Lecture I. appeared in our issue of May 31st.

be discovered until operation is undertaken. When the surgeon attempts enucleation, the tissues at the bladder neck are found to be leathery and resisting so that no impression can be made with the finger. This is one type of the so-called "fibrous prostate" and has already been discussed. The second area that may be affected is the periphery of the enlarged gland. In these cases the examining finger recognises an enlarged prostate of elastic consistence. At one part there is a firm area, and there may be some loss of mobility of the tissues at this part. At the operation the enucleation proceeds easily except at this area, where the gland is tough and adherent, and not infrequently a leathery plaque is left behind in the wall of the prostatic bed. In the open operation this may be dissected away after removal of the prostate.

The third type is where the malignant change has developed in the substance of the enlarged prostate. The clinical features are those of a simple enlargement of the gland and at operation the enucleation proceeds smoothly. The specimen has the usual appearance of a simple enlargement of the gland. The report of the pathologist is that there are one or more areas in which the stroma of the organ has become invaded by columns of cells, and that these areas are of a malignant nature. Attention was first drawn to this type of case by Albarran and Hallé,³ who examined 100 specimens removed as simple enlargement of the prostate and found evidence of carcinoma in 14. The subject has also been discussed by Wade,⁴ Swan,⁵ and myself.⁶ I have since extended my observations. In 521 cases in my private practice, where a report was obtained from the pathologist on the specimen removed by suprapubic prostatectomy, there were 96 cases (18 per cent.) in which areas of carcinoma were discovered. In these cases there was no suspicion of malignancy before the operation, and the operation was performed by enucleation under the belief that the prostate was the seat of simple enlargement. In the following series of cases (Table II.) malignant disease was found on microscopical examination of prostates enucleated for simple enlargement.

TABLE II.

	Cases.	Malignant.
Albarran and Hallé ..	100	14
Wade ..	134	14
Swan ..	20	4
Thomson-Walker ..	521	96
	783	126 (16%)

The prognosis in such cases is important and interesting. I endeavoured to trace the subsequent history of the 96 cases in my series. (Table III.)

TABLE III.—After-history of Ninety-six Cases of Enucleated Prostate in which Malignant Areas were Found.

Died within a year from other diseases ..	13
Not traced ..	17
Alive without recurrence ..	41
Dead without recurrence ..	23
Dead with recurrence ..	2
	96

Sixty-four Cases without Recurrence.

	Alive.	Dead.
1-5 years ..	6	9
5-10 " ..	28	8
10-17 " ..	15	6
	41	23

It will be seen in Table III. that of 66 cases traced for a sufficiently long time there were only two (3 per cent.) in which the malignant growth recurred.

URINARY COMPLICATIONS.

Of all the risks to which the sufferer from enlargement of the prostate is exposed, those connected with the urinary organs are the most common and also the most frequently fatal. These complications

are, however, to a large extent amenable to treatment before operation. They are renal inefficiency and sepsis.

Renal inefficiency.—With the increasing obstruction of an enlarged prostate and the accumulation of residual urine the renal function is impaired, nitrogenous products are eliminated in reduced proportion by the kidneys and accumulate in the blood, and a train of symptoms, that we know indicate a varying degree of uræmia, arises. These clinical symptoms are invaluable in the diagnosis of renal inefficiency, but there are cases of serious impairment of the renal function where they are slight or absent, and they frequently fail to record the variations in the renal efficiency which accompany surgical measures used in the relief of urinary obstruction. For over 30 years urinary surgeons have endeavoured to measure the renal function accurately by means of special tests,⁷ and of late years they have received valuable assistance from the biochemist and the physician. It is not my intention to pass in review all the tests of the renal function at present in use. It will be of greater value if I relate my personal experience in the tests that I use.

The form of renal inefficiency that results from urinary obstruction is that in which the nitrogenous products are excreted in diminished quantity in the urine and accumulate in the blood. It follows, therefore, that estimation of the activity of the kidney in excreting nitrogenous bodies, together with an estimation of the nitrogenous bodies in the blood, should give an accurate indication of the efficiency of the renal function in urinary obstruction. Urea is the chief of these nitrogenous bodies, and it is sufficient to estimate the urea excretion and the urea retention. The activity in nitrogenous excretion is measured by the urea-concentration test introduced by MacLean⁷ and de Wesselow, and the nitrogenous retention is measured by estimating the urea content of the blood. In MacLean's test a urea meal is given and the blood is overloaded with urea. The urea excretion of the kidney is thus forced up to its full limit. This test overcomes one of the difficulties of the tests of the renal function—namely, that the functional activity of the kidneys is not fully exercised at any time under ordinary conditions of health. There is a margin of safety in the amount of renal tissue that amounts to more than half the total renal tissue, and there is a corresponding margin of potential function. In a series of 274 cases of enlargement of the prostate gland in which prostatectomy was performed, I have tabulated the figures of the urea-concentration test. (Table IV.)

TABLE IV.—Urea-concentration Test in 274 Cases of Cystotomy and Prostatectomy.

	Cases.	Deaths from uræmia.
2.0% and over ..	194	0
1.8 to 2% ..	21	1 (4.7%)
1.5 to 1.8% ..	34	3 (8.8%)
1.0 to 1.5% or under ..	25	3 (12%)

In 194 of these cases the urea-concentration figure was 2 per cent. or over. In this class there were no deaths from uræmia. There were 21 cases where the urea-concentration figure was from 1.8 to 2 per cent. In this class there was one death from uræmia (4.7 per cent.). The urea-concentration figure was 1.5 to 1.8 per cent. in 34 cases, and of these three died of uræmia (8.8 per cent.). One death followed cystotomy, and the other two deaths were after the second stage of a two-stage prostatectomy. In 25 cases the urea-concentration figure was from 1.5 to 1 per cent. or under. Of these, three died of uræmia (12 per cent.). The principal interest in these figures lies in the cases where a high urea concentration was obtained and the patient died from uræmia, or where a low urea concentration was recorded and the patient survived.

The single death that occurred in the class 1.8 to 2 per cent. was after the second stage of a two-stage prostatectomy.

The bladder had been drained through a suprapubic cystostomy wound for six weeks on account of renal inefficiency. The urea-concentration tests made from time to time were always 1.0 or below this, but on one occasion the test rose to 1.9 per cent. The operation was a difficult and severe one, and the patient died on the third day with auricular fibrillation and symptoms of uræmia. Old-standing heart disease was present. It is possible that had the operation been a simple one this patient might have survived, but the solitary observation of 1.9 per cent. was evidently not sufficient to justify a severe operation.

The cases where the urea concentration was 1.5 per cent. and below are of extreme interest. Of the three cases that died of uræmia, two died after cystostomy without removal of the prostate. One case was a two-stage prostatectomy. Twenty-two cases with a urea-concentration figure of 1.5 or under survived the operation of prostatectomy. In three of these a preliminary cystostomy was performed, and the urea-concentration figure, after an interval of one to several weeks, rose to 2 per cent. or over, and all survived the second stage. In ten cases where the urea remained at 1.5 or under a second-stage prostatectomy was performed and the patients survived. Nine cases where the urea concentration was 1.5 per cent. or under survived a single-stage prostatectomy, following preliminary drainage by the indwelling catheter.

The conclusion that may be drawn from these 274 cases is that there is no risk of uræmia following prostatectomy if the urea-concentration figure is 2 per cent. or over, but that there is a slight risk where the reading is 1.8 to 2 per cent., and that a single reading of 1.9 per cent. is not sufficient to establish the case in this safe zone. There is a very serious risk where the figure is below 1.8 per cent., and more so where it is under 1.5 per cent. Further, with extreme care it may be possible to operate successfully even where the urea concentration is below 1.5 per cent. Such patients may recover where no complications arise such as bronchitis, hæmorrhage, or sepsis, but they stand very little chance of surviving a complicated post-operative course.

Estimation of the urea content of the blood gives additional information about the functional activity of the kidneys in the excretion of nitrogenous bodies. In the azotæmic type of renal disease that occurs in urinary obstruction urea does not begin to accumulate in the blood until the kidneys are seriously damaged. It is, therefore, only in cases of advanced disease of the kidney that the estimation of the blood-urea is likely to be of use to the surgeon. The normal urea content of the blood is from 20 to 40 mg. per 100 c.c.m. MacLean points out that these figures are too low in dealing with old men, and a blood-urea of 40 to 60 mg. per 100 c.c.m. may be present without indicating serious impairment of the renal function. It is recognised that the ultimate cause of the symptoms grouped under the term uræmia is not the accumulation of urea in the blood, but this accumulation runs closely parallel with the production or the accumulation of the chemical body that causes uræmia. The parallelism is not, however, always so close as to make the blood-urea figure an absolutely reliable test of the imminence of uræmia. It is possible, for instance, for a patient to die of uræmia and the blood show a low urea content. MacLean describes a case where the blood-urea was reduced from 120 mg. to an average 30 or 40 mg. per 100 c.c.m., yet the patient died of uræmia. A very low protein diet may so reduce the blood-urea as to make the observation worthless. Again it is possible to have a very high blood-urea and the patient be in no danger of uræmia. As Dr Wessclow points out, "there is a whole series of conditions in which inadequate water is available for excretion of urea, and in which the blood-urea reaches a high level as the result, even though no renal lesion is present. The rise in blood-urea is favoured by the fact that desiccation in itself leads to excess of katabolism of protein and to excessive urea formation." Further,

an excessive protein diet will raise the blood-urea content. In most cases, however, the urea content of the blood varies inversely to the percentage of urea secreted in the urea-concentration test and, as the range of figures is wider, the test is more sensitive to temporary variations in the renal function, if sources of fallacy such as diet and fluid intake be controlled. I have noticed that while the urea-concentration figures may remain steady for some time at a low level, the blood-urea figure may during this time show considerable variation, which closely corresponds to the improvement or retrogression in the general condition of the patient. The blood-urea content is invaluable in watching the progress of a case where the bladder has been drained for chronic retention with serious renal inefficiency.

In another class of case blood-urea estimation is of great value. A patient known to suffer from renal inefficiency develops symptoms of coma or cerebral irritation or some other group of symptoms that are not clearly uræmic. The presence of a high blood-urea may elucidate an otherwise obscure problem. I have met with examples of this in relation to renal tuberculosis, as well as during convalescence from prostatectomy.

It is not necessary for a successful prostatectomy that the renal function should be perfect or even approximately perfect. A reduced renal function may be adequate for the operation. The laboratory figures of the renal function tests form only one factor among many in estimating the prognosis for operation. The general build and constitution of the patient, the soundness of other organs, the experience and skill of the operator and of those who have the immediate care of the patient after the operation, and the surroundings in which recovery from the operation will take place are all factors that profoundly influence the result.

Sepsis.—Sepsis in relation to the enlarged prostate and prostatectomy is a failure of surgical methods. The infection may occur before the operation, it may be introduced at the time of the operation, or it may occur subsequent to the operation when the cystostomy wound is still open. At present I am concerned with infection before the operation. The simpler cases are those in which the infection is confined to the bladder. These are sometimes complicated by attacks of epididymitis. In old-standing cases a very heavy infection may remain localised to the bladder and have no general toxic effect on the patient. The more complicated cases have pyelitis or pyelonephritis in addition to the cystitis. In the latter cases there are recurring attacks of fever, and eventually the patient drifts into the condition known as urinary septicæmia, a combination of bacterial toxæmia and uræmia.

If the infection is recent and moderate, and there is no evidence of renal involvement, a few weeks' preparation by thorough bladder washing and removal of the residual urine, either by intermittent catheterisation or by the resident catheter, together with diuresis and urinary antiseptics, will suffice as a preparation for the removal of the prostate. When a more severe grade of sepsis is present it will be necessary to perform suprapubic cystostomy and drain the bladder. This is prostatectomy in two stages, and I shall refer to the two-stage operation later. The question that I wish to discuss at present is the selection of cases for prostatectomy where sepsis is present and has been treated. In the mild cases, when the infection has been confined to the lower urinary tract, there is no difficulty. Some extra care in regard to irrigation after the operation will be necessary in such cases. Where the infection has been severe the decision is a more difficult one. When the sepsis has been confined to the bladder it usually clears up quickly as the result of drainage and constant irrigation. When pyelitis and pyelonephritis are present the general condition of the patient will usually improve with bladder drainage, and the question of prostatectomy will have to be faced.

The tests that can be applied to such a patient, and their value, may be considered under the following headings: (1) general condition of the patient; (2) condition of the urine; (3) renal function tests; and (4) cholesterol content of blood.

The first two of these headings I need not discuss further. The renal function tests have been used to decide the question of prostatectomy in these cases, but do no more than indicate the secretory activity of the kidneys at the time of the test. Although in the later stages of bilateral pyelonephritis the renal function is profoundly altered, a kidney may be the seat of septic infection and yet maintain a high grade of functional activity. The danger in these septic cases, where prostatectomy still appears feasible, is that the operation will cause a flare up of the infection which is fatal, either by bacterial toxæmia or uræmia or both.

A method which promises greater accuracy is the estimation of the blood cholesterol. Cholesterol plays an important but as yet ill-defined part in the process of immunity, stimulating, it is believed, the production of antibodies. Macadam and Shiskin¹⁰ have suggested that the cholesterol content of the blood should be used as a measure of the resistance to infection possessed by the individual. These investigators concluded that the cholesterol content of the blood was a fair measure of the degree of resistance to infection, and should form a useful guide to the degree of operation risk in cases of urinary obstruction. The normal average cholesterol content of the blood was stated at 0.161 per cent., with a range of 0.191 to 0.133 per cent. More recent observations by Gardner¹¹ extend the limits of the normal cholesterol content of the blood in health, this observer having found figures varying between 0.08 and 0.23 per cent. in normal adults. Maxwell¹² holds the view that probably each individual has a definite level somewhere within these limits, from which level there is very little variation in health. In disease it is possible for the cholesterol content to vary to quite a considerable degree before the figure transcends the normal limits laid down above. Thus the minor abnormalities may pass unnoticed. The blood cholesterol is liable to be affected by many external factors, all of which are not fully recognised. It is known to be increased in arterio-sclerosis, granular kidney, and other degenerative conditions of later life. In anæmia, especially where the red cell count falls below 50 per cent. of the normal, the cholesterol content is diminished (Macadam and Shiskin). In malignant disease high figures have been reported by Luden,¹³ but the results of Brunton and of Maxwell in such cases were variable. In myxœdema, and still more in subacute parenchymatous nephritis, there is an increase in the blood cholesterol (Gardner and Gainsborough).¹⁴

In 18 cases with a blood cholesterol content less than 0.13 per cent., which Macadam and Shiskin held was the lowest normal limit, they found that 16 died of pyelonephritis after prostatectomy and two recovered. Maxwell had ten cases where the blood cholesterol was below 0.13 per cent., and three of them died of infection, and one of uræmia, while of 16 cases with a normal cholesterol content four died of infection and one of uræmia. Dr. R. D. Lawrence has carried out the test for me in a variety of diseases of the urinary organs. Among these there were 50 cases where the prostate was removed by suprapubic prostatectomy. There were ten cases where the cholesterol content of the blood was 0.13 g. per cent. or under. Of these, four died from the effects of sepsis (40 per cent.). On the other hand, there were a number of cases where the cholesterol content of the blood was within the normal figures, and epididymitis developed or the cystotomy wound healed slowly on account of sepsis. The average figure of the cholesterol content of the blood in seven cases where epididymitis followed prostatectomy was 0.129 g. per cent. In this group there was one case where the figure was 0.286 g. per cent., and another with a cholesterol content of 0.077 g. per 100 c.cm.

The average cholesterol content of the blood in four cases of pyelitis and pyelonephritis following prostatectomy was 0.134 g. per cent. Rapid healing of the cystotomy wound followed operation in 15 cases, with an average cholesterol content of the blood of 0.17 g. per cent.; slow healing from sepsis in nine cases with an average cholesterol content of 0.141 g. per cent.

It would seem, therefore, that on the average the cholesterol tends to run in high figures where rapid healing takes place, and in low figures where the healing is delayed by sepsis. But there are individual cases that completely upset the clinical application of these figures. The question that the surgeon has to face in regard to such a test is, can he make the important decision as to whether an operation should or should not be performed from the figure of the cholesterol content of the blood? My view is that he cannot do so at the present time, and much careful work is required before this test of the resistance to sepsis is brought up to the level of reliability that the urea content of the blood or the urea-concentration tests have reached in relation to renal efficiency.

CIRCULATORY RISKS.

A large proportion of the patients that are submitted to prostatectomy show signs of arterio-sclerosis, a few have valvular disease, and some have impairment of the myocardium. The degree of circulatory strain that is permissible in any given case will be decided by the physician and the anaesthetist. Some of the cases in this series run very grave circulatory risks from the condition of the heart, as well as from the state of the blood pressure. Here I will merely make some general remarks on the surgical aspect of high and low blood pressure in prostatectomy.

The first point is that a large number of the patients submitted to prostatectomy have a low blood pressure, and a considerable number have a very low pressure. Thus in 107 consecutive cases 44, or 41.1 per cent., had a systolic pressure of 140 mm. of mercury or under, and 10, or 17.7 per cent., had a systolic pressure of 120 or under. This is contrary to what one would expect, for the average age of these patients was 67 years. It is certainly against the view held by some that senile enlargement of the prostate is always accompanied by arterio-sclerosis. If we look at the other end of the scale there were a number of cases where the systolic blood pressure was very high. In 15 the pressure was 200 and over, and it rose to 230 in two, 250 in two, and 260 in one case. In 24 (22.4 per cent.) the pressure was over 180.

With a very high blood pressure one would expect a large number of cases of serious hæmorrhage, yet in 15 cases with a systolic pressure of over 200 there were only two cases (13.3 per cent.) of severe post-operative hæmorrhage, and no cases in which the hæmorrhage at the time of the operation was serious. In the low grade pressures of 120 or under there was more severe hæmorrhage—namely, four cases of severe hæmorrhage at the time of operation (21.0 per cent.); and two cases of post-operative hæmorrhage (10.5 per cent.). Thus, taking all the cases of hæmorrhage, there were six in 19 (31.5 per cent.) at a pressure of 120 or under, and two in 15 (13.3 per cent.) at a pressure of 200 or over. In none of these cases did hæmorrhage decide a fatal issue. The occurrence of thrombosis in a proportion of cases of very low blood pressure, where the patient is immobilised in bed for a period of time, seems almost inevitable. When a septic focus lies in close relation to and practically in direct communication with a large plexus of veins, such as the prostatic plexus, clotting becomes almost a certainty.

Examined in this light we find that the lower the blood pressure the greater the probability of thrombosis and of pulmonary embolism. In 19 cases where the blood pressure was 120 and under there were three cases of thrombosis of pelvic or cerebral veins, and two cases of pulmonary embolism (26.3 per cent.), while in the remaining 88 cases of the blood pressure

series there were only two cases of thrombosis (2.2 per cent.). Only one case in the whole series died of sudden cardiac failure (systolic pressure 200).

My experience in regard to the various grades of blood pressure leads me to fear the low blood pressure patient on account of the danger of thrombosis and pulmonary embolism. The death-rate from pulmonary embolism is a serious one, and there are numerous cases of smaller emboli that recover. In the prevention of pulmonary embolism the prevention and treatment of sepsis has the first place, and next come measures which have for their object the prevention of stagnation in the pelvic veins. So far as is compatible with safety from hæmorrhage, patients with low blood pressure are kept on stimulants. They are encouraged to move the limbs and gentle massage is given. Deep breathing exercises are practised daily. The prevention of coagulation by means of citrates or other drugs is of doubtful value.

MENTAL AND NERVOUS DISEASE.

A mild delirium becoming more evident at night and some mental confusion is not very uncommon in patients in the advanced stages of prostatic obstruction from enlargement of the prostate gland. The condition is partly due to uræmia and partly due to loss of sleep and rest from constant bladder irritation. Where adequate preliminary treatment by drainage, diuresis, and diet is carried out these patients usually do well after the operation of prostatectomy. In some cases the delirium reappears and becomes more active and the patient more and more difficult to nurse and control, food is refused, and there is great restlessness and desire to get out of bed; occasionally the patient becomes violent and difficult to restrain. These patients frequently become exhausted from their struggles, and from want of nourishment and fluids, and die. Suprapubic cystotomy is probably the best treatment for them and prostatectomy should be deferred sometimes for several months. Such cases are not confined to prostatectomy, although the factors that produce the condition are frequently combined in the cases in which prostatectomy is performed—namely, the presence of a mild chronic toxæmia in an old and rather feeble subject.

Another type of post-operative delirium amounting almost to mania occurs without preoperative warning and without the presence of toxæmia. Here the patient becomes quite uncontrollable after the operation, sedatives having little, or at least short-lived, effect. The condition may settle down after a few days when the patient is exhausted and heavily drugged. Such patients often die of some intercurrent complication.

Another type is met with where a patient suffering from increasing mental irritation and confusion has the symptoms of enlargement of the prostate with an adequate renal function and no urinary infection. The prostate is regarded as a source of irritation and its removal suggested. I have operated on two such cases without in any way improving the condition of the patients, who gradually sank and died some weeks after the prostatectomy.

DISEASE OF THE SPINAL CORD.

It would seem an easy matter to distinguish between the bladder atony of disease of the spinal cord and the obstruction of an enlarged prostate, yet mistakes do sometimes occur in cases of early or arrested tabes dorsalis. Cases of disease of the spinal cord are not infrequently met with when the most prominent group of symptoms are those relating to the bladder. In such cases careful examination will usually reveal some symptom that points to nervous disease. All doubtful cases should be submitted to the neurologist for investigation.

There is another group of cases that give rise to difficulty in diagnosis. These I have described as "atony of the bladder without obstruction or symptoms of nervous disease." Such cases of idiopathic atony are now fully recognised. The

diagnosis is difficult and necessitates the exclusion of early disease of the spinal cord and of minor changes in the prostate at the neck of the bladder. For fuller information in regard to these cases I would refer those interested to my original article¹¹ and to an exhaustive article by Braasch.¹²

The patient who suffers from tabes dorsalis may develop enlargement of the prostate gland. It is a matter of some difficulty to estimate whether the residual urine is due to obstruction or to atony. The bladder symptoms may be due to the enlarged prostate and the bladder, relieved of the obstruction by prostatectomy, may resume its normal function; on the other hand, the removal of the prostate may leave the patient with an atonic bladder due to the disease of the cord and a urethra through which it is difficult to pass a catheter. The diagnosis between prostatic obstruction and nerve atony of the bladder in a case of tabes dorsalis will rest upon the following points.

- (1) Absence of or diminished desire for micturition.
- (2) Impairment of sensation in the prostatic urethra.
- (3) Spasmodic contraction of the compressor urethra.
- (4) Relaxation of the internal meatus from atony of the internal sphincter seen by cystoscopy and urethroscopy.
- (5) Fine trabeculation and sacculation of the bladder wall on cystoscopy.
- (6) General sacculation of the bladder wall and funnel-shaped bladder neck and prostatic urethra on cystography.

I have operated on three cases of enlargement of the prostatic gland in patients suffering from tabes dorsalis, and have been fortunate in each case in obtaining as good a result as if the nervous system were normal.

GLYCOSURIA.

Prostatectomy has shared with other operations the benefit of modern progress in medicine, and glycosuria, which at one time was regarded as a contra-indication to prostatectomy, is now only a cause of delay. Diabetes is a disease of a rather earlier period of life than enlargement of the prostate and the point has been discussed whether senile glycosuria is the same as ordinary diabetes. Graham¹³ and Lawrence¹⁴ consider that the two conditions are identical, but MacLean¹⁵ inclines to the view that there is some unproved but essential difference between the two types. So far as prostatectomy is concerned, no distinction can be drawn. The evil effects of diabetes are particularly dangerous in the subject of enlarged prostate who undergoes prostatectomy. The two dangers are coma and infection and sloughing of the wound with delay in healing, and the latter may be the cause of death from chronic sepsis many weeks after the operation. Before the introduction of insulin it was occasionally possible to obtain a successful result from prostatectomy in a case of glycosuria, and I have treated two striking examples. I have notes of 16 cases of glycosuria on which I performed prostatectomy. Of these, 12 (75 per cent.) recovered from the operation and four died (25 per cent.). Of the four fatal cases, two died of diabetic coma within three days of the operation. These cases were operated before the modern advance in the treatment of diabetes was made. One patient died of pyelonephritis 21 days after, and the other of pneumonia on the thirty-second day after operation. The wound in this case healed rapidly, the bladder being closed on the twenty-third day. Of the 12 cases that recovered, six healed rapidly and four healed slowly. The rapidly healing cases were those that were treated by modern methods; only two of these healed slowly. The reduced resistance to bacterial invasion in these diabetic cases was shown not only by the delay in healing in some of the cases but also by the liability to septic complications such as cystitis, pyelitis, pyelonephritis, and epididymitis. Further, if sepsis became established, it appeared more difficult to overcome in these diabetic cases than in the average non-diabetic patient. The difference in the safety with which operation can be undertaken and the rapidity with which the wounds

heal in cases of glycosuria treated under modern conditions compared with those operated before insulin was introduced is very striking. It is perhaps too much to say that under modern treatment cases of glycosuria cause no more anxiety than the average case of prostatectomy, but it is safe to state that from being almost a complete contra-indication to prostatectomy, glycosuria now only delays the operation and somewhat increases the risks.

TIME FOR OPERATION.

It is generally accepted that the best form of treatment for the adenomatous prostate is removal by operation if no contra-indication exists in the urinary organs or other systems of the body. In the majority of cases seen by the surgeon no doubt will arise as to the necessity for operation. But where the prostate is moderately enlarged, and the symptoms are not severely disabling and the residual urine at no time exceeds 2 ounces and is sterile, the problem is a more difficult one. Is it wise to allow these cases to go on indefinitely or should the surgeon insist that operation should be done here as well as in the cases where the prostate is large and the residual urine abundant? Wherein lies the necessity for early operation? Does the growth of a prostate once definitely enlarged ever become arrested? My experience is that while the prostate may in some cases remain in a state of moderate enlargement for a number of years (five or six) without any appreciable increase in the size or the amount of obstruction as measured by the quantity of residual urine, the gland eventually enters on a period of more rapid enlargement with rapidly increasing residual urine. An accident such as a chill, holding the water too long, dietetic indiscretion, or fatigue, may precipitate the second stage by producing acute retention, after which the residual urine becomes permanently and progressively increased. But while the prostate may in its earlier stages remain apparently stationary for some years, the patient is growing older. What influence has the age factor on the seriousness of the operation of prostatectomy should it eventually become necessary? It is the experience of all urinary surgeons that the operation can be successfully performed in extreme old age. Freyer relates that in 1825 cases of prostatectomy he had operated on 92 octogenarians between 80 and 90 years, and 13 bordering on this age in their eightieth year with 12 deaths (11½ per cent.). This is a fine record of work, but the mortality here is twice that of his total average. In my own cases there were 27 patients of 80 years or over with three deaths, a death-rate of 11.1 per cent., which closely corresponds to Freyer's figures. Very constant skilled attention is necessary in these old men after operation. They may pass safely through an uncomplicated convalescence, but they have little chance of surviving an attack of bronchitis, an exacerbation of sepsis, or a severe hæmorrhage. In spite of the surprisingly moderate death-rate of prostatectomy in patients over 80 years, we cannot be indifferent to advancing age as an argument in favour of prostatectomy early rather than late.

Another point in favour of early operation is the "silent" prostate with chronic urinary retention. These cases are among the most difficult and dangerous to treat in prostatic surgery. The only way to prevent the development of so grave a complication is to examine thoroughly all cases of frequent micturition in old men and keep them under observation. If residual urine is found, operation should be recommended. Two further reasons why operation on an enlarged prostate should not be indefinitely delayed are the danger of sepsis and of malignant changes in a prostate which is the seat of simple enlargement.

Drainage of the Bladder.

Many of the complications of enlarged prostate that contra-indicate immediate prostatectomy and necessitate a period of preliminary treatment are of a purely medical nature. There are two groups of

complications, however, that call for surgical treatment—namely, chronic retention of urine with consequent uræmia, and urinary sepsis. The treatment of these conditions leads to the discussion of preliminary drainage of the bladder either by catheter or by cystotomy. I shall consider the question in relation to four types of case commonly met with in practice.

- (1) Chronic retention with symptoms of renal inefficiency.
- (2) Severe urinary sepsis.
- (3) Serious extra-urinary complications.
- (4) Cases without serious back pressure or sepsis or extra-urinary complications.

1. *Cases of Chronic Retention with Symptoms of Renal Inefficiency.*—The danger of suddenly emptying a bladder containing a large quantity of residual urine in a patient suffering from enlarged prostate is universally recognised. The question that arises is what is the best method of emptying the chronically over-distended bladder? There are two methods—namely, the indwelling catheter and suprapubic cystotomy. The advantages of the resident catheter are that the fluid in the distended bladder can be withdrawn very slowly in measured quantities, that the suprapubic area, the field of the future prostatectomy incision, is untouched, that asepsis is more easily maintained, that the method is a much less severe one in debilitated and uræmic patients, and that only one cutting operation is performed. Suprapubic cystotomy is followed immediately by a rise in the blood-urea, whereas the tying-in of the catheter is not. The following two cases are extreme examples, but they serve to illustrate this difference between catheter drainage and suprapubic cystotomy.

CASE 1.

Chronic retention.
No symptoms of uræmia.
Urea concentration 1.03%.
Blood-urea 50 mg.*
Cystotomy.
6th day: blood-urea 119 mg.*
8th " " 164 mg.*
10th " died, uræmia.

CASE 2.

Chronic retention:
Mild symptoms of uræmia.
Urea concentration 1.05%.
Blood-urea 60 mg.*
Catheter drainage 14 days.
14th day: urea concentration 1.4%. Blood-urea 47 mg.*
Prostatectomy.
15th day after operation, wound dry.
18th day after operation, home.

* Per 100 c.cm.

At the end of 10 or 14 days' continuous drainage the decision about prostatectomy will have to be made. If the renal function is satisfactory, and the general condition is good, it may be done, otherwise more prolonged drainage is necessary. If this drainage has been by indwelling catheter cystotomy will now be required, and will be maintained until the condition of the renal function is satisfactory. In 80 per cent. of cases where there is chronic retention, and signs of uræmia are present, the renal function has returned to normal or improved sufficiently for prostatectomy to be safe at the end of ten days' catheter drainage.

2. *Cases of Enlarged Prostate and Serious Urinary Sepsis.*—Drainage of the bladder is imperative before the prostate is removed. In such cases the retained urethral catheter is worthless, for the lumen is much too small to allow the free discharge of purulent urine. The only really effective method is suprapubic cystotomy, and the introduction of a large open tube. A catheter is tied in the urethra, and continuous irrigation is installed.

3. *Cases of Chronic Retention with Enlarged Prostate* where the patient suffers from a serious complication, such as severe bronchitis or pneumonia, and in which catheter drainage is difficult and suprapubic drainage is preferable.

4. *Cases with Enlarged Prostate Without Chronic Retention of Urine or Serious Urinary Sepsis.*

It has been the custom with some surgeons, especially in France and America, to divide the operation of suprapubic prostatectomy into two stages in all cases, and the two-stage operation has been

adopted in some surgical centres in this country. The advantages claimed for the two-stage operation are that there is less shock, less hemorrhage, and less sepsis, and that the back pressure on the kidneys is relieved. In the ordinary straightforward case the two-stage operation does not appear to me to be safer than the one-stage operation. Shock is not a factor in uncomplicated one-stage prostatectomy. My experience has been that the second stage of a two-stage prostatectomy is much more likely to produce shock than a single-stage operation. If the open operation is performed where cystotomy has been previously done it becomes necessary to dissect away the whole of the scar tissue and to mobilise the bladder. The operation is, therefore, much more serious than a single-stage one. Hemorrhage is not less in a two-stage than in a one-stage operation. There is no question of sepsis being reduced in the cases now under discussion, for the bladder is aseptic. In the two-stage prostatectomy the bladder practically always becomes infected during the period of drainage before the prostatectomy. If one accepts infection as a necessary sequel to prostatectomy, the two-stage operation has the advantage that the preliminary stage of infection is passed through before the prostate is removed, and possibly some degree of immunity to sepsis may develop before the second operation. This is certainly a great advantage in hospital work where the post-operative treatment cannot be closely supervised by the surgeon or by permanent assistants. An important disadvantage in the two-stage operation is that there are two operations and two anaesthetics, and that the total period during which the patient remains in bed is longer.

RADIUM FOR JERSEY.—A public subscription, which has yielded £2611, plus interest, has been raised in Jersey in thanksgiving for the King's recovery. The money has been made over to the States (the Parliament of the island) for the purchase of radium and the creation of a radium clinic. The radium is to be kept at the General Hospital, and is to be available for issue to all practitioners in the island under regulations to be drawn up by the States General Hospital committee.

COOPTED HOSPITAL REPRESENTATIVES.—The constitution of the public assistance committee of the Warwickshire County Council does not permit of the cooption of persons who are not members of the council. The executive committee of the Rugby Association of Hospital Contributors has decided to protest against this arrangement on the ground that the Hospital of St. Cross in that town, which serves a population of 40,000, ought to be represented on the committee, especially in view of the committee's statutory power to coopt up to one-third of its number. The protest is to be sent to the Minister of Health, and other voluntary hospitals are to be asked to join in it.

THE TREATMENT OF CHRONIC ENCEPHALITIC PARKINSONISM WITH DRIED PREPARATIONS OF STRAMONIUM.

By C. WORSTER-DROUGHT, M.D. CAMB.,
M.R.C.P. LOND.,

PHYSICIAN TO THE METROPOLITAN HOSPITAL AND TO THE WEST
END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM;
CONSULTING PHYSICIAN, POST-ENCEPHALITIC UNIT,
METROPOLITAN ASYLUM BOARD;

AND

T. R. HILL, M.D., M.R.C.P. LOND.,

ASSISTANT MEDICAL OFFICER IN CHARGE OF POST-ENCEPHALITIC
UNIT, METROPOLITAN ASYLUM BOARD, CHIEF CLINICAL
ASSISTANT, WEST END HOSPITAL FOR DISEASES OF
THE NERVOUS SYSTEM.

In the investigation of different forms of treatment likely to benefit chronic encephalitic parkinsonism, it soon becomes apparent that no actual curative effect is possible. The symptoms and signs presented result almost entirely from neuronal destruction, and although it is possible that in some cases the severity of the condition may be increased by toxic depression of neurones owing to the presence of an active infection in the brain, there is little doubt that the progressive changes exhibited by most chronic cases are due to the destructive effects of such an active infective process. In these cases the attempt to find some means of eradicating the chronically active infection is logical, but even if such a method were forthcoming the most that could be expected would be that the progressive changes were arrested or that the risk of acute recurrences was removed. The treatment of the parkinsonian syndrome, therefore, resolves itself into what is essentially palliative treatment under which the patient has permanently to remain to avoid relapse.

Palliative Treatment of Chronic Encephalitic Parkinsonism with the Atropine Group of Alkaloids.

In 1906 Erb¹ recorded the value of hyoscyne as a specific palliative in the treatment of idiopathic paralysis agitans. Owing to the close clinical similarity between this disease and chronic encephalitic parkinsonism, it is natural that hyoscyne and its related alkaloids were early tried in the latter condition. In 1921 Babinski and Souques² drew attention to the value of hyoscyne in encephalitic parkinsonism, and this observation soon received general confirmation. Other alkaloids related to hyoscyne were also found to exert similar beneficial effects in varying degrees, and the application of this class of drugs has since become the established treatment. It was found that the muscular rigidity diminished, tremor lessened, sialorrhoea reduced, and that the patients became less helpless and more active in movement. These beneficial effects, however, speedily disappeared if the drug was omitted. Hyoscyne hydrobromide appeared the most effective, and is now the substance most generally used. It is administered orally or hypodermically, but the benefit conferred is much greater when it is given by the latter route. It has been our object in the work recorded in this communication to find a palliative treatment of chronic encephalitic parkinsonism that is equally or more effective than the hypodermic administration of hyoscyne but in which the drug can be given by the mouth so that patients may receive the maximum benefit without admission to hospital, or the irksome routine of at least three hypodermic injections daily. At the stage to which the investigation has now progressed, it has been found that this result is best obtained by the use of dry preparations, and particularly the dried extract of stramonium in suitable doses.

Treatment with Stramonium.

In 1925 Juster³ described the value of stramonium in diminishing parkinsonian rigidity, and in 1926 Laigral-Levastine and Valance⁴ reported the results of a year's treatment with stramonium in 24 cases of parkinsonism. These observers found in their cases amelioration of the muscular rigidity, bradykinesia, salivation, and tremor, and the state of mental inertia—bradyphrenia—was improved. Other favourable reports on treatment with stramonium were made in 1928 by Shapiro⁵ and in the same year by Carmichael and Green.⁶ The latter observers used tincture of stramonium, B.P., in doses which they succeeded in raising to 90 minims three times a day, and they stated that the optimum dose was 45 to 60 minims by the mouth. Carmichael and Green's conclusion, which we are unable to confirm, was that tincture of stramonium in these doses was quite as effective in palliating parkinsonism as hyoscine administered hypodermically. In 1928 Shapiro⁵ also reported on the effects of stramonium given by Juster's method—viz., the oral administration of the powdered dried leaves of *Datura stramonium*. The dried leaves were first given in doses of gr. 1 three times a day, and this dose was rapidly increased until grs. 14–16 were being taken daily. When the optimum effect was reached the dose was diminished until grs. 7–8 were given daily. Of the 23 cases treated without ill-effects 10 were suffering from encephalitic parkinsonism and 7 from senile paralysis agitans. The results in 14 cases (11 of encephalitic parkinsonism and three of paralysis agitans) were reported as excellent. In the remaining nine cases improvement was slow. The degree of benefit was greater in the encephalitic patients than in those suffering from paralysis agitans, a result that we can fully confirm. Muscular rigidity, speech, gait, sialorrhoea, and mental condition were all favourably influenced. Occasionally slight diarrhoea and some mydriasis occurred but were satisfactorily relieved by omitting the drug for a day or two. Finally, in 1929, Jacobsen and Epplen⁷ commented upon the action of tincture of stramonium, U.S.P., and summarised the treatment of parkinsonism with stramonium.

Personal Experiments with Stramonium.

1. *Tincture of Stramonium.*—Six typical cases of chronic encephalitic parkinsonism were treated, originally with tincture of stramonium, B.P., given three times a day. The patients began with doses of 20–30 minims, t.d.s., and these were rapidly increased to 90–120 minims, t.d.s., that is, up to as much as eight times the maximum pharmacopoeial dose. Definite improvement resulted in the muscular rigidity and bradykinesia in all cases, and the result was distinctly better than that obtained from hyoscine gr. 1/200–1/100 t.d.s., given by the mouth in tablet form. The benefit from tincture of stramonium in the doses mentioned, however, was not nearly so great as that resulting from gr. 1/200–1/100 of hyoscine given hypodermically. The patients continued treatment with the stramonium tincture over a period of two years and at no time were any signs of intolerance exhibited.

2. *Dried Stramonium Leaves.*—A series of 12 cases, all of whom had previously been under the hypodermic hyoscine, were then treated by Juster's method with the exception that his recommendations as to dosage were not strictly followed. The dried leaves of *Datura stramonium* were given in capsules or pills three times a day, the initial dose being either 0.1 or 0.2 g. t.d.s. This dose was found to be too small to produce benefit and was therefore increased by the addition of 0.1 g. to each dose until the patients were receiving 1.2 to 1.6 g. three times a day. At this point some of the cases showed intolerance in the form of mild delirium of short duration. Nevertheless, this level of dosage was maintained for three months, and during that period the condition of the 12 patients was equal, and in some

instances superior, to that previously produced in the same patients by the hypodermic administration of hyoscine in maximum doses—i.e., the highest doses that could be tolerated being in no case less than gr. 1/100 t.d.s.

All the cases treated were classified as severe. When not under treatment they were all quite helpless, exhibiting pronounced generalised parkinsonian rigidity and, in most instances, inability to stand or walk, to feed themselves, or to dress and undress. All showed much limitation and indistinctness of speech and excessive salivation. Striatal tremors and greasy skins were common. During the period of treatment with maximum doses of dried stramonium leaves their muscular rigidity was much reduced, often practically abolished. They were able to stand and also to walk; in fact, in most cases walking became quite free. The general bradykinesia and helplessness was much diminished and all patients could feed themselves, talk well, dress, and undress. Nine became fully capable of looking after themselves and of doing a considerable amount of work, such as sweeping and tidying the wards. Several appeared almost physically normal. Bradyphrenia was much improved, sialorrhoea abolished, and tremor somewhat diminished. We estimated that the clinical effect, as regards benefit, of 1 g. of dried stramonium leaves was approximately equal to that produced by gr. 1/100 of hyoscine hydrobromide given hypodermically.

3. *Dried Extract of Stramonium.*—The dried stramonium leaves were given in capsules and pills, and also in powder form. In the larger doses reached, however, the amount required became unreasonably bulky; consequently a dried preparation of stramonium leaves containing a higher percentage of total alkaloids was given, so that a proportionately smaller dose would produce the same effects. The preparation was the extractum stramonii of the United States Pharmacopoeia, which is manufactured from the dried leaves by percolation with alcohol, evaporation of the percolate to a pillular consistence, and adjustment of the strength so that the extract contains 1 per cent. of total alkaloids. The alkaloidal content of dried stramonium leaves varies from 0.1 to 0.7 per cent., the average being 0.25 per cent.; the dried extract, therefore, was approximately four times as strong as the dried leaves. Extractum stramonii, U.S.P., was preferred to the B.P.C. extract, as the latter is a coarser powder and is said to be more deliquescent.

The 12 patients under treatment with dried stramonium leaves were then transferred to treatment with extractum stramonii, U.S.P., the doses administered being one-quarter by weight of those of the dried leaves. Thus the initial doses with the extract of stramonium were 0.25 to 0.375 g., three times a day by the mouth. The transference was made at once in all cases, and the smaller bulk of the extract was found to be far more acceptable than the larger one of dried leaves. The substitution proved to be perfect, the great improvement in the condition of each patient being fully maintained.

Dried stramonium leaves in doses of 1 g. t.d.s. produced a clinical effect equal to that of maximum doses of hyoscine given hypodermically three times a day. The average maximum dose of the latter in the 12 patients was gr. 1/100 t.d.s. Thus it was concluded that, as regards clinical effect, the potency of gr. 1/100 hyoscine was approximately equal to 1 g. of dried stramonium leaves, and, therefore, to 0.25 g. of extract of stramonium. A series of 53 cases of encephalitic parkinsonism under treatment with hyoscine gr. 1/200 to gr. 1/100 hypodermically three times a day were then transferred directly to treatment with extract of stramonium, U.S.P., in the calculated equivalent doses. In severe cases it was found that if the hyoscine were suddenly omitted the patients rapidly relapsed into a state of helplessness and had difficulty in swallowing the stramonium extract. In addition, in some cases, the absorption of the stramonium extract and the conse-

quent exertion of its full effect was slower than the elimination of the hyoscine, with the result that the patient relapsed. To avoid this, therefore, the substitution was carried out in stages. Each dose of hyoscine was reduced by gr. 1/200 and 0.125 g. of stramonium extract given instead. A day or two later a further gr. 1/200 of hyoscine was replaced by the equivalent amount of stramonium (0.125 g.). Consequently the patient was then receiving 0.25 g. of stramonium extract instead of gr. 1/100. of hyoscine. This was continued until complete substitution had taken place. In some cases it was found necessary to carry out the substitution even more slowly.

Case Results.

This series of 53 cases, together with the 12 cases originally treated with dried stramonium leaves as described above and, in addition, with 15 further cases who were receiving hyoscine by mouth as out-patients, making a total of 80 cases, have now been treated with extractum stramonii, U.S.P. The ages of the patients range between 12 and 40 years, the majority being over 10. The 80 cases have continued on the extract for the past six months and all the patients that had previously been receiving maximum doses of hyoscine hypodermically have remained quite as well as they were on the latter and in many instances are even improved. It was found possible quite rapidly to increase the amounts of extractum stramonii that were given at first, and at the present time the average dose in a moderately severe case of generalised parkinsonism is 0.75 g. three times a day by the mouth. Many of the patients are in a satisfactory condition on 0.5 g. three times a day, while one or two cases are receiving doses of more than 1 g., the largest being 1.375 g. three times a day. The case on the latter dose is an extremely severe one; he has been utterly helpless for over four years, with greatly impaired speech, inability to feed or dress himself, to stand or to walk, and with much bradyphrenia. On the heavy dosage mentioned he can walk slowly by himself, can talk well, feed himself, and is much brighter mentally. His case illustrates the increase in tolerance of the atropine group of alkaloids that is associated with parkinsonism; the greater the severity of the syndrome the greater the tolerance. In this series of 80 cases the improvement is present in all features of the syndrome. It occurred to the same degree in the original series of 12 cases—i.e., most of the patients previously helpless become able fully to look after themselves, capable of much physical work and activity, and mentally brighter. Muscular rigidity is the symptom most relieved and in many cases is totally abolished; sialorrhoea and greasiness of the skin also disappear. Bradykinesia and bradyphrenia are much ameliorated; tremor, although not abolished, is mitigated; speech is fluent and comparatively easy; standing and walking are not only possible and almost normal in many cases, but the extreme flexion of limbs, trunk, and neck is considerably diminished in most of the patients. The improvement is such that many cases are able to look after themselves quite satisfactorily in the outside world, although probably few of them would be capable of earning their living. We have tried the stramonium extract in several cases of idiopathic paralysis agitans, but we find the relief of symptoms and especially of tremor is considerably less than in encephalitic parkinsonism.

The Relative Failure of the Tincture.

Having obtained such satisfactory results with dried preparations of stramonium, it was interesting to inquire why tincture of stramonium was less successful. It has been stated above that extractum stramonii, U.S.P., is prepared from the dried leaves and standardised to contain 1 per cent. of total alkaloids. Tinctura stramonii, B.P., is also made from the dried leaves by percolation with alcohol in a similar manner to the extract. Thus, the tincture should contain the same alkaloids and any other

constituents as the extract, and should be capable of producing identical pharmacological effects. It was found, however, after calculation, that the average content of total alkaloids in the tincture was only 0.05 per cent. Thus tinctura stramonii, B.P., is 20 times weaker than extractum stramonii, U.S.P. To prove this conclusion clinically, several patients who were being treated with dried preparations of stramonium had an equivalent amount of tincture substituted. Patients receiving 0.25 g. of extractum stramonii, t.d.s., had this withdrawn and were given tinctura stramonii, B.P., 3 iii. t.d.s., instead. Their condition remained exactly the same as when receiving the extract. When the dosage of tincture was appreciably reduced the patients relapsed and when it was appreciably increased they showed signs of intolerance similar to those exhibited when their dosage of extract was increased. The theoretical calculation of equivalent doses was therefore borne out in practice. Similar substitution was successfully carried out in cases receiving hyoscine and dried leaves on the basis of the equations: hyoscine gr. 1/100 = dried stramonium leaves 1 g., extractum stramonii, U.S.P., 0.25 g. = tinctura stramonii, B.P., 3 iii. Other workers with tinctura stramonii have not reported the employment of such large doses, and the small benefit that we obtained from exhibiting the doses that they recommended is explained by the fact that, on the basis of the above experiments, they were administering doses that were much too small.

We find that extractum stramonii, U.S.P., is preferable to tinctura stramonii, B.P., because, firstly, the administration of adequate doses of the tincture entails the daily consumption of a certain amount of alcohol, and, secondly, the tincture is twice as expensive as the extract. Extractum stramonii exsiccatum, B.P.C., is of exactly the same strength as the U.S.P. extract, but is a coarser powder and is said to be more deliquescent. We have tested it in several cases, however, and find that it produces the same clinical benefit as the U.S.P. extract; it can be used, therefore, in the same doses as the latter.

No deleterious effects result from the prolonged administration of stramonium nor, indeed, from any of the atropine group of alkaloids and there is no cumulative action. Owing to the exceptional tolerance of these alkaloids shown by parkinsonian cases, over-dosage is not easy to produce and is rarely serious. Acquired increase of tolerance occurs, but its development is slow and a patient normally persists for many months in a satisfactory condition on doses such as those mentioned above. Two principles in the palliative treatment of parkinsonism are important: (1) the maximum dosage should rapidly be found, and (2) the dosage should be maintained continuously for the rest of the patient's life.

Pharmacological Action of the Atropine Group of Alkaloids.

The mode of action of the atropine group of alkaloids in specifically ameliorating parkinsonism is somewhat obscure. Is the action central or peripheral? These substances are known to act peripherally on the parasympathetic nervous system, giving rise, for example, to paralysis of the nerve-endings of the secretory fibres to the salivary glands, of the fibres to the sphincter pupillae and of the vagus nerve. Also, they depress the nerve-endings of the secretory fibres to the sweat glands throughout the body and, as most authorities agree that these fibres originate from the sympathetic nervous system rather than from the parasympathetic, this action would suggest some effect upon sympathetic nerve-endings. In experimental animals there is evidence of slight depression of ordinary sensory and motor nerves. Consequently, it may be said that this group of alkaloids tends to paralyse all nerve-endings, the effect being most marked upon those of the parasympathetic system.

These alkaloids are also known to act centrally, atropine producing general cerebral stimulation with a

subsequent depression, which is evident after large doses, when drowsiness and coma may supervene. Hyoscine produces a very short period of cerebral stimulation and the stage of depression is more pronounced. The action of hyoscine on nerve-endings is more powerful but passes off sooner than that of atropine. Hyoscyamine is isomeric with atropine, which is optically inactive and composed of equal quantities of *lævo*- and *dextro*-rotatory hyoscyamine. As the latter substance is said to be comparatively inactive, the effects of atropine are due to *lævo*-rotatory hyoscyamine. Thus, a given weight of atropine is only half as active as the same amount of hyoscyamine. The degrees of central action of the three alkaloids are grouped as follows:—

—	Atropine.	Hyoscyamine.	Hyoscine.
Stimulation ..	Marked.	Moderate.	Slight.
Depression ..	Slight.	"	Marked.

Theoretically, hyoscyamine (that used in medicine being the pure *lævo*-rotatory form) should be twice as stimulant to the central nervous systems, as atropine, yet it is given as being less stimulant. If this is so, it may be possible that much of the deliriant action of the atropine is due to the 50 per. cent of *dextro*-hyoscyamine contained in it. The latter is a stimulant to the central nervous system in animals. *Datura stramonium* is said to contain chiefly hyoscyamine together with a little atropine and hyoscine; its action, therefore, should be mainly that of hyoscyamine. It has been suggested, however, that *Datura stramonium* contains unknown alkaloids which may modify its action. Degrees of benefit in parkinsonism similar to those obtained from stramonium are not obtained from atropine or belladonna; our experience is that they are rather more toxic and less specific in their clinical effects.

According to the theory of dual innervation of muscle as elaborated by Hunter, postural muscle tone is said to be maintained by impulses passing down sympathetic nerve-fibres to skeletal muscles. On this hypothesis the tonic excess of muscle tone in parkinsonism, suggesting an excess of postural tone, is possibly diminished by a depressant action of the atropine group of alkaloids on sympathetic nerve-endings. The soundness of this theory, however, is in considerable doubt and there is sufficient clinical evidence to show that the action of these drugs is largely central. A number of the distinctive features of parkinsonism relieved by their use are certainly central in origin; for example, the bradyphrenia and the tremor. On the other hand, the diminution of sialorrhœa is almost certainly due to peripheral action. The difference in effectiveness of these drugs in encephalitic parkinsonism and in senile paralysis agitans is probably due to the fact that there are distant clinical differences in the two syndromes and that the pathological lesions are localised with the greatest intensity in the areas of the brain somewhat removed from one another. Thus in paralysis agitans the main incidence of neuronie degeneration is in the globus pallidus, while in encephalitic parkinsonism the destructive lesions are most extensive in the substantia nigra. Further, at the comparatively late age at which paralysis agitans occurs, there is probably less power of response on the part of the nervous system to the effect of the alkaloids than at the earlier age of most encephalitic cases.

"Positive" signs or symptoms in the nervous system, in Hughlings Jackson's sense, cannot be the immediate effects of a disease process producing structural loss. They must be due, if they are not the result of pathological irritation and stimulation of neurones, to a loss of inhibition by higher over lower centres. Thus in parkinsonism the hypertonus is probably due to destructive lesions involving an area of the brain of which the function is the inhibition of lower centres concerned with the central origination of postural muscle tone. It is suggested that the

specific palliative effect of the atropine group of alkaloids on parkinsonian rigidity is due to a depression of those centres over which inhibition has been diminished by the disease process.^a Cruchet demonstrated that hyoscine, whilst benefitting parkinsonian rigidity, had less effect on the bradykinesia. It is probable that muscular rigidity contributes only secondarily to general bradykinesia, which appears to be largely a negative sign in the Jacksonian sense. Thus the incomplete efficacy of the atropine group would be explained. The undoubted benefit in that state of instinctive and emotional depression in parkinsonism known as bradyphrenia is difficult to account for. Bradyphrenia is not present in paralysis agitans. It is possible that central disturbances of the autonomic nervous system (producing signs of thalamic depression) are the basis of the condition and that the action of the atropine group of alkaloids on this system may explain the beneficial effect. The blood calcium in bradyphrenia is abnormally low and the condition is usually associated with marked bradykinesia, the two conditions appearing to be related. Both are distinctly benefited by Collip's parathyroid extract when this is given hypodermically in addition to drugs of the atropine group.

Summary and Conclusions.

Results as satisfactory as those from hypodermic hyoscine are obtained by the administration of extractum stramonii, U.S.P., by the mouth in doses of 0.25 g. to 1 g. or more three times a day; the average dose being 0.75 g. Similar results are obtainable with doses containing equivalent quantities of alkaloid of extractum stramonii exsiccatum, B.P.C., dried stramonium leaves, and tinctura stramonii, B.P.

The disadvantage of dried stramonium leaves is the excessive bulk of adequate doses, and of tinctura stramonii that it is twice as expensive as the stramonium extract.

The equivalent therapeutic doses of the preparations are as follows: hyoscine gr. 1/100 (hypodermic) = dried stramonium leaves, 1 g. = extractum stramonii, U.S.P., 0.25 g. = extractum stramonii exsiccatum, B.P.C., 0.25 g. = tinctura stramonii, B.P., 3iii.

THE CANCER HOSPITAL, Brompton Road, S.W.—The annual report shows that last year 1162 patients were admitted, an increase of 189. There were 1557 new out-patients, and the 988 operations were an increase of 120. The electrotherapeutic department treated 177 new cases. Plans have been prepared for the new building which will cost £93,000; at present only £17,500 has been received. A larger supply of radium is badly needed.

CHEMIST'S CARE OF DRUGS.—At Brighton police-court on May 23rd a chemist was summoned for failing to keep drugs in a locked receptacle. A police officer found a cupboard containing morphia, cocaine, and tincture of opium in a cupboard in the shop, the padlock being broken. At the time of the officer's visit the chemist was out, and an unqualified assistant and an errand boy were in the shop and could have had access to the cupboard. A plea of guilty was entered on behalf of defendant, and it was stated that the padlock had worked properly on the day of the inspection by the officer, but before the officer entered it could not be opened and was forced. When the officer called the defendant had gone out to buy a new one. The justices, by a majority, fined the defendant £2.

CUTANEOUS PAPILLOMATA IN THE RAT FOLLOWING EXPOSURE TO ULTRA-VIOLET LIGHT.

By G. M. FINDLAY, O.B.E., D.Sc., M.D. EDIN.

(From the Wellcome Bureau of Scientific Research and the Laboratories of the Imperial Cancer Research Fund, London.)

OF the theories which seek to explain the aetiology of cancer the only one which has received experimental proof is that which assigns the exciting rôle to chronic irritation. The forms of stimulation which are now known to cause cancer are, however, of a most diverse character, though the properties of the cancerous cell are similar in all cases. It therefore follows that whatever the forms of external stimulus, the metabolic changes in the tissues produced by these stimuli must of necessity be essentially similar. The nature of the metabolic changes set up by carcinogenic stimuli is, however, one of the essential points in connexion with cancer on which knowledge is still lacking, though work such as that of Lewis (1927) on the responses of the blood-vessels of the human skin to various forms of stimuli is highly suggestive of the type of investigation which must be carried out in order to throw light on this question.

In the meantime much can be learnt in regard to prophylaxis from a study of the external forms of stimulus which may give rise to cancer. Comparatively little attention has, however, been paid to the possibility of carcinogenic action by ultra-violet rays, though there is abundant clinical evidence to suggest that prolonged exposure to sunlight rich in ultra-violet light is a cause of skin cancer in man.

In certain parts of America, and more especially in Australia, there is a Northern European population exposed to prolonged and intense sunlight, with the result, as Molesworth (1927) points out, that rodent ulcer and epithelioma of the skin are far commoner in Australia than in Great Britain. In addition, white cattle in Australia are especially liable to develop epithelioma. Drabble (1929), for instance, in New South Wales found 190 cases of skin cancer among 955,798 cattle slaughtered in four years. The colour incidence of the affected animals was of considerable interest, as in all cases the animals which were wholly or partly white showed evidence of chronic dermatitis on the unpigmented portions of the skin, and where malignant changes had occurred the areas of skin involved were also partly or wholly white except in three cases. In these three cases the growths had arisen from old brand-scars.

Of the 190 cases of epithelioma described, no less than 137, or 72.1 per cent. of the total, occurred in white or partly white cattle, and of the 30 roan-coloured cattle with skin cancer many were so lightly pigmented as to be approaching white. Only one black animal was affected.

Similar evidence is available from Queensland, where practical farmers have now abandoned the breeding of white cattle owing to their liability to develop cancer of the skin.

The parallelism with extreme liability to skin cancer of poorly pigmented persons, described by Molesworth from Australia, is very striking and strongly suggests that chronic dermatitis due to excessive exposure to sunlight rich in ultra-violet light plays a not unimportant part in the aetiology of skin cancer both in man and in cattle. Unfortunately, no particulars are available as to the length of time necessary to initiate these cancerous lesions in cattle. There is not wanting direct evidence to suggest that exposure to ultra-violet light from artificial sources may initiate precancerous and cancerous lesions in man. Colquhoun (1927) has reported a case of keratoses on the chest of a man treated with ultra-violet light, while Ferrari (1920) has recorded a skin tumour

which developed after ultra-violet light treatment of an area of skin that had previously been the site of a radio-dermatitis.

Ultra-violet Light as a Cause of Skin Tumours in Rats.

In a previous communication (1928) I brought forward evidence to show that exposure to the rays of a mercury-vapour lamp is capable of exciting carcinomatous changes in the skin of the mouse, provided the exposures are continued for a period of at least eight months. Experiments have now been carried out to determine whether rats exposed to the mercury-vapour lamp are also liable to develop epithelioma. Six albino rats, about six months old, were epilated with sodium sulphide on an area of the back and were exposed to the light of the mercury-vapour lamp at a distance of 18 inches for one minute three times a week.

The technical details of the lamp are similar to those reported in connexion with the experiments on mice. The rats were first exposed on Dec. 20th, 1927; 18 months later three rats were still alive and in apparently normal health. On July 25th, 1929, however, one of the two surviving rats was noticed to have a small greyish-

FIG. 1.

The development of multiple tumours in the rat following exposure to the mercury-vapour lamp.

white opacity on the cornea of the right eye. This opaque area gradually increased in size and at the same time the eyeball began to enlarge. On Sept. 6th, 1929, 616 days after the commencement of the experiment, a small papilloma was noticed on the dorsal surface of the right ear, and, though the exposures to ultra-violet light were abandoned, the papilloma grew rapidly into a large horny excrescence. About a month later, two tiny papillomata appeared on the dorsal surface of the left ear.

Unfortunately the rat, which by this time was showing signs of senility, died on Nov. 13th, 1929, with bronchopneumonia. At the post-mortem the right eyeball was about three times the size of the left, while the cornea was uniformly opaque. The skin of the back, where epilation had been carried out, was entirely devoid of hair, although no depilatory had been used for some months; there was no evidence of tumour formation, the skin appearing smooth and atrophied. Microscopically the tumour on the right ear had all the appearances of a rapidly growing papilloma with cell-nest formation and much keratinisation; the cartilage of the ear was intact. The absence of infiltration and of metastases does not warrant a diagnosis of carcinoma in this case, although the rapid rate of growth, as shown in Fig. 1, strongly suggests that infiltration would have occurred had the animal lived. It is noticeable also that growth continued in the absence of further exposures to the mercury-vapour lamp. The right eye exhibited what may have been a sarcomatous condition of the conjunctiva but is more probably a chronic inflammatory lesion. The surface epithelium of the cornea was intact and of normal thickness at the periphery but had disappeared over the central part of the eye; the substantia propria was greatly thickened and consisted of a cellular fibrous tissue with mast cells and mitotic figures, while scattered throughout the tissue were numerous giant cells. Small capillary vessels were present throughout the growth. Sections stained for tubercle bacilli by Ziehl-Neelsen's method and for bacteria by toluidin-blue and van Gieson did not show the presence of micro-organisms.

Although exposure to the rays of the mercury-vapour lamp is thus undoubtedly capable of initiating precancerous and cancerous changes in the skin of

the mouse and rat, the question remains as to whether the ultra-violet rays are alone responsible or whether the infra-red rays given out by the lamp may also play some part in causing the cells to become malignant. Experiments with suitable screens are in progress to determine this question, but exposure of mice to a 1000-watt radiant heat bulb (glass) for 12 months has up to the present failed to induce malignant lesions in any of the exposed mice, while experiments with a thermopile show that under the conditions of the experiment the rise in temperature caused by the mercury-vapour lamp is not greater than 5°C. It is thus obvious that the carcinogenic action of the light from the mercury-vapour lamp is not attributable to the heat rays. It has been suggested also that the irritant action of the sodium sulphide may, in association with the ultra-violet rays, be the cause of the malignant change. If this were so, the tumours should have arisen on the skin of the back rather than on

The Time Factor.

A further point of interest is the time required to produce neoplastic changes in the skin of the rat and

FIG. 3

Papilloma from left ear of rat ($\times 18$)—fixed formol saline, stained Weigert's haematoxylin and van Gieson.

FIG. 2.

Papilloma from right ear of rat ($\times 9$)—fixed formol saline, stained Weigert's haematoxylin and van Gieson.

the ears, which had never been treated with the depilatory.

The lesion produced in the cornea is of considerable interest. While the irritant effects on the eye of a single long exposure to ultra-violet light have received considerable attention (W. S. and P. M. Duke-Elder, 1929), the effect of frequent short exposures has not been intensively studied. Although the time at which the corneal lesion began is suggestive of a neoplastic condition, nevertheless the general appearances are more suggestive of a chronic inflammatory reaction than of a new growth. The question of differentiating between chronic inflammation and sarcoma is, however, one of the greatest difficulty.

mouse respectively. In the latter animal the minimal period of exposure is eight months, in the former 21 months. This great increase in the time necessary for the induction of tumours in the rat by the mercury-vapour lamp is comparable with the time necessary to produce cancer in the same animal by means of tar. In the mouse, as is well known,

a minimum period of about four months' tar-painting is necessary to induce skin cancer; in the rat a much longer period is required, for Russell (1922 and 1923), who was the first to produce sarcomata in the rat by the injection of tar, found that in one rat 11½ months and in a second 18 months was the necessary time. Very few skin carcinomata have been produced in the rat by tar. Herly (1926), however, reported the occurrence of one such tumour, but unfortunately it is difficult to estimate the time necessary for the induction of this tumour, as after 226 days tarring was suspended, to be resumed after an interval of five months. In certain unpublished

experiments initiated by the late Dr. B. R. G. Russell and continued by myself, in which tar was injected subcutaneously once a week into the right flank of rats, a sarcoma appeared in one rat after 20 months, a skin carcinoma in another after 19 months, and a malignant adenocarcinoma of the breast in a third after 20 months.

The period necessary for the induction by tar of sarcomata and carcinomata in the rat is thus obviously much longer than in the mouse. In man the time necessary to produce cancer of the skin by means of tar is from 10 to 15 years, while at least 15 years is required for cancers due to exposure to sunlight.

It will be seen that the time necessary for the induction of malignant growth depends less on the irritant and the particular tissue involved than on

Animalspecies.	Time necessary for the induction of papillomata and carcinomata with—	
	Tar.	Mercury-vapour lamp.
Mouse	4-6 months.	8-10 months.
Rat	19	21
	Shale oil.	Sunlight.
Man	10-15 years.	15-20 years.

the species of animal. The time necessary for the production of cancer thus increases with the length of life of the species.

Conclusions.

By exposure to a source of ultra-violet light rapidly growing skin papillomata have been produced in a rat, together with a chronic inflammatory reaction in the cornea. The period (21 months) necessary for the induction of these skin tumours in the rat is longer than that required in the mouse; the time necessary to produce skin cancer in the rat by tar is also longer than that necessary in the mouse. It is, therefore, probable that the time required for the induction of cancer is dependent on the particular species involved rather than on the nature of the stimulus.

GAS-OXYGEN AS A ROUTINE ANÆSTHETIC.

A SUMMARY OF TWO HUNDRED CASES.*

By A. H. MACKLIN, O.B.E., M.C., M.D. MANCHESTER,
 ANÆSTHETIST, DUNDEE ROYAL INFIRMARY.

For many years I have felt dissatisfied with both ether and chloroform as routine anæsthetic agents in general surgery. It is probable that many anæsthetists will object to my use of the word "routine," and I agree that one must approach individual cases with an open mind as to what will constitute the most suitable anæsthetic, having regard to such factors as age, type of patient, history of alcohol, and the condition of heart, lungs, and kidneys. Yet I think it must be admitted that in the British Isles generally ether is looked upon as the great stand-by, with chloroform second, gas-oxygen being used for exceptional cases only. When gas-oxygen is used it is more often than not passed through ether, and sometimes through chloroform also. This series of cases was carried out with a view to discovering to what extent gas-oxygen (pure) could displace ether and chloroform in a general surgical theatre.

My chief objections to chloroform and ether are, in both cases, the unpleasant induction and the disagreeable after-effects. There are various ways of minimising these effects, such as careful preparation, suitable premedication, and the use of ethyl-chloride for induction. No amount of care, however, can totally eliminate the unpleasant headache, nausea, and sometimes very distressing vomiting which follow their use, and which create such a bad effect upon the

morale of the patient; every surgeon knows how the victims of multiple operations become resigned to anything that may be done to their bodies but grow more and more to hate and dread the anæsthetic. Personal experience of three operations under chloroform and ether went a long way to remove any lingering doubts which may have remained in my own mind of their unsuitability. I think it will be generally admitted that from the point of view of toxicity alone chloroform cannot be regarded as a suitable routine agent. Ether is safe "on the table" but, all other considerations apart, the high incidence of post-operative pulmonary complications makes some substitute highly desirable as a routine anæsthetic.¹

I have long looked upon nitrous oxide, with its easy, pleasant induction and amazingly short recovery period, as the ideal agent, but difficulty in securing accurate dosage up to the time that I commenced this series prevented my adopting it personally or regarding it as a suitable all-round anæsthetic for general surgical purposes. My enthusiasm for gas-oxygen was first aroused when I saw it used by American anæsthetists during the war, but it subsequently received a check owing to the poor results obtained with the appliances in general use in this country—viz., various forms of the Boyle apparatus. This apparatus must be regarded as a very effective, all-round useful instrument, and there can be no doubt that with it, in its more perfected form, a very good anæsthetic can be given by using gas-oxygen-ether, with or without the addition of a little chloroform, but even in its latest pattern, as modified by Dr. Ross Mackenzie of Aberdeen, I do not regard it as a successful apparatus for pure gas-oxygen. When the apparatus is put into practical use one encounters several factors which make the administration difficult.

1. To ensure good anæsthesia the proportion of oxygen to gas must be capable of very fine adjustment, a difference of 2 to 3 per cent. in the mixture being sufficient to spoil a smooth course. The bubble system, controlled directly from the cylinder valves, is not sufficiently accurate, since nitrous oxide does not always flow in a smooth stream but is apt to come away in rather jerky file and starts.

2. With this apparatus ether and chloroform, if they are to be used at all, must be used in quantities which spoil the effects of pure gas-oxygen. The reason for this is that with gas-oxygen alone, to ensure good relaxation in the majority of cases it is necessary at some stage of the operation to give a saturation of nitrous oxide which produces rather an unpleasant cyanosis. Most of us dislike the idea of giving even small amounts of ether to a patient with any degree of cyanosis, and to give chloroform at such a time is simply asking for trouble. Therefore, if one just fails to obtain relaxation with pure gas-oxygen (as usually happens with this apparatus) it is necessary first considerably to reduce the saturation of nitrous oxide, leaving a larger balance to be overcome with the additional anæsthetic.

3. The most complete relaxation is secured by what is called "secondary saturation," which is obtained by pushing the nitrous oxide to a stage just short of producing signs of distress and then quickly increasing the proportion of oxygen. This is a valuable method in difficult cases when, for example, the edges of peritoneum are about to be sutured, and by this means relaxation equal to that of full ether anæsthesia can be obtained. This process is only safe with a machine fitted with a safety-valve, a device for instantly shutting off the supply of gas and delivering pure oxygen under pressure or, better still, oxygen with a small percentage of carbon dioxide, which is a powerful respiratory stimulant.

The McKesson Apparatus.

A safety device for instantly inflating the lungs with oxygen is in my opinion a sine qua non for any apparatus designed to give gas-oxygen anæsthesia. Such an arrangement is unfortunately lacking in the standard Boyle. For the series of cases which I am about to summarise I selected and ultimately acquired for use in this theatre a McKesson (Model G) apparatus, which satisfies the essential features I have enumerated.

1. The mixture is independent of the flow from the cylinders, and the proportion, once set, remains constant.

2. The proportion of oxygen to nitrous oxide is capable of very fine adjustment.

* Read before the Forfarshire Medical Association.

¹ Fuller, C. J.: THE LANCET, 1930, i., 115.

3. In case of emergency the lungs can be instantly inflated with pure oxygen.

4. There is no need to be constantly turning taps on and off; when the patient breathes the gases flow; when he does not they stop automatically.

5. The machine is simple and easy to use.

A Series of Cases.

This series includes not only my own anæsthetics but a number given by Dr. W. H. Jeffrey, house surgeon to the unit. The first case was a woman aged 72 years, admitted with acute intestinal obstruction due to carcinoma of the descending colon, and complicated with very troublesome adhesions. The anæsthetic lasted 60 minutes and was a complete success, the patient waking up immediately the operation was finished in apparently better condition than when she arrived on the table. This good start was encouraging. From that date to the writing of this paper (approximately four months) the number of operations requiring anæsthesia in Mr. Alexander's theatre has been 315, classified as follows:—

Gas-oxygen	200
Ether and ether-chloroform mixtures	101
General ethyl chloride	3
Rectal (avertin)	2
Spinal	1
Local	8

The ratio of gas-oxygen to all other anæsthetics given concurrently with this series is, therefore, 200/115; but of these only the chloroform and ether are concerned in this summary. Of the 101 chloroform and ether cases, 24 were for face and mouth operations and endoscopic examinations; of the remainder, 59 were given by house surgeons from other units who were unfamiliar with the apparatus at times when I was not available and Dr. Jeffrey was assisting the surgeon. Thus within the unit there were only 28 cases in which gas-oxygen was abandoned in favour of ether and chloroform. This number includes 11 cases operated upon on days when, owing to transport difficulties, the supply of nitrous oxide failed, and two were children under six months to whom I preferred to give alcohol, chloroform and ether mixture. The remaining 15 operations were nearly all performed during the first half of this series before the potential capabilities of gas-oxygen were fully realised, the second half including only two, both of them operations involving extensive breaking down of adhesions and anastomosis for the elimination of faecal fistula.

The 200 gas-oxygen cases may be classified as follows:—

1. Upper abdominal.—Gall-bladder, 9; perforated gastric and duodenal ulcer, 2; other gastric operations, 6; and laparotomies (various) involving the handling of upper abdominal organs, 15	32
2. Lower abdominal.—Appendicectomies including every laparotomy in which the appendix was removed, 60; and acute intestinal obstructions (various), 5	65
3. Kidney operations (lumbar)	5
4. Bladder and prostate	3
5. Radical amputation of breast	3
6. Thyroidectomy	1
7. Bone-plating and wiring	15
8. Hernia (various), varicocele, &c.	17
9. Anal and rectal	7
10. Empyema	4
11. Various	48
Total	200

Of these 200 cases nine required additional anæsthetic (ether or chloroform) to secure the necessary relaxation, as follows: gall-bladder cases (2); gastro-enterostomies (2); appendicectomies (2); hernia (one strangulated) (2); bone-wiring (1).

The figures speak for themselves; they show that it is possible to anæsthetise a very wide range of cases, including high abdominal cases, with gas-oxygen alone. A critical inquiry must go further, however, and inquire whether the individual anæsthetics have been entirely successful both from the surgeon's point of view and that of the anæsthetist.

Success of the Anæsthetic.

There are three stages to be considered in connexion with the effects of any anæsthetic agent:—(1) the stage of induction; (2) the state of relaxation during the operation; (3) after-effects, both immediate and remote.

In this series the period of induction was found to last from three to ten minutes, with an average of five minutes; but even in cases where the patient "went away" quickly better results were obtained when the anæsthetic could be continued for fully ten minutes before commencing the operation. About half the cases passed through a definite stage of excitement, but, generally speaking, induction was quiet and characterised by absence of struggling. Robust alcoholic cases offered considerable resistance, but settled down, usually rather abruptly, in time. Recovery was rapid in every single case and was rarely accompanied by headache, nausea, or vomiting. A number complained of fuzziness or thickness of the head, which I attribute largely to the effects of the preliminary injection. It was most marked when hyoscine or atropine had been used. (At first patients received morphine sulphate gr. $\frac{1}{4}$, and either atropine sulphate or hyoscine hydrobromide gr. 1/100 for adults, and others in proportion. Latterly the atropine and hyoscine were stopped, with better results generally.) Vomiting, when it did occur, took place immediately and was slight, the ejected matter consisting of a frothy, clear fluid. The fact that on three occasions vomiting occurred simultaneously amongst a group of patients for whom the same cylinder had been used suggests impurities in the gas as a possible cause. A few abdominal cases ejected bile after manipulation about the gall-bladder. In fully three-quarters of the cases recovery was so rapid that the patients had opened their eyes and were talking and answering questions or making jokes before leaving the theatre. The marked analgesic effect of nitrous oxide was frequently noted in patients who were allowed to come round before the last stitches or clips had been inserted, and who seemed to be unconcerned at what was being done, but occasional hyperæsthesia made it unsafe to let the patient round till the operation had been completed.

An interesting and rather instructive example of the rapid recovery from gas-oxygen was our own theatre sister, who had been trained in the wards to expect and deal with post-anæsthetic sickness. She awoke on the operating table after appendicectomy to treat with contempt and as a poor attempt at flippancy the statement that her operation was over and finished! She later wrote to another sister, "I have had the most wonderful anæsthetic with gas-oxygen; I could scarcely believe that I had been done; and had no sickness or felt anything afterwards except a little stiffness in my wound." Another example was a large powerfully built cattle-man who came up to the theatre from the out-patient department for removal of a bursa from the elbow. He had a strong alcoholic history and, indeed, warned us beforehand to secure him with a strap because during a previous anæsthetic he had fought and struggled so badly that it required two students and four nurses to hold him. He was given gas-oxygen (pure); induction lasted seven minutes, during which there was considerable fidgeting and muttering into the facepiece, but he suddenly settled down and remained quiet during the 20 minutes that the operation lasted. He had no sickness or bad after-effect; and when seen one hour later was fully dressed, feeling quite well, and anxious to get home in time for his dinner.

This series has demonstrated most markedly the overwhelming advantages of gas-oxygen during induction and after operation, the contrast in this respect with other anæsthetics being most noticeable and remarked upon by patients, ward sisters, and even probationers who found that they had less stained bed linen to wash. Remote effects were entirely absent, with one noticeable exception. This is a case which I find difficult to appraise.

The subject was a man aged 45, a butler, with an alcoholic history, toxic, suffering from duodenal ulcer for which he was having a second operation (gastro-enterostomy). Induction was not markedly difficult for the type, lasting seven minutes. There was cyanosis at the first incision, and it was found necessary to maintain a slight duskiness during the whole of the manipulative stage. The colour was deepened just before closure of the peritoneum, and good relaxation obtained at the time of suturing by increasing the percentage of oxygen, after which the patient remained a healthy pink. Recovery as usual was rapid, the patient answering questions before leaving the operating table, and remained uneventful during the next four days. There was no indication of chest trouble

until the fifth day, when slight dyspnoea was noticed. Death took place rather suddenly the same day and was attributed to massive collapse of the lung. Permission for a post-mortem examination was not obtained. Just what part gas-oxygen played in this result is difficult to say. It was the only case in the series which showed untoward remote after-effects.

The condition of the patients during the second stage is, of course, the most important, and the chief criterion of any anæsthetic is, "Does it satisfy the surgeon?" That Mr. R. C. Alexander, the surgeon in charge of the unit, has endured the anæsthetic over a series of 200 cases lasting four months says a great deal in itself, and I think I can safely go further and say that both he and Mr. R. S. Melville have not only put up with, but are enthusiastic about, this form of anæsthesia.

It would be foolish of me to suggest that all the anæsthetics in this series have been perfect. The chief factors leading to trouble have been:—

1. Allowing air to leak under the facepiece. It will easily be understood how much this spoils the balance of an anæsthetic where accuracy in proportion is such an essential.
2. Starting the operation too soon as a result of the smooth quiet induction. In these cases movement occurred at the first incision, but afterwards there was no trouble.
3. Instinctive efforts by the anæsthetist in two directions: (a) to avoid cyanosis, letting the patient come round; (b) to increase an already deep anæsthesia by giving more gas when what was required was more oxygen—causing spasm and jactitation.

We had difficulty throughout the whole series in preventing air-leaks in sunken toothless faces. Experiments to ensure a satisfactory air-tight inhaler are still being carried out, and several models are under test. The second and third points apply chiefly to the earlier cases of the series and have largely been eliminated by greater experience with the apparatus.

With regard to muscular relaxation, I think all the members of this surgical unit are agreed that gas-oxygen (pure) has met the requirements of every non-abdominal case (where there was no mechanical difficulty in placing the inhaler—e.g., mouth and face operations) and with the easy induction and absence of after-effects have come to regard this agent as the routine anæsthetic of choice. The abdominal group, from the same standpoint, may be divided into operations on the upper and lower abdomen respectively. For all lower abdomen operations in this series gas-oxygen has proved almost without exception to be particularly successful especially for "grid-iron" appendicectomies, for which it has approached the ideal.

This leaves for consideration the most important group of all, both from the surgeon's and the anæsthetist's point of view: the upper abdomen cases (gall-bladders, gastro-enterostomies, partial gastrectomies). The number of these in the series is 32. In one-third of these the anæsthesia was restful and quiet, with perfect relaxation; in another third the patient was distressed by the manipulative efforts of the surgeon, but relaxation at the time of suturing the peritoneum was good. In the last third there were, in more or less marked degree, restlessness, uneven breathing, spasm of the glottis, rigidity of the masseters, and even slight jactitation of the limbs, and the cases were from the anæsthetist's point of view far from satisfactory. Yet in all of them a very interesting thing was noticed—viz., that the peritoneum itself was very lax, that lifting it did not increase spasm of the rectus muscles, and though the viscera showed a marked tendency to bulge into the wound, this was controlled without great difficulty, and the laxity of the peritoneum made suturing less arduous than in many other anæsthesias which I have seen (and given).

Taking the series as a whole, we had much more success than previous experience of the agent had led us to expect. The number of cases is far too small to base any definite claims on it. The results do indicate, however, that gas-oxygen (pure) given with a suitable apparatus can be substituted for ether and chloroform (and mixtures) as a standard routine agent for a very wide range of cases and with distinct advantage to all concerned.

Cyanosis.

The great controversial point in connexion with anæsthesia by pure gas-oxygen is, of course, the question of "cyanosis." In this series it was found impossible, except in very blonde and anæmic patients, to produce full surgical anæsthesia without cyanosis at some stage of the operation. Generally, at the first incision dark-coloured blood welled into the wound. This is apt to disturb surgeons who are not used to gas-oxygen administration. It is usually taken for granted that this dark blood leads to greater bleeding in the operation area, and one must admit that this is often true, but from the view of various operation wounds which I get from my position at the head of the table, I am quite sure that this is not always the case; in fact, I think that most bleeding comes from the red congested wound frequently met with in open ether anæsthesia. If the surgeon finds in any instance that bleeding is free and disturbing to his work, the anæsthetist must, of course, adapt himself to the requirements, diminish the saturation of gas, and make up the balance with ether. In this series congestion at the wound was never found to be so much a source of trouble as to call for correction, but changes in colour of the mucosa naturally contra-indicate this agent for cystoscopic and proctoscopic examinations; consequently it was never used for this type of case.

Of course, every effort must be made to keep the cyanosis within reasonable limits and to reduce it at the earliest possible moment. It was found possible in this series to let patients return to a pink colour during the quieter parts of the operation, but always before the first incision, on entering or closing the abdomen, and whilst viscera were in any way being pulled upon, it was necessary to give a saturation which caused dusksiness of varying degree, amounting in some cases to a definite cyanosis. There at once arises the question of the safety of this degree of saturation. In this series we have had no mishaps; nor has any case (with the doubtful exception quoted) caused anxiety on the table or after, though on one or two occasions signs of commencing distress called for use of the safety valve, which in every case produced relief and restored the patient to a bright pink within 30 seconds. Without an arrangement for instantly giving oxygen under sufficient pressure to inflate the lungs I would not deliberately let a patient become blue or remain so for a moment longer than I could help.

A factor making for safety with gas-oxygen is the rather fortunate fact that one cannot over-saturate with nitrous oxide and get good anæsthesia, for as soon as one reaches a certain limit of anaemia, before signs of real distress appear, the patient begins to get rigid, and relaxation can only be obtained by giving more oxygen; moreover the observation that, as a case progresses, less and less gas has to be given was amply borne out in this series.

Anæsthetists, whilst agreeing that gas-oxygen is the safest known agent, are practically unanimous in laying down very clearly that this is only so in the absence of cyanosis. It is a matter of common experience, however, that if a patient is to be kept pink throughout with pure gas-oxygen, he will in over 90 per cent. of cases fall short of the state required for even the simplest operation, and the balance necessary for relaxation must be made up with ether. As a matter of fact this is usually what happens and one has frequently felt that in many so-called gas-oxygen anæsthetics the gases have simply formed convenient media for carrying an amount of ether that completely spoils the effect of gas-oxygen. A small quantity of ether given in a closed apparatus corresponds to a very much larger amount poured on to an open mask, and this is especially the case if rebreathing has been employed. "Barely an ounce

* Since reading this paper the number of the series has more than doubled. There has been one death "on the table" during induction in a case shown to have been suffering from cerebral syphilis. There was also a death in another theatre during the later stages of an operation for perforated gastric ulcer. Both anæsthetics were given by house surgeons. In my own hands there has so far been no unusual difficulty with this anæsthetic.

3. In case of emergency the lungs can be instantly inflated with pure oxygen.

4. There is no need to be constantly turning taps on and off; when the patient breathes the gases flow; when he does not they stop automatically.

5. The machine is simple and easy to use.

A Series of Cases.

This series includes not only my own anæsthetics but a number given by Dr. W. H. Jeffrey, house surgeon to the unit. The first case was a woman aged 72 years, admitted with acute intestinal obstruction due to carcinoma of the descending colon, and complicated with very troublesome adhesions. The anæsthetic lasted 60 minutes and was a complete success, the patient waking up immediately the operation was finished in apparently better condition than when she arrived on the table. This good start was encouraging. From that date to the writing of this paper (approximately four months) the number of operations requiring anæsthesia in Mr. Alexander's theatre has been 315, classified as follows:—

Gas-oxygen	200
Ether and ether-chloroform mixtures	101
General ethyl chloride	3
Rectal (avertin)	2
Spinal	1
Local	8

The ratio of gas-oxygen to all other anæsthetics given concurrently with this series is, therefore, 200/115; but of these only the chloroform and ether are concerned in this summary. Of the 101 chloroform and ether cases, 24 were for face and mouth operations and endoscopic examinations; of the remainder, 59 were given by house surgeons from other units who were unfamiliar with the apparatus at times when I was not available and Dr. Jeffrey was assisting the surgeon. Thus within the unit there were only 28 cases in which gas-oxygen was abandoned in favour of ether and chloroform. This number includes 11 cases operated upon on days when, owing to transport difficulties, the supply of nitrous oxide failed, and two were children under six months to whom I preferred to give alcohol, chloroform and ether mixture. The remaining 15 operations were nearly all performed during the first half of this series before the potential capabilities of gas-oxygen were fully realised, the second half including only two, both of them operations involving extensive breaking down of adhesions and anastomosis for the elimination of fæcal fistula.

The 200 gas-oxygen cases may be classified as follows:—

1. Upper abdominal.—Gall-bladder, 9; perforated gastric and duodenal ulcer, 2; other gastric operations, 6; and laparotomies (various) involving the handling of upper abdominal organs, 15	32
2. Lower abdominal.—Appendicectomies including every laparotomy in which the appendix was removed, 60; and acute intestinal obstructions (various), 5	65
3. Kidney operations (lumbar)	5
4. Bladder and prostate	3
5. Radical amputation of breast	3
6. Thyroidectomy	1
7. Bone-plate and wiring	15
8. Hernia (various), varicocele, &c.	17
9. Anal and rectal	7
10. Empyema	4
11. Various	48
Total	200

Of these 200 cases nine required additional anæsthetic (ether or chloroform) to secure the necessary relaxation, as follows: gall-bladder cases (2); gastro-enterostomies (2); appendicectomies (2); hernia (one strangulated) (2); bone-wiring (1).

The figures speak for themselves; they show that it is possible to anæsthetise a very wide range of cases, including high abdominal cases, with gas-oxygen alone. A critical inquiry must go further, however, and inquire whether the individual anæsthetics have been entirely successful both from the surgeon's point of view and that of the anæsthetist.

Success of the Anæsthetic.

There are three stages to be considered in connexion with the effects of any anæsthetic agent:—(1) the stage of induction; (2) the state of relaxation during the operation; (3) after-effects, both immediate and remote.

In this series the period of induction was found to last from three to ten minutes, with an average of five minutes; but even in cases where the patient "went away" quickly better results were obtained when the anæsthetic could be continued for fully ten minutes before commencing the operation. About half the cases passed through a definite stage of excitement, but, generally speaking, induction was quiet and characterised by absence of struggling. Robust alcoholic cases offered considerable resistance, but settled down, usually rather abruptly, in time. Recovery was rapid in every single case and was rarely accompanied by headache, nausea, or vomiting. A number complained of fuzziness or thickness of the head, which I attribute largely to the effects of the preliminary injection. It was most marked when hyoscine or atropine had been used. (At first patients received morphine sulphate gr. $\frac{1}{4}$, and either atropine sulphate or hyoscine hydrobromide gr. 1/100 for adults, and others in proportion. Latterly the atropine and hyoscine were stopped, with better results generally.) Vomiting, when it did occur, took place immediately and was slight, the ejected matter consisting of a frothy, clear fluid. The fact that on three occasions vomiting occurred simultaneously amongst a group of patients for whom the same cylinder had been used suggests impurities in the gas as a possible cause. A few abdominal cases ejected bile after manipulation about the gall-bladder. In fully three-quarters of the cases recovery was so rapid that the patients had opened their eyes and were talking and answering questions or making jokes before leaving the theatre. The marked analgesic effect of nitrous oxide was frequently noted in patients who were allowed to come round before the last stitches or clips had been inserted, and who seemed to be unconcerned at what was being done, but occasional hyperæsthesia made it unsafe to let the patient round till the operation had been completed.

An interesting and rather instructive example of the rapid recovery from gas-oxygen was our own theatre sister, who had been trained in the wards to expect and deal with post-anæsthetic sickness. She awoke on the operating table after appendicectomy to treat with contempt and as a poor attempt at flippancy the statement that her operation was over and finished! She later wrote to another sister, "I have had the most wonderful anæsthetic with gas-oxygen: I could scarcely believe that I had been done; and had no sickness or felt anything afterwards except a little stiffness in my wound." Another example was a large powerfully built cattle-man who came up to the theatre from the out-patient department for removal of a bursa from the elbow. He had a strong alcoholic history and, indeed, warned us beforehand to secure him with a strap because during a previous anæsthetic he had fought and struggled so badly that it required two students and four nurses to hold him. He was given gas-oxygen (pure); induction lasted seven minutes, during which there was considerable fidgeting and muttering into the facepiece, but he suddenly settled down and remained quiet during the 20 minutes that the operation lasted. He had no sickness or bad after-effect; and when seen one hour later was fully dressed, feeling quite well, and anxious to get home in time for his dinner.

This series has demonstrated most markedly the overwhelming advantages of gas-oxygen during induction and after operation, the contrast in this respect with other anæsthetics being most noticeable and remarked upon by patients, ward sisters, and even probationers who found that they had less stained bed linen to wash. Remote effects were entirely absent, with one noticeable exception. This is a case which I find difficult to appraise.

The subject was a man aged 45, a butler, with an alcoholic history, toxic, suffering from duodenal ulcer for which he was having a second operation (gastro-enterostomy). Induction was not markedly difficult for the type, lasting seven minutes. There was cyanosis at the first incision, and it was found necessary to maintain a slight duskiness during the whole of the manipulative stage. The colour was deepened just before closure of the peritoneum, and good relaxation obtained at the time of suturing by increasing the percentage of oxygen, after which the patient remained a healthy pink. Recovery as usual was rapid, the patient answering questions before leaving the operating table, and remained uneventful during the next four days. There was no indication of chest trouble

on radium with its comparatively limited application. There is without doubt, however, a call in this country for an efficient, cheap, portable outfit and for better and cheaper gas. It is likely that a more general demand for gas-oxygen would stimulate production. The actual cost of the nitrous oxide and oxygen used in this series worked out at slightly less than 2s. 6d. per case; this includes transport of the cylinders, a considerable item which would be largely eliminated with more general use and the laying down of more depôts.

Gas-oxygen has, of course, a much wider application than has been considered in this summary, which deals only with its advantages in a general surgical unit.

One of the most satisfying features in carrying out this series has been the number of successful anaesthetics given by Dr. Jeffrey, house surgeon to the unit, who, though he has an undoubted flair for this kind of work, had no previous experience of anaesthesia except that gained as a student. His successful use of gas-oxygen in acute abdominal cases has been particularly valuable.

In conclusion, I must thank Mr. Alexander and Mr. Melville, not only for their ready acquiescence in the carrying out of the series, but for their whole-hearted encouragement throughout.

Clinical and Laboratory Notes.

FURTHER REMARKS ON ENTERIC AND THE WIDAL TEST.

BY EUSTACE THORP, O.B.E., M.B. BELF.,
L.R.C.P. EDIN., D.P.H.,

DEPUTY MEDICAL OFFICER OF HEALTH FOR SUNDERLAND.

RECENT communications from bacteriologists on the value of the Widal test from their point of view lead me to elaborate my previous remarks¹ on this test from the clinical aspect, in view of further cases seen since that time. In the former note I drew attention to the long delay in the appearance of the reaction in many cases of enteric fever, including abortive and ambulant cases. Indeed, the test often only became positive long after a clinical diagnosis was possible and sometimes only late in convalescence after repeated negative results. So doubtful did I become of the test after seeing undoubted cases of clinical enteric die before a positive result was obtained, that I held up other negative cases and took repeated blood tests and in many instances finally obtained positives from the twenty-sixth day onwards. Frequently a test with negative result had been taken by the practitioner outside hospital, and this negative had postponed or altogether prevented the patient's admission. The history of a negative Widal would no doubt also modify the after-treatment, enteric being ruled out both in the patient and in other members of the family who might become ill.

I have formed the opinion that the margin of error in the reaction is much greater than is generally supposed, that a negative reaction is not of importance where clinical evidence is present, and that a late Widal or repeated Widals must be taken before excluding the disease. I now add a few selected examples from cases where the patient lived long enough to obtain a positive result—as some unfortunately did not. They show how possible it is for such cases to be missed or written off as "pyrexia of unknown origin," and the existence of such cases shows where the old sporadic case comes from.

CASE 1, aged 39. Her father died on Jan. 1st, 1930, of "broncho-pneumonia"; the patient nursed him and took

to bed on Jan. 14th. The Widal test was negative on Feb. 3rd and positive, 1-125, on Feb. 20th. Clinically enteric was diagnosable on Jan. 22nd.

CASE 2, aged 57, was ill for five weeks with irregular pyrexia. He had a typhoid tongue and a somewhat enlarged spleen. On account of a stool containing blood, a Widal was taken by the practitioner on March 3rd, 1930, the eighteenth day of the illness, and was negative then and again on March 13th. It was positive on March 23rd and 31st. This was admittedly an atypical case but it is just such cases which require detection.

CASE 3, aged 20, was admitted on the fourth day of the illness, having had vague abdominal pains, and was notified as enteric on account of a typhoid tongue, a slightly enlarged spleen, and a high remittent pyrexia. In hospital the patient appeared well except for pyrexia. Blood culture was negative on March 3rd, 1930. The faeces and urine were negative on March 7th. Widals were negative on Feb. 20th and 24th. The chest was X-rayed and showed no abnormal findings; sputum was negative. The Widal was positive on March 15th, 1-500.

CASE 4, aged 28, was admitted on the fifth day of the disease; the temperature fell on the eighth day. The Widal was negative on the ninth day, but ten days later was positive, the temperature having remained down.

The following points impressed me most in these atypical and ambulatory types: (1) The typhoid tongue was usually recognisable. (2) No typical temperature chart was common to all, nor did the continued type of pyrexia appear; apyrexia was common. (3) The appearance of rose spots was delayed, if they appeared at all, and Widals were negative until well into convalescence. (4) Any haemorrhage from the bowel, however slight, in supposed pneumonia is of great importance, especially in apparent convalescence; a positive Widal is frequently obtained after this. (5) When pneumonia is prevalent, cases such as the above may masquerade as pneumonia. (6) To obtain a positive Widal the stay in hospital may have to be prolonged. (7) Death may occur from haemorrhage or toxæmia before a "positive" can be obtained. (8) The Widal usually came down, even in ill patients, in dilutions up to 1-500.

SOME ASPECTS OF IODINE THERAPY.

BY W. MITCHELL STEVENS, M.D., F.R.C.P. LOND.,
SENIOR PHYSICIAN TO THE CARDIFF ROYAL INFIRMARY;
FELLOW OF UNIVERSITY COLLEGE, LONDON.

In his "Principles and Practice of Medicine" Osler writes: "Longevity is a vascular question, which has been well expressed in the axiom, 'A man is as old as his arteries.' In a majority of men death comes primarily or secondarily through this portal." The truth of the above remarks is indisputable, but, nevertheless, one naturally feels inclined to ask the question, Can these vascular affections (and associated heart affections) be prevented, be delayed or, having once set in, be arrested for a shorter or longer period?

For many years I have been studying the uses of iodine (as iodides) in arterial affections such as aneurysm, arterio-sclerosis, high arterial blood pressure, and other related conditions, whether such be of syphilitic or other origin, or merely the accompaniment of what is termed "senility." I am confident that the exhibition of iodides may prevent or retard arterial changes and arrest them, when present, for shorter or longer periods, and that the doses required for various purposes vary from very small, even minute, quantities to large amounts, and that no ill-effects whatever occur from the drug itself when judiciously given.

I regard the arterial changes occurring in what is called "old age" to be similar in kind to the changes due to other causes. It appears that senility is, in one sense, a disease and, doubtless, an inevitable one if a person survives long enough, so to speak, but I am inclined to think that, as far as the arteries are concerned, it is a deficiency manifestation or, in other

¹ THE LANCET, 1928, II, 372.

words, that some substance normally present in the blood which defends the arteries becomes deficient either in quantity or quality or both, and that this deficiency may be the expression of a defect in what may be broadly called iodine metabolism, and that it may be corrected, at least for a time, by giving iodine, even in minute doses, bearing in mind the remarkable selective absorption shown for this element where needed.

Iodine is present in all plants and animals, and maybe this extraordinary element will come to be recognised as the harmoniser of the hormones. I visualise the day when the duration of life of a considerable proportion of the human race may be extended, and when distressing heart affections not due to what may be called external agencies may be far less prevalent than they are at the present time.

Medical Societies.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Leeds on April 11th, with Dr. J. W. BURNS, the President, in the chair.

Clinical Cases.

Dr. A. M. CLAYE (Leeds) described a case of congenital rectovulval fistula with multiple fibroids impacted in the pelvis and obstructing the progress of a full-time labour. Her menstrual history had been normal throughout life, and she had no discomfort during gestation. Dr. Claye delivered her of a living male child by Cæsarean section, and followed this by performing subtotal hysterectomy. Both patient and baby recovered well. He had been able to find in the literature only two cases in which a patient became pregnant with this abnormality.

The PRESIDENT recalled that in 1929 he had reported a similar case to the society where the patient, who had three children, was unaware of her abnormality.—Mr. W. GOUGH (Leeds) said he had seen a similar case.

Mr. A. GOUGH (Leeds) described two cases of excessive uterine hæmorrhage associated with enlarged ovaries in young women. In one case the patient, aged 22, had suffered from menorrhagia and metrorrhagia for two years, which continued in spite of curettage. An operation was performed in which the right ovary was removed and half the left ovary resected. The excessive loss was improved. In the other case the patient, aged 23, gave an identical history, though the losses had only been excessive for seven months. In each case the removed ovary was between three and four times the normal weight, of a "succulent consistence," showing histologically increased stroma and numerous small cysts. He said there were few references to this condition, which he considered rare, but that similar observations had been made by Blair Bell, Whitehouse, Wilfred Shaw, Cotte, and Fekete.

Mr. ERIC STACEY (Sheffield) said he thought this condition of hypertrophy and formation of cysts of the ovary, associated with excessive losses, in young women was very common indeed, and he had operated on many cases in which by partial resection he had reduced the bulk of the ovaries, with cure of the patient. In his opinion the condition was associated with most of the causes of pelvic congestion, whether physical or psychological.—Mr. A. A. GEMMELL (Liverpool) thought this was true of some cases, but many young women suffered from menorrhagia in which the cause was excessive function of the thyroid and would be cured by applications of X rays to that organ, whilst others had similar symptoms due to hypothyroidism, and were improved by taking

thyroid daily for some months.—Dr. J. W. A. HUNTER (Manchester) considered that administration of calcium chloride intravenously with the addition of parathyroid would usually prevent operation in these cases.

Spinal Anæsthesia.

Dr. HUNTER read a short note on the Value of Spinal Anæsthesia in Cases of Difficult Midwifery. He thought its scope was limited, but there was an advantage in the greater relaxation of the birth passage without interference with the uterine contractions; also chest complications seemed to be less and there was easier breathing than under general anæsthesia. The greatest advantage of spinal anæsthesia was that it improved the prognosis in cases where an otherwise healthy patient had developed a temporary acute anæsthetic bronchitis as a result of one or several previous and badly administered anæsthetics. He advocated its use, therefore, in cases of failed forceps. He had also used it in three cases in which a dry, prolonged labour, with a rigid, undilated cervix was ended by cervical hysterotomy and forceps delivery. He had also used it in heart disease.

Dr. BURNS read the communication published in THE LANCET of May 10th, p. 1012. He considered that the scope of spinal anæsthesia in midwifery was limited to Cæsarean section, and by its use in this operation had found there was a diminution in the amount of blood lost with no increased risk to mother and child, and a more speedy recovery of the patient, without chest complications.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

A MEETING of this Section was held on May 23rd, with Dr. R. J. ROWLETTE, the President, in the chair.

Meningitis and Encephalitis.

Dr. R. H. MICKS read a communication entitled Atypical Meningitis. Last year, he said, he had seen three cases of meningitis which had presented the following symptoms: (1) a cerebro-spinal fluid which was turbid with polymorphs; (2) absence of organisms as tested both by direct film examination and culture on standard laboratory media; (3) negative Boveri reaction; and (4) an atypical course in that two out of the three recovered, and the third showed a very striking and well-maintained improvement until the patient died suddenly with a normal temperature. Mild recoverable meningitis was undoubtedly more common now than was once believed. Encephalomyelitis and associated meningitis of various types had increased in frequency—especially the type associated with vaccinia and measles—and there had been sporadic cases which were not associated with exanthems and were not apparently similar in course or post-mortem appearance to encephalitis lethargica. Six cases of this kind had been described by Russell Brain and others.¹ But in all these examples of mild meningitis the cell count was usually low, and the predominating cell the lymphocyte. A marked polymorph increase was apparently very rare in a meningitis which was not due to recognisable bacteria. For this reason he had thought these three cases worth recording as something well-removed from a lymphocytic meningitis or a "meningismus." In Dr. Micks's opinion Boveri's reaction, if properly carried out, was of great diagnostic value in clear or nearly clear cerebro-spinal fluid. He had noticed that a very marked polymorph leucocytosis might follow intrathecal injection of a foreign protein. This rather alarming phenomenon was not sufficiently known;

¹ THE LANCET, 1929, i., 221.

indeed he had only been able to find one reference to it in the literature.

Dr. V. O. MCCORMACK described the illness of one of the patients. There were no localising symptoms from the first day of the illness.

Dr. V. M. SYNGE read a paper on Mumps Meningitis.

His patient, a boy aged 9, first complained of severe headache and vomiting on May 4th. He was seen by Dr. J. F. O'Grady late the following evening and was sent into the Royal City of Dublin Hospital. His temperature was 104° F. and the pulse-rate 138. He was delirious, vomit-conscious, and incontinent of urine; the neck was stiff, and there was a slight doubtful Kernig sign. The pupils were equal and reacted to light; the knee-jerks brisk, especially the left, and the right parotid swollen. Lumbar puncture (on May 6th) gave a clear fluid under slightly increased tension; globulin was increased, sugar absent, and the Boveri test negative; the fluid was sterile on culture and showed no tubercle bacilli; it contained 300 cells (lymphocytes) per c.mm. The patient gradually improved and left hospital on May 21st perfectly well.

The enlarged parotid, the character of the cerebro-spinal fluid, and the rapid recovery left no doubt, said Dr. Syngé, of the diagnosis of mumps meningitis. Roux stated that meningitis occurs in 1 per cent. of cases of mumps, while Dopfer gave 0·8 as the percentage of cases which showed meningeal symptoms, though he did not regard all of them as true meningitis. In Dublin meningeal complications certainly did not reach these figures.

The PRESIDENT spoke of a case of urticaria which he had treated some years ago and which showed symptoms of meningitis. He gave salicylate of soda, and the patient got perfectly well. No lumbar puncture had been done, and there had been no such thorough examination as would now be made.

Dr. J. O'CONNOR mentioned a case which he was looking after in hospital, a baby of 10 months old.

Vaccinated on May 3rd he became ill on the 10th, being cross and very restless with vomiting. Next day he was quiet and apathetic, and on admission to hospital his condition resembled tetanus. Lumbar puncture was done and fluid was removed under tension, but proved to be perfectly clear. The Boveri reaction was positive. After lumbar puncture the tetanic spasms completely disappeared, but next night further spasms occurred, and there was some rigidity of the neck. When Dr. O'Connor tried to obtain Kernig's sign, the whole musculature of the child's body was thrown into action. A further lumbar puncture was done, and again Boveri's reaction was positive. Lumbar puncture had been done three times subsequently, and that day a ventricular puncture had been done through the fontanelle, clear fluid being removed under tension.

At first, said Dr. O'Connor, it was thought that the case might be one of encephalitis following vaccination, but the vaccination had not taken, and there had been no reaction at all. The child was afebrile, and no focus of infection could be found.

Dr. CYRIL MORRIS mentioned the possibility of the infection coming from the antrum and producing inflammation of the dura and a slight Boveri reaction. He referred to a case of this kind in which the patient ultimately made a good recovery. He thought that too much reliance should not be placed on the Boveri reaction.

Dr. A. HALPENNY said she had found that cases in which the cerebro-spinal fluid was clear and contained lymphocytes and polymorphonuclear cells and in which an immediate positive Boveri reaction was obtained were invariably tuberculous.

Dr. G. E. NESBITT referred to cases which might or might not be classed as meningismus, in which the fluid was opalescent.

One evening a lady got a severe headache and vomiting, and next day she stayed in bed. On the following day she was no better and was seen by Dr. Nesbitt. She was very dazed, and had indefinite symptoms. He did a lumbar puncture and removed turbid fluid. Antimeningococcal serum was then injected. No organism was found in the fluid.

Lumbar puncture was done again the following day, and more serum was injected. After three days a few meningococci were found with great difficulty. The patient made a complete recovery.

Dr. Nesbitt thought it possible to have meningococcal infections in which the organisms were so few that it was impossible to find them. He mentioned a case of encephalitis with undoubted signs of meningeal infection which he had recently seen.

Dr. J. LAIT mentioned a case of tetanus which had been admitted to hospital with definite trismus.

A lumbar puncture was done and the fluid was quite clear, but there was a slight increase in the cell content. Serum was injected, and on the following day another lumbar puncture was done, and 10 c.cm. of turbid fluid was removed. More serum was injected, and the fluid on examination proved to be full of pus cells. The patient's symptoms did not increase, in fact, his condition rather improved. In a couple of days the fluid was sterile.

This case, Dr. Lait thought, brought out the fact that an increase in polymorphonuclear cells following the injection of serum took place. The patient made a complete recovery.

Dr. A. R. PARSONS suggested that it was rather rash to inject antitoxin "on the offchance." He personally always had the fluid examined first to see if meningococci were present.

Dr. MICKS, in replying, said his cases had all been ones in which there were clearly marked symptoms of meningitis, and in which the fluid had come out quite turbid. He did not regard any of his cases as meningococcal meningitis. He thought that whenever turbid cerebro-spinal fluid was found it was necessary to inject meningococcal antiserum before receiving the report on the fluid, for it was sometimes very hard to find meningococci. If the infection was not meningococcal no harm was done, provided care was taken to avoid protein shock in a sensitive patient.

Spirochetal Jaundice.

Dr. NESBITT described the case of a man aged 22 who was sent to hospital in November last as a case of "acute abdomen."

About 10 A.M. three days previously, when working in the fields, he got violent pain between his shoulder-blades. This pain travelled down, and in the afternoon became so severe that he had to stop working. A couple of days later he came to hospital. He looked very toxic, and there was a definite icteric touch in the skin. His tongue was very furred, temperature normal, pulse 100. He vomited almost without ceasing from the time of his admission. The urine contained albumin and there was a slight reduction of Benedict solution. The case was at first thought to be one of either acute pancreatitis, typhoid fever, spirochetosis, icterohæmorrhagia or trichinosis.

On the second day after admission his condition was much the same, the vomiting persisted, and he complained of severe thirst, and very severe pain in his legs. Morphine gr. 4 was given without relief, but after the dose had been repeated an hour later the patient slept. A blood film showed eosinophilia; a blood culture was negative. That evening he was a little better, and his pains had quite gone, apparently owing to the morphine. Next day, though jaundice was very marked, he said he felt better, and had no pain; but he was still vomiting, very thirsty, and passing no urine, and he developed a crop of red spots on his shoulders. Next day he had a bad hiccup, was still vomiting, and was very heavy and drowsy. Fisher's solution was injected. On the day afterwards he was still passing no urine, and complained of great abdominal pain, much like the pains in his legs. It was then thought that he must be suffering from some acute abdominal condition. On the following morning he passed about 2 c.cm. of urine, greenish in colour, but containing no spirochetes. The abdomen was rather distended and tympanitic, but soft. Pituitrin was given, and immediately relieved the abdominal pain. At 1 o'clock he became very weak and said he could not breathe, and at 1.45 P.M. he had a similar attack and died.

Post-mortem examination showed nothing very remarkable. The liver and kidneys were large and smooth. The mucous membrane looked as if some strong acid had been put over it while it was dissolving it away. All the organs were intensely bile-stained, but histologically showed very little damage considering the toxic condition of the patient clinically.

Spirochetal jaundice, said Dr. Nesbitt, had been described by Weil in 1886, but it appeared that the same disease had previously been described by

many authors. In 1914 spirochaetes were found in the liver of a guinea-pig which had been inoculated with the serum of an infected patient.

Dr. T. T. O'FARRELL said he had examined specimens from the lungs, liver, pancreas, spleen, intestine, and a gland from the stomach in this case. He found nothing in the pancreas, but in the spleen he found an organism, but failed to find organisms anywhere else, except in the kidney where he found a few. He was quite convinced that they were spirochaetes, but it was impossible to say whether they were leptospira or whether the spirochaetes were the causal organisms.—Dr. LAIT said he had examined specimens from this case and had not found any spirochaetes. He thought it possible, however, that they might have been present, but was confident that there were no leptospira.—Dr. W. H. ASHMORE mentioned the possibility of the case being one of metallic poisoning, and asked if the organs had been examined for arsenic.

Dr. O'CONNOR referred to a case reported by V. de Lavergne² of a man who fell into a ditch, and a few days later developed well-marked jaundice and epistaxis and complete anuria. In this case it was proved that the man had not swallowed any virus, and infection must have been via a scalp wound 16 days old.

Dr. NESBITT, in replying, said he had thought of arsenical poisoning, but no evidence of arsenic had been found in the organs examined. He thought the organs would have shown more damage histologically if it had been a case of arsenic poisoning. Patients with spirochaetal jaundice were usually said to suffer from diarrhoea, but his patient had obstinate constipation.

Dr. LEONARD ABRAHAMSON showed a patient suffering from myelogenous leukaemia.

Reviews and Notices of Books.

RHEUMATISM.

Arthritis and Rheumatoid Conditions. By RALPH PEMBERTON, M.S., M.D., Physician to the Presbyterian Hospital, Philadelphia; Associate Professor of Medicine in the Graduate Medical School of the University of Pennsylvania; Chairman of the American Committee for the Control of Rheumatism. London: Baillière, Tindall and Cox. 1929. Pp. 354. 25s.

THIS book will prove of great value to all wishing to become familiar with recent work on rheumatoid conditions and arthritis. The treatment of these diseases has too long been a fruitful field for the unqualified practitioner, and the whole subject needs to be thoroughly investigated and placed on a more scientific basis; this Dr. Pemberton and his associates have attempted to do, and in as far as our present state of knowledge allows they have been successful. Especially interesting is the section named rather oddly "dynamic pathology," which is the study of the nature of the disturbances in the normal physiology in early stages of arthritis. The importance of this line of investigation is self-evident and the work on sugar metabolism, capillary circulation, and the constitution of the synovial fluid is of great significance from the point of view of aetiology and treatment. Physiotherapy will no longer merit the reproach of being an empirical form of treatment if these careful researches reveal that the general beneficial results can be explained by its effects on the biochemistry of the blood and on the circulation. The work already done demands the abandonment of several popular theories, such as the supposed rôle of lactic and uric acid in these diseases. The

proper treatment of arthritis is, as the author says, one of the most involved chapters in modern medicine, and this book should help to clear the way.

Der Sogenannte Rheumatismus. By Dr. JULIUS BAUER, Professor an der Universität Wien. Dresden and Leipzig: Verlag von Theodor Steinkopff. 1929. Pp. 136. M.10.50.

THE purpose of this little book is to summarise for the benefit of the general physician the most significant work that has been done of recent years on the so-called rheumatic conditions. The localisation, pathology, anatomy, and aetiology of the different manifestations are first discussed, then each type is described separately, together with appropriate therapeutic measures; particularly those the author has from personal experience found of value. In discussing the aetiology of primary chronic arthritis Dr. Bauer says that the streptococcus which can occasionally be isolated from the joint and can in 90 per cent. of cases be found in the gut wall, on intravenous injection into a rabbit, produce a non-suppurative arthritis; on the other hand, the strain found in the tonsils and the teeth will not produce typical joint changes. He makes the observation that a positive blood culture in these cases can only be obtained in autumn and winter, never in summer or spring. In our experience a positive blood culture in chronic arthritis is very rare. In the treatment of acute rheumatism Dr. Bauer considers sodium salicylate as good or better than any of the modern preparations, and in order to avoid upsetting the stomach with the large doses he finds necessary, part is given twice daily per rectum and the rest by the mouth. Iodine he finds of value in both specific and non-specific joint affections; it is given intravenously and may be injected directly into the joint. This book can be strongly recommended. It is relatively short and is easy to read.

MODERN TREATMENT OF DISEASES OF THE THROAT, NOSE, AND EAR.

By H. LAWSON WHALE, M.D. Cantab., F.R.C.S. Eng., Surgeon to the Special Department at the Hampstead General Hospital. London: Jonathan Cape. 1930. Pp. 128. 5s.

THIS little book is one of a series on Modern Treatment, so planned that the general practitioner should be able to acquire for a small price, and to keep at his elbow or in his pocket reliable guides to the present state of opinion and practice in some of the special branches of medicine and surgery. Mr. Lawson Whale has made a brave attempt to cover an enormous field within the limits of 128 small pages, and the bibliography at the end of each chapter will be of use to those wishing to go more thoroughly into any particular detail. Written on a strongly personal note, the book makes interesting and amusing reading.

CANCER OF THE LARYNX.

Treatment of Intrinsic Cancer of the Larynx and Hautant's Method of Hemilaryngectomy. By MARCEL OMBRÉDANNE, Assistant in the Otolaryngological Department of the Tenon Hospital. Paris: Masson et Cie. 1930. Pp. 135. Fr.25.

Dr. Hautant's experience of intrinsic cancer of the larynx has not been entirely, or even principally surgical, for most of the 200 cases which have come under his observation during the last ten years have been treated by radiotherapy at the Curie Institute. He has, however, in the last four years treated 65 cases by operation, and has elaborated a technique which Dr. Ombredanne, his assistant and former resident, describes in the present work. The author, therefore, takes a wider standpoint than that of purely surgical intervention, and we have not seen a better résumé of the present position of the treatment of endolaryngeal cancer than that contained

² Bull. et mém. Soc. méd. des hôp. de Paris, 1928, III., 1498.

in the preliminary chapters of this book. The result of treatment by X rays and by radium is discussed, as well as those of the operations of laryngotomy and laryngectomy. The experiences are detailed of the more prominent exponents of these methods throughout the world, and a very complete bibliography is appended. Though the author is not dogmatic, his point of view may be summed up as follows. Radiotherapy is giving very good results, but it is at present impossible to foresee the effect of this treatment in individual cases and therefore surgery still remains our principal weapon, especially in cases of epithelioma of the cutaneous or intermediate types. Laryngotomy is achieving better results than formerly, largely because the indications for operation are more strictly formulated, and cases are no longer considered operable when the arytenoid is even slightly swollen or the anterior wall of the pyriform sinus a little bulged. On the other hand, laryngotomy has extended its sphere, largely under the influence of St. Clair Thomson in England, to include cases involving the anterior commissure and the subglottic region, and has indeed become a kind of internal hemilaryngectomy.

Under these circumstances Dr. Hautant believes that there is scope for an intermediate operation of the type of hemilaryngotomy which Dr. Ombrédanne here describes minutely with the assistance of a series of excellent drawings. The chief features of this operation are that the section through the thyroid cartilage is made a little to the sound side of the anterior commissure; the anterior part of the cricoid on the diseased side is resected and the posterior two-thirds of the thyroid ala are spared, the anterior third being removed in one piece with the growth. Posteriorly, the section is made through the body of the arytenoid cartilage; the posterior wall of the larynx, forming the interarytenoid curtain, is not removed; the lumen of the larynx is not opened until the last stage of the operation; the cavity is packed until the fourth day, and the patient is able, and encouraged, to drink immediately after the operation. The tracheotomy tube is removed at the end of three weeks, but a permanent cannula has been necessary in the only two women submitted to operation. The author is of opinion that cases with invasion of the anterior commissure or subglottic region, too extensive for the operation of laryngotomy, can be treated by this method with far better functional results than can be obtained by laryngectomy. Well and clearly written, this little book should be read by all interested in the treatment of cancer of the larynx.

SOME ASPECTS OF THE CANCER PROBLEM.

Edited by W. BLAIR BELL, B.S., M.D. (Lond., F.R.C.S. Eng.), Director of the Liverpool Medical Research Association. London: Baillière, Tindall and Cox. 1930. Pp. 543. 6s.

Prof. Blair Bell has undertaken a considerable task in editing this comprehensive collection of papers on the cancer problem. Most of them have appeared in the medical press at various times, and many of them were originally published in *THE LANCET*. The book links up the various steps in the development of lead therapy from its inception in 1920 to its present interesting but still indecisive position. The earlier papers are chiefly concerned with the theory of the similarity between malignant cells and chorionic epithelium, which gave rise to the use of lead as a therapeutic agent, and with the nature of cancer, viewed as a specific process, rather than as the consequence of a specific cause. Reports on a number of elaborate biochemical investigations of the normal and the malignant cell membrane follow, with reference to their permeability, and a series of papers on the hydrogen-ion concentration of the blood and tissues in normal persons, cancer patients, and fetal rabbits. Some inferences are drawn from experiments showing similar metabolic behaviour in chorionic epithelium and malignant

tissue, and the effects of metallic salts on the metabolism of various tissues are discussed, with especial reference to the action of lead. Several papers follow on the effects of lead on growth in plants and animals, and some detailed work on its action on the chorion and on cancer cells; various preparations of lead, their fate in the body, and their toxicity are discussed. The final chapters include papers on the treatment of cancer with lead, and the present position of lead therapy, followed by a detailed series of cases in which the treatment has been used. In some of these the results appear to have been inconclusive, in some it is still too early to draw definite inferences, but there remain a proportion in which lead therapy appears to have produced a temporary or permanent benefit. The book ends with a brief summary of the position—too brief perhaps to convey a balanced idea of the whole; indeed, the book itself, in spite of the paragraphs connecting the reprints is rather incoördinate. But it provides a valuable aggregate of the literature on lead therapy which has emanated from the Liverpool school.

MICROSCOPIC PHARMACOLOGY.

By WILLIAM MANSFIELD, A.M., Phar.D., Ph.G., Dean and Professor of Botany and Materia Medica, Union University, Albany College of Pharmacy, Albany, N.Y. London: Chapman and Hall, Ltd. 1929. Pp. 211. 15s.

AN essential part of the training of the student of pharmacy is in the technique of examining powdered drugs by the microscope, so that he may become familiar with the cellular structure and cell contents of the different parts of plants in common use. In this text-book, designed for such students, the author has selected typical drugs in order to include practically every type of cell to be found in the official pharmacopœias, and has illustrated every part of the description with numerous drawings drawn to scale. The reader is thus offered a pictorial as well as a written description of each drug. The book should prove of value to students of pharmacy, and will be appreciated as a handy work of reference by pharmacists and drug analysts.

HOW TO STAIN THE NERVOUS SYSTEM.

By J. ANDERSON, Head Laboratory Assistant at the National Hospital for Diseases of the Nervous System, London. Edinburgh: E. and S. Livingstone. 1929. Pp. 139. 5s.

THIS excellent manual of staining methods should be of value to the general as well as the special histologist. Among many useful stains, two, tested by the reviewer, may be specially recommended. The one gives directions for ripening carmine solutions, and has been found satisfactory on dye from six different sources; the second is a counter-stain and mordant for nuclei to be used with Mallory's aniline-blue-orange-G. Its constituents are at hand in any laboratory, and the difficulty of nuclear staining is overcome without recourse to azan.

DISEASES TRANSMITTED FROM ANIMALS TO MAN.

By T. G. HULL, Chief Bacteriologist, Illinois Department of Public Health. London: Baillière, Tindall and Cox. 1930. With 29 text figures. Pp. 350. 25s.

IN 1796 Jenner wrote "the deviation of man from the state in which he was placed by nature seems to have proven to him a prolific source of diseases. From the love of splendour, from the indulgences of luxury, and from his fondness for amusement, he has familiarised himself with a great number of animals, which may not originally have been intended for his associates." And in this book Dr. Hull gives a straightforward satisfying account of the consequences of man's interference with the order of nature, and details the various human diseases

in the causation and transmission of which the higher animals play an essential or substantial part. Most of the information is not difficult to come by in other books, but it is convenient to have it put together in this form, especially perhaps for veterinarians.

PARENTHOOD: DESIGN OR ACCIDENT?

Second edition. By MICHAEL FIELDING. Introduction by H. G. WELLS. London: Noel Douglas. 1930. Pp. 168. 3s. 6d.

THIS is a revised and enlarged edition of the book that was reviewed in our columns two years ago. "Michael Fielding" is a pseudonym; the author is a medical man who wishes to remain anonymous. This edition has been brought thoroughly up to date, and will prove of much value, not only to the couple wanting information on the control of conception, but also to the medical practitioner desirous of knowing what research is being done on the subject, and what the prospects are of improving the existing methods. A valuable chapter on "Methods of the Future" includes accounts of temporary sterilisation by spermatoxins, hormones, and X rays, and of some of the researches of the Birth Control Investigation Committee. An excellent description of the recently popularised German spermaticides includes a short note on some of the findings of Dr. J. K. Baker with regard to the comparative spermaticidal power of soluble pessaries on the market. The book fully bears out the introductory remark of Mr. H. G. Wells, who says: "It is at once the most exact, plain and unexciting handbook on these intimate mysteries that I have ever

read." It is, moreover, impartially written. Upon the relative value of different contraceptive methods, and upon the general satisfactoriness and reliability of these methods—which are more and more being called into question—the author writes objectively and without bias. The book is unique of its kind, and can be warmly recommended to medical readers.

THE SEX FACTOR IN MARRIAGE.

By HELENA WRIGHT, M.B., B.S. Introduction by Rev. HERBERT GRAY, M.A. London: Noel Douglas. 1930. Pp. 100. 3s. 6d.

THE reader is informed in the introduction that this book "is addressed to those about to be married in the hope that it may save them from mistakes and sufferings which have darkened married life for thousands of couples." It contains six chapters on the sexual side of marriage, the nature of the sex act, the sex organs of men and women, difficulties in early marriage, the perfect sex act, and finally, a chapter entitled "Other practical issues." The volume is prefaced by a quotation from the Archbishop of Canterbury, in which freedom of discussion on sexual matters is demanded, and it stresses throughout the spiritual side of marriage. From this, it must not be inferred that the physical aspects of the relation are glossed. On the contrary, they are described in detail, and the comprehension of the layman is aided by familiar diagrams of the genital organs.

Though it may be thought by some that too much stress is laid on processes of genital manipulation, the book can safely be recommended by medical men to those about to get married who ask for advice.

New Inventions.

A TRACTION FRAME FOR FRACTURES OF THE LEG.

I HAVE had made a portable extension apparatus (shown in the illustrations) which may prove useful in such hospitals as are not equipped with special orthopaedic facilities. It presents the following advantages: (1) It is simple and quick to adjust. (2) Although possessing enormous power, any degree of extension can be provided without effort, as

The traction frame attached to an operating table.

gradually and as gently as desired, in order to overcome muscular contraction without unnecessary damage to the soft parts. (3) If open operation is required the actuating mechanism is distant from the site of the wound. The desired result is obtained with less disturbance of the periosteum and the neighbouring tissues than is inevitably produced by powerful manipulation with forceps, or by turning the ends of the bone out of the wound, in the attempt to engage the fragments in shoe-horn fashion. It should be readily adaptable to any ordinary type of operating table.

The suggestion is not made that this apparatus should take the place of preliminary extension by ordinary methods, but the frame offers certain facilities for operative work, particularly in the case of malunited fractures with muscular retraction. Under such circumstances it is simple and positive in use. The extension is applied through the medium of a leather ankle, which is attached by a hook to a flexible steel cable. Where it is desired to maintain only a moderate degree of extension to enable the limb to be encased in plaster, the ankle may be made of coarse flannel, this being incorporated in the splint. Counter extension is provided by a perineal post or by perineal bands attached to the head of the table. The apparatus consists of the usual zinc top mounted upon a frame which is attached to the foot of the operating table. In the case of the Quadrant Model table, the traction frame has been made of sufficient length to temporarily replace the normal leg-rest. The mechanical extension is by screw gear controlled by a crank at the far end. The cable passes over two pulleys and it is so guarded that it cannot leave the wheels when in action. The end of the cable is fixed to a slide block working on an endless screw. The complete gear is carried on parallel tubular bearings to afford sufficient lateral adjustment for a direct pull on either leg. Ratchet wheel or other retaining device is not required since no degree of tension will cause the crank to unwind when released from the hand; this retains its position until deliberately reversed. The whole of the gear is so arranged that it is situated under or at the far end of the table. The legs which are adjustable for height are made to fold and the perineal post is detachable.

The frame is made by Messrs. Down Bros., St. Thomas's-street, London, S.E.

NORMAN FLOWER, M.B., B.Ch. Ox.

The traction frame folded.

LANCET.

WEDNESDAY, JUNE 7, 1930

ITS FROM THE UNITED
V
TATES.

be appended to the report of the General Medical Council elsewhere; they deal with the work which has been created, especially in the last three years, by the application of the new standards for admission to British universities, and the consequent intention to raise the standards of qualifications. The matter was discussed by Sir DONALD MACALISTER in his address to the Council, when that body elected him President that in some of his applications exceeded the requirements of the home, thus compelling the Council to take into the educational standards they should be inferior to those of British students. The Council has also considered the General and Foreign Students' report of that Committee, and the views expressed by Sir NORMAN WALKER, President of the Council, the difficulties of the situation, and these are so real and so pressing that it will do well on both sides to

[illegible]

their foundation, down to the crudest degree-shops where, in return for so many dollars and the production of a thesis (which might or might not have been written by the man who signed it) a degree in medicine or philosophy or what not could be obtained. A crusade of vigorous reform, steadily carried on in America during the last 15 years or so, has been extremely creditable to the energy of the reformers, who often have had the bitterest opposition from interested corporations or wealthy individuals. The result of this process of cleaning-up has been severe pressure upon medical schools attached to the great universities, and it is from the western and middle-western centres of education that those who are unable to carry through the medical curriculum in the States look for accommodation in British institutions. Where the clinical education has not started, but a satisfactory standard from the American point of view has been reached in the ancillary subjects, the British schools are unable to ascertain exactly what that standard has been, or what any particular American high school may demand as a reasonable grounding in biology, chemistry, and physics. This information cannot be obtained categorically from a country where the examination system, as we here understand it, has no existence, yet the General Medical Council, with a certain responsibility for the instruction of British medical students in these subjects, must feel the same responsibility in relation to all students where the object is to obtain a place on the British Register. In the case of students who, having been accepted as sufficiently proficient in these ancillary subjects for admission to an American school, and who seek to continue their education in this country, the procedure is even more delicate. For these students, or many of them, have proved themselves, for this or that reason, unwanted in their American schools, being in the odd position of an honourable suspension. This curious plight is reached by a student who fails to satisfy instructors from year to year sufficiently to obtain promotion from one course of studies to another course of studies, until the position is reached when he or she cannot proceed with the curriculum. The students are examined by their teachers, promoted, deferred, or weeded out, and in the main it is those who have been much deferred who apply to the British schools.

In Sir NORMAN WALKER's memorandum, the close of which will be found on page 1262 of this issue of THE LANCET, the extreme inconvenience which may result from this situation is set out very clearly ; on the one hand, the British schools do not want to earn the reputation of taking in and qualifying those whom the American universities have found unsuitable, nor on the other hand can they continue to irritate American centres of education by providing a portal for qualification which can be entered with shorter preparation than is demanded in the United States. The brevity of the British course is one of appearance only as far as science is concerned, and is due to the pattern of the high-school examinations ; but it exists, and creates a situation which has to be dealt with, as the new regulations of the English Conjoint Examination Board appear to recognise.¹ The various documents published this week by the General Medical Council show that mutual arrangement between the educational authorities of the two countries is needed, while the evidence is complete that there is every intention on both sides to reach complete accord.

THE CHLORINATION OF WATER.

CHLORINATION has long been known as a means of deodorising sewage-polluted streams or, with more success, for sterilising drinking water. ROSCOE treated the polluted Thames with bleaching powder, but a study of the rather conflicting evidence leaves it doubtful whether he did much good. In 1905 HOUSTON arrested the development of an epidemic of typhoid in Lincoln by chlorinating the drinking water. During the late war chlorination was largely used as a means of rendering all kinds of contaminated water safe to drink, a technique being devised for the employment either of bleaching powder or liquid chlorine. Since that time chlorination has passed into the routine of many water undertakings, and the shortcomings of the process have been revealed; fortunately the appropriate remedies have in the main also been found. The vast literature of the subject has been reviewed in a conveniently brief sketch by Mr. J. H. COSTE, reprinted from the annual report¹ of the Society of Chemical Industry. From this it appears that chlorination has again been taken up as a treatment for sewage, ancillary to the main processes of purification. The original idea underlying the use of chlorine was its action as an oxidiser, combining with the hydrogen of water, and thus liberating nascent oxygen. But the use of a chemical oxidiser for sewage, when there is available the large and gratuitous supply of oxygen in the air, seems unsound; to be effective enormous quantities of reagent would be required, and the resulting hydrochloric acid might have inconvenient results. Sterilisation of crude sewage is not desirable, as it is better for biological action to reach its utmost useful degree of purification in the works rather than in the diluting stream. Chlorine has however been applied with some success in retarding anaerobic action in long sewers with few branches and a relatively slow flow, when the sewage is fresh enough to form chloro-compounds which have a small but definite sterilising action, sufficient to delay the production of unpleasant odours. Chlorine will, of course, oxidise sulphuretted hydrogen, but it does not seem economical to use it so; it is better not to let H₂S form. The dosage for deodorisation or the prevention of odour is large—up to 20 parts per million. Chlorine has also been found useful for reconditioning filter beds which have become offensive and inactive, and for sterilising final effluents. For the latter purpose the dose must be carefully regulated, or the fish which it is desired to protect from sewage may be killed by chlorine. Judicious use of chlorine may enable sewage works which are reaching their limit of capacity to carry on without extension.

The dose of chlorine required in the treatment of drinking water is much smaller than that used for sewage, and it may be still further kept down by letting suspended matter settle and allowing such self-purification as the capacity of the works and the through-put of water may necessitate. HOUSTON has found that previous chlorination lowers the cost of filtration, but chlorination is apt to lead to the iodoform-like taste which consumers strongly dislike and believe to be unwholesome. In the United States of America the ill-taste is ascribed to chlorophenol, and in some cases, where the staves of wooden pipes have been creosoted or washings from tarred roads get into streams, this ascription may be sound.

B. A. ADAMS has shown in our own columns that water-side plants such as willows, alders, and meadow-sweet are likely to yield salicylic derivatives to water flowing past them. Whatever their cause, tastes must be removed if consumers are to be kept contented, and means of doing this have been found. In his last report HOUSTON states that about two million people have (with intermissions due to floods) been supplied with chlorinated water since May, 1916, without any complaint. He has used ammonium sulphate to prevent the production of taste by forming chloramines, and permanganate which may be presumed to oxidise the taste-producing substances; in some cases the latter has given rise to a brown discoloration of colloidal manganese which has led to its abandonment. L. H. ENSLOW, at Toronto, has had success with sulphur dioxide; activated carbon and other sulphur-containing reducing agents have been found effective. A by-product of this work has been the discovery of means to detect and estimate free chlorine and the less active chloramines. Orthotolidine, although a favourite reagent for the purpose, cannot be regarded as specific as it gives a colour with nitrous acid similar to that produced by chlorine; the old test with potassium iodide and starch still retains its popularity. Naphthoflavone, the basis of *Chloritest* Kahlbaum, depends on the use of iodide to produce the blue colour, and seems to have no advantage over starch and iodide.

Any discussion of the action of chlorine on water would be incomplete without an allusion to the chlorination of public bath water, a practice advocated in the pioneer stage by that fearless veteran, Dr. F. W. ALEXANDER. The advantage of clear, sterile water as obtained when chlorination follows filtration, has been set out in the recent monograph² on swimming baths by H. T. CALVERT, J. A. GLOVER, and E. A. S. FAWCETT. Chlorination is not a panacea, and SPITTA has wisely pointed out that it should supplement, not replace, the ordinary precautions: a good source of supply and reasonable purification. Chlorination alone might lead to a sense of security which any breakdown would rudely shatter. Nevertheless chlorine appears to have a specific purifying action.

CARE OF THE EYES IN CHILDHOOD.

WITH certain exceptions the diseases to which the eyes of children are liable are to a great extent avoidable. The exceptions are congenital defects, inherited constitutional diseases, and the ophthalmia of the new-born, the effects of which sometimes persist. Even the infective conjunctivitis which occasionally assumes epidemic form in schools could be in large measure prevented by insistence on a rigid hygiene in the matter of towels. Blepharitis is commonly conveyed to the follicles of the eyelids by dirty fingers. Phlyctenular disease, which seldom attacks well-to-do children, owes its origin to the absence of good and sufficient food. Even more important than such external conditions are those that directly affect the sight. These are mainly two, squint and myopia. Internal squint is still too frequent in children of school age, who, when tested, are found to be partially or completely amblyopic in the squinting eye. There has certainly been an improvement in this respect since the establishment of efficient medical inspection in public elementary schools, but

¹ Reports of the Progress of Applied Chemistry, 1929, xiv., 635.

² Ministry of Health Special Report No. 32, 1929.

the mischief is often done before the age of compulsory attendance, and among the well-to-do there are still many mothers who look upon a squint as a trivial complaint out of which the child will grow. They are unaware that, unless appropriate measures are taken, by the time the child has grown out of the squint he may also have grown out of the power of using his affected eye. During the only time in his life when it is possible for him to acquire the power of correctly interpreting the images which fall upon the retina it has been impossible for him to do so, and the unused eye has become more or less blind. With regard to myopia, there are cases in which, from hereditary or unknown causes, children become highly myopic at a very early age, but these are comparatively rare, and the defect in vision is so obvious to the mother that they are not likely to remain untreated. Far commoner are cases where a child is born with a predisposition to myopia, or with an astigmatic defect which, from about the time he begins to learn to read, causes him to acquire the bad habit of excessive convergence in order to obtain clear images. The result is an abnormal lengthening of the anterior-posterior axis of the eyes which comes on insidiously. Sometimes mere stooping over lessons may induce this stretching of the eyeball, even without the excuse of astigmatism.

Mr. C. H. BRYANT, who addressed the last meeting of the Brighton and Sussex Medico-Chirurgical Society on the common-sense care of eyes, suggested that the excessive looking at picture books by young children when in the nursery stage is a responsible factor in the production of myopia. This would, we think, only be the case with those infants who have a strong hereditary predisposition to myopia, and it would be a pity to debar normal children from what is, after all, a normal means of educating both eye and brain. The habit of stooping should certainly be checked. In any case, if a child's sight should appear to be weak the eyes should be examined under a mydriatic, when any tendency to myopia would be discovered and appropriate measures taken. From this point of view the establishment of nursery schools with medical inspection is highly desirable. Careful judgment is called for on the part of the doctor in deciding whether or not the constant wearing of glasses is to be insisted on. In the case of the myope, however slight the degree of error, it is probably wise to do so, as this is the most practical method of preventing its increase. That the glasses should be worn for near work is especially important, and this should be explained to the parent who will remark that as far as the child's sight goes the glasses only improve distant vision and not near. In the case of simple hypermetropia, the constant wearing of glasses is only called for in the higher degrees where the distant as well as the near vision is improved by them. In moderate degrees where the child can easily neutralise his hypermetropia by means of his accommodation, it will be sufficient for him to wear glasses for near work or during school hours. In low degrees, or degrees which are low in relation to the age of the child, he will probably be quite as well without glasses at all. When a child's visual acuity is imperfect, and the only defect discoverable is the existence of one or two dioptries of simple hypermetropia, we judge that his accommodation is weak owing to some temporary cause connected with his general health, and it is better to have this put right rather than to prescribe glasses. In the case of astigmatism the decision is not always easy. Considerable degrees, of course, need the constant wearing of glasses and so does any degree

of myopic astigmatism. In the case of low degrees of hypermetropic astigmatism, in which the acuity for distance is not materially affected, it will be sufficient in most cases to prescribe correcting glasses for near work, in order to prevent the change from hypermetropic to myopic astigmatism; but there are cases in which even low degrees of astigmatism in children cause symptoms of headache or eye-strain, and these call for the constant wearing of glasses.

Annotations.

"Ne quid nims."

THE BIRTHDAY HONOURS.

THE following is a list of the Birthday Honours as far as they relate directly to the medical profession. No medical names are among the new peers or baronets.

Knights.

Norman Godfrey Bennett, M.B., B.Ch., L.D.S., President of the British Dental Association.

Harold Delf Gillies, C.B., F.R.C.S., Major, R.A.M.C. (retd.), Chief Plastic Surgeon to the Ministry of Pensions.

Prof. Leonard Erskine Hill, M.B., F.R.S., Hon. A.R.L.S.A., Director, Department of Applied Physiology, National Institute of Medical Research.

Thomas Eustace Hill, O.B.E., M.B., B.Sc., F.I.C., lately Medical Officer of Health in the County of Durham.

Khan Bahadur Behramji Hormasji Nanavati, C.I.E.
John Randall Phillips, O.B.E., M.B., President of the Legislative Council, Barbados.

K.C.B. (Military Division).

Surgeon Vice-Admiral Arthur Gaskell, C.B., O.B.E., F.R.O.S., D.P.H., K.H.S.

Air Vice-Marshal David Munro, C.B., C.I.E., M.B., Ch.B., F.R.C.S. (Royal Air Force, Retired).

C.M.G.

Major Gerald Joseph Keane, D.S.O., M.D., Director of Medical and Sanitary Services, Uganda Protectorate.

Herbert Chavasse Squires, M.D., Director, Khartoum Civil Hospital.

C.I.E.

Major-General Godfrey Tate, I.M.S.; Surgeon-General to the Government of Bengal.

Lieut.-Colonel William Jackson Powell, I.M.S., Inspector-General of Prisons, Central Provinces.

Lieut.-Colonel Hugh Reginald Dutton, I.M.S., lately Principal, Prince of Wales' Medical College, Patna.

M.V.O.

Clifford Viney Braimbridge, F.R.O.S.

C.B.E. (Military Division).

Wing-Commander Harold Edward Whittingham, M.B., Ch.B., F.R.F.P.S. Glasgow.

O.B.E. (Military Division).

Major John Hare, M.D., F.R.F.P.S., R.A.M.C.

Lieut.-Colonel James Alfred Seymour, T.D., The Army Dental Corps.

O.I.E. (Civil Division).

John Rhodes Dickson, M.B., Deputy-Surgeon-General and Medical Inspector of Health, Colony of Trinidad and Tobago.

Lieut.-Colonel William Clayton Smiles, D.S.O., R.A.M.C., lately Medical Officer of Health, Gibraltar.

Miss Alexandrina Matilda Macphail, L.R.C.P., Superintendent, Rains Hospital, Madras.

Hon. O.B.E.

Abdul Al, Medical Officer, Hebron.
Saleman, Saleman, Medical Officer, Jerusalem District. These honorary distinctions were awarded for services during the disturbances in Palestine in August, 1929.

Kaisari-i-Hind Medal.

Miss Eleanor Isabel Dodson, L.S.A., in charge of the Church Missionary Society Zenana Hospital, Multan, Punjab.

THE CHLORINATION OF WATER.

CHLORINATION has long been known as a means of deodorising sewage-polluted streams or, with more success, for sterilising drinking water. ROSCOE treated the polluted Thames with bleaching powder, but a study of the rather conflicting evidence leaves it doubtful whether he did much good. In 1905 HOUSTON arrested the development of an epidemic of typhoid in Lincoln by chlorinating the drinking water. During the late war chlorination was largely used as a means of rendering all kinds of contaminated water safe to drink, a technique being devised for the employment either of bleaching powder or liquid chlorine. Since that time chlorination has passed into the routine of many water undertakings, and the shortcomings of the process have been revealed; fortunately the appropriate remedies have in the main also been found. The vast literature of the subject has been reviewed in a conveniently brief sketch by Mr. J. H. COSRE, reprinted from the annual report¹ of the Society of Chemical Industry. From this it appears that chlorination has again been taken up as a treatment for sewage, ancillary to the main processes of purification. The original idea underlying the use of chlorine was its action as an oxidiser, combining with the hydrogen of water, and thus liberating nascent oxygen. But the use of a chemical oxidiser for sewage, when there is available the large and gratuitous supply of oxygen in the air, seems unsound; to be effective enormous quantities of reagent would be required, and the resulting hydrochloric acid might have inconvenient results. Sterilisation of crude sewage is not desirable, as it is better for biological action to reach its utmost useful degree of purification in the works rather than in the diluting stream. Chlorine has however been applied with some success in retarding anaerobic action in long sewers with few branches and a relatively slow flow, when the sewage is fresh enough to form chloro-compounds which have a small but definite sterilising action, sufficient to delay the production of unpleasant odours. Chlorine will, of course, oxidise sulphuretted hydrogen, but it does not seem economical to use it so; it is better not to let H_2S form. The dosage for deodorisation or the prevention of odour is large—up to 20 parts per million. Chlorine has also been found useful for reconditioning filter beds which have become offensive and inactive, and for sterilising final effluents. For the latter purpose the dose must be carefully regulated, or the fish which it is desired to protect from sewage may be killed by chlorine. Judicious use of chlorine may enable sewage works which are reaching their limit of capacity to carry on without extension.

The dose of chlorine required in the treatment of drinking water is much smaller than that used for sewage, and it may be still further kept down by letting suspended matter settle and allowing such self-purification as the capacity of the works and the through-put of water may necessitate. HOUSTON has found that previous chlorination lowers the cost of filtration, but chlorination is apt to lead to the iodoform-like taste which consumers strongly dislike and believe to be unwholesome. In the United States of America the ill-taste is ascribed to chlorophenol, and in some cases, where the staves of wooden pipes have been creosoted or washings from tarred roads get into streams, this ascription may be sound.

B. A. ADAMS has shown in our own columns that water-side plants such as willows, alders, and meadow-sweet are likely to yield salicylic derivatives to water flowing past them. Whatever their cause, tastes must be removed if consumers are to be kept contented, and means of doing this have been found. In his last report HOUSTON states that about two million people have (with intermissions due to floods) been supplied with chlorinated water since May, 1916, without any complaint. He has used ammonium sulphate to prevent the production of taste by forming chloramines, and permanganate which may be presumed to oxidise the taste-producing substances; in some cases the latter has given rise to a brown discoloration of colloidal manganese which has led to its abandonment. L. H. ENSLOW, at Toronto, has had success with sulphur dioxide; activated carbon and other sulphur-containing reducing agents have been found effective. A by-product of this work has been the discovery of means to detect and estimate free chlorine and the less active chloramines. Orthotolidine, although a favourite reagent for the purpose, cannot be regarded as specific as it gives a colour with nitrous acid similar to that produced by chlorine; the old test with potassium iodide and starch still retains its popularity. Naphthosulfone, the basis of *Orthotest* Kahlbaum, depends on the use of iodide to produce the blue colour, and seems to have no advantage over starch and iodide.

Any discussion of the action of chlorine on water would be incomplete without an allusion to the chlorination of public bath water, a practice advocated in the pioneer stage by that fearless veteran, Dr. F. W. ALEXANDER. The advantage of clear, sterile water as obtained when chlorination follows filtration, has been set out in the recent monograph² on swimming baths by H. T. CALVERT, J. A. GLOVER, and E. A. S. FAWCETT. Chlorination is not a panacea, and SPITTA has wisely pointed out that it should supplement, not replace, the ordinary precautions: a good source of supply and reasonable purification. Chlorination alone might lead to a sense of security which any breakdown would rudely shatter. Nevertheless chlorine appears to have a specific purifying action.

CARE OF THE EYES IN CHILDHOOD.

WITH certain exceptions the diseases to which the eyes of children are liable are to a great extent avoidable. The exceptions are congenital defects, inherited constitutional diseases, and the ophthalmia of the new-born, the effects of which sometimes persist. Even the infective conjunctivitis which occasionally assumes epidemic form in schools could be in large measure prevented by insistence on a rigid hygiene in the matter of towels. Blepharitis is commonly conveyed to the follicles of the eyelids by dirty fingers. Phlyctenular disease, which seldom attacks well-to-do children, owes its origin to the absence of good and sufficient food. Even more important than such external conditions are those that directly affect the sight. These are mainly two, squint and myopia. Internal squint is still too frequent in children of school age, who, when tested, are found to be partially or completely amblyopic in the squinting eye. There has certainly been an improvement in this respect since the establishment of efficient medical inspection in public elementary schools, but

¹ Reports of the Progress of Applied Chemistry, 1929, xiv., 635.

² Ministry of Health Special Report No. 32, 1929.

interment and had fired over the grave. It was identified by the hair which yet remained and by the teeth, all of which were still in their sockets except one which had been lost during life. Head, trunk, and limbs were entire, so that the stature could be measured. The chest had fallen in and the heart and lung tissues had become blended together, presenting the appearance of a dark oleaginous substance. The whole was without smell. The entire trunk was then removed—the head and extremities being regarded as unnecessary to the investigation. The portion reserved for examination weighed nine pounds, of which two pounds were set aside for a second set of experiments lest those made on the first should prove unsatisfactory. In the investigation, Drs. Ozinam and Ide proceeded on the supposition that arsenic was the poison.

The matter was first boiled, and the fluid therefrom evaporated to dryness, the residuum thus obtained being dissolved in distilled water. This produced a deep-coloured liquid which, treated with chlorine, was but imperfectly deprived of its colour. The distilled water charged with this extract from the remains was again evaporated to dryness, and four ounces of potassium nitrate, placed in a matras, were exposed on ignited charcoal. The suspected matter well-dried and after rolling it into little portions, was introduced. Each time this was done a deflagration was produced and perceived. It was now allowed to cool and the residue was again dissolved in distilled water. This resulting solution was now saturated with nitric acid and afterwards subjected to the usual reagents, all of which indicated the presence of arsenic. Some small portions were treated with vegetable charcoal introduced into a glass tube and then heated. This gave off aqueous vapour at first, soon after which small grey-coloured and brilliant points were seen. A grain of metallic arsenic was thus obtained. Another portion treated with hydro-sulphuric acid furnished sulphuretted of arsenic and this, when heated and acted upon by caustic potash, afforded a portion of shining matter which was easily dissolved in distilled water by directing upon it a current of oxygen gas.

By these various experiments the fact of a considerable quantity of arsenic having been administered seven years earlier was demonstrated. From the ability of witnesses to recognise the features after seven years' burial it is clear that the preservative effect of the arsenic had been remarkable. Since that time other cases have established this effect, which has long been recognised by medico-legal writers. Instances are given in the text-books of Dixon Mann and R. J. M. Buchanan, while J. Glaister cites in detail the appearance of the victims of Flannagan and Higgins who were tried at Liverpool in 1884. By reason of arsenical poisoning having been established in one of the three victims, the bodies of two others—Mary Higgins, aged 10, and John Flannagan, aged 24—were exhumed and examined. Although the body of the former had been buried for about 13½ months, and that of the latter for 37½ months, both were found to be in an excellent state of preservation: indeed, in the case of John Flannagan, the face and body generally could easily be identified. The abdominal organs of Mary Higgins were found on analysis to contain one grain, and those of John Flannagan, 3½ grains of arsenious acid. Another noteworthy appearance found after burial in the stomach and intestines of the bodies of those to whom arsenic has been administered and which, moreover, was also observed in the bodies of the above-named individuals, is a golden-yellow pigment or coating of the mucous membrane. It has been contested whether this yellow pigment is composed of arsenic sulphide or of yellow bile-pigment. Campbell Brown and Davies analysed the pigment in these cases and found that it did not contain any appreciable amount of arsenic, but chiefly consisted of bile-pigment. On the other hand, Littlejohn and Drinkwater have recorded two cases of poisoning with arsenious acid in which the yellow sulphide was found in the alimentary canal. Like preservative effects on the bodies of victims of poisoning by antimony are also well established. The account of the exhumed bodies in the Chapman or Kłowski case in London (1903) by the late Sir Thomas Stevenson,

abundantly shows this. Similar effects had been previously noted in the case of Palmer in 1850, and also that of Captain Caw poisoned by his son-in-law in New Zealand.

A RECEPTION BY THE ROYAL SOCIETY OF MEDICINE.

A WELL-ATTENDED reception was held by the Royal Society of Medicine on May 20th, when Lord Dawson, as President of the society, received the guests with Lady Dawson. In the course of the evening two films were shown; the first, "Turksib," was a Russian picture showing the construction of a railway in Turkestan. This, like other Russian films which have reached this country, was an artistic and clever production. The railway was presented as almost finished, for it was due to be completed in 1930, as the audience was repeatedly told; but in actual fact it is still, we understand, in an early stage of development, and will most certainly not be finished this year. It was interesting to notice that the big machinery being used in the construction was English; also that sheep, cattle, and horses have been imported from England to stock the country through which the railway is to run. The second film was an amusing comedy, entitled "Habeas Corpus," and provided a pleasant contrast to the more serious picture. The popularity of these social evenings has increased to such an extent that many applications for cards have to be refused for lack of accommodation. It is a tribute to the attractions offered by the society that this is true at the very height of the London season.

THE VIRUS OF PSITTACOSIS.

THE claim that certain of the so-called filtrable viruses can be demonstrated by the current microscopical methods is no new one. The bodies described by Paschen, Borrel, and others in virulent vaccinia material are, perhaps, the best known example, but similar appearances have been observed in connexion with other members of the group, such as the viruses of fowl-pox, influenza, poliomyelitis, and dengue. Opinion is sharply divided on the nature of these bodies. They are not easily stained, and do not reveal themselves to casual or haphazard study, which probably accounts for the lack of attention which they have received, many investigators having dismissed them after a cursory examination as precipitate of stain or protein. Nevertheless the view that they are the viruses is held by many whose opinion is entitled to respect. Recently bodies of a somewhat similar nature have been described in connexion with the virus of psittacosis. These appear most commonly as small cocci, 0.2 μ -0.4 μ in diameter, single or in pairs, but occasional bacillary forms are met with which may be as much as 2 μ in length. They are readily demonstrated by prolonged staining with Giemsa, but can be stained, though less well, with Löffler's methylene-blue or carbol fuchsin. Levinthal,¹ who was the first to describe them, does not commit himself on their relationship to other virus bodies, though he does throw out a hint of the possibility of the virus of psittacosis being a member of the Brucella group; apparently he considers these bodies to be the virus. Both Coles² and Lillie,³ whose papers closely followed that of Levinthal, incline to the view that these bodies belong to the rickettsias; in fact, the latter author goes so far as to coin the name *Rickettsia psittaci*. Undoubtedly there are strong resemblances with the rickettsias. The presence of bacillary forms, the appearance of the coccid and bacillary forms when stained by Giemsa, their occurrence in masses inside endothelial phagocytes, and the fact that they are Gram-negative,

¹ Levinthal, W.: Klin. Wochn., 1930, ix., 631.

² Coles, A. C.: THE LANCET, May 10th, p. 1011.

³ Lillie, R. D.: U.S. Pub. Health Rep., 1930, xlv., 773.

favour of this relationship. Then, at almost everyone who has studied *psittacosis* has seen these bodies suggests something more definite and more illustrated than the Paschen and other. Whether this minute *cocco-bacillus* is *psittacosis* remains to be demonstrated, tant presence in virulent material, whether in man, birds, or mice, makes this more note possibility.

THE TRAINING OF THE DEAF.

SE who attended the meeting of the National Institute for Promoting the Welfare of the Deaf which place last week and to which we elsewhere make reference, had the good fortune to hear from Mr. Stanley Baldwin a very clear exposition of the trials of the large number of people who have lost their sense of hearing. Mr. Baldwin, in a studiously simple address, confined attention to the unsympathetic attitude which the public, through a sort of unheeding ignorance, manifests towards the deaf population, contrasting that attitude with the prompt and deep commiseration which is always extended to the blind. The situation which was described is one of which medical men are becoming increasingly aware, for many doctors are now realising how much can be done for the deaf by classification and suitable education, where full advantage can be taken of the proper training. They will recognise the good sense of Mr. Baldwin's words by as much as they have recognised the possibilities for good work and good citizenship possessed by a large proportion of the deaf. The plight of these is undoubtedly aggravated by the thoughtlessness of those with whom they mix, but the capacities of the deaf require development by methods of education that are hard to come by, and for the provision of which the aid of the State is needed. Expressions of official sympathy have now been received from the relevant Ministers of State under two administrations, and while there is reason to hope that the untiring work of the National Institute will soon bear fruit, towards this end Mr. Baldwin's words of wisdom will play an influential part. By making little organised attempt to train the deaf the State is on the one hand doing little to ease a burden which the country has to bear, and on the other is leaving undeveloped the capacities of a large number of persons perfectly fitted, if only they can be equipped, to help themselves and help others.

THE OBJECT OF A PHARMACOPEIA.

In a presidential address to the United States Pharmacopoeial Convention, delivered on May 13th, Dr. Reid Hunt quoted from the founders of the U.S.P. in 1820: "It is the object of a Pharmacopoeia to select from among substances which have medicinal power those the utility of which is most fully established and best understood; and to form from them preparations and compositions in which their powers may be exerted to the greatest advantage." He suggested how far it was possible to stray from this ideal by recalling the words of another president of the Convention, who had remarked that there were preparations in the U.S.P. no more active or useful than brickdust; and that doubtless brickdust would also be included if a demand for it arose. But though useless drugs or preparations which enjoy a temporary vogue may encumber the Pharmacopoeia, can always be removed by judicial editing; on the other hand, the full value of remedies long known to pharmacologists and doctors may often be lost for years. Dr. Hunt cited other instances known for nearly 300 years of remedies discovered, and Epsom salt, for example, was not known to the medical profession since it was first injected.

disinfectant by Lister, which was to lead indirectly to the development of aseptic surgery, was suggested to him by observing its action at a Scottish sewage plant—a haphazard origin for a revolution in surgical technique. The moral Dr. Hunt draws from these instances is the need for the rational use of experiment to investigate completely the properties of drugs at present recognised, many of which are still given empirically. The use of anaesthetics once believed to be impossible is now beginning to extend, with the safety and efficiency afforded by modern technique; but Dr. Hunt reproaches surgeons with treating the subject of anaesthesia as though it were a closed chapter, whereas he questions "if man has even got on the right track in regard to general anaesthesia." The effective anaesthetic dose of the substances in use is more than 50 per cent. of the fatal dose—a smaller margin of safety than with any other class of important drugs. And in this view Sir Francis Shipway is in accord, for in a letter on another page of our present issue he describes the position of surgical anaesthesia as very unsatisfactory, and calls for search after an agent which will eliminate the fear of going under, provide a safe induction, and avoid the later complications, whether toxic or irritant. Dr. Hunt holds it probable that in other directions some of the drugs at present in common use have equally far-reaching potentialities. Ehrlich, who combined an encyclopaedic knowledge of pharmacology and of organic chemistry, believed that the future of medicine lay in pharmacology. His many contributions to the science were made as the result of patient experiment. The introduction of almost every modern drug into medicine has depended on pharmacological experiments; further, the use of synthetic drugs is rapidly increasing, and to this field of activity it is impossible to imagine a limit. In 1835 Bigelow placed epilepsy and angina pectoris among the "self-limited diseases," declaring that their paroxysms could be neither "foreseen, prevented, nor, as far as we know, materially abridged in their duration." Dr. Hunt referred to the value of the bromides and amyl nitrite, since employed in these two conditions, and mentioned the extreme specificity of action of certain drugs. The destruction of a few cells of the retina, only, by methyl alcohol poisoning was remarkably suggestive; there were possibly a vast number of known but untested compounds which might have a similar effect upon the cancer cells. We have no right to consider any disease "self-limited," or to think it essential to discover the cause before attempting the cure. But, as Dr. Hunt pointed out, "at the present rate of progress it would require not only decades but centuries, perhaps a millenium, for the medical profession to examine what the chemists already have to offer." He left a stimulating impression that no time should be lost in setting about the task.

ROAD ACCIDENTS.

THE harm that is often caused in accident cases on the roads by well-meant but misguided zeal on the part of the public is the subject of a letter addressed to the *Times* of May 28th by the Director of the Home Ambulance Service of the British Red Cross. This applies in particular to cases with fractures of the limb bones; examples are given of patients with a fractured femur taken to hospital in the back seat of tiny cars, and others of simple fracture becoming compound after transport in a lorry without splintage. The British Red Cross Society has done a great deal to minimise the results of the increasing number of road accidents by establishing a network of motor ambulances throughout the country, by educating the public in the principles of first-aid, and by the provision of boxes of first-aid equipment. There is a real danger that the public by its interference to help may nullify these efforts. It is known that in the majority of road accidents it is far better to

leave the injured person at rest, provided he is kept warm, until a doctor or an ambulance arrives, than to hurry him to hospital without skilled attention to his injured limb. One of the most striking lessons of the war from a surgical point of view was the importance of adequate immobilisation of a fractured limb during transport, and indeed throughout the course of its treatment. That lesson took a long time to learn, and it is now in danger of being forgotten. Its importance applies not only to the transport of the accident case to hospital, but also to the treatment offered on arrival there, where mistaken efforts to clean and comfort the patient by removal of clothing and boots too often produces considerable increase both in local injury and general shock. The new order to London police, by which all detectives up to the rank of first-class sergeant, and all uniformed officers up to the rank of station sergeant, are required to make themselves thoroughly proficient in methods of first-aid, having to obtain a certificate equivalent to that held by members of the St. John's Ambulance Brigade, will do much towards helping the patient who has had a road accident. In spite of the good work of the Automobile Association and Royal Automobile Club, however, there are still too few wayside telephone stations. The provision of these in increased number and the spread of teaching that the best way to help in a road accident is to telephone for a doctor and an ambulance and to be content to keep the patient warm and quiet until their arrival, should do much to minimise the consequences of accidents.

AN INTERNATIONAL CONFERENCE ON MINERS' PHTHISIS.

It is common knowledge that the organisation of methods to prevent and diagnose silicosis and to estimate the damage sustained by any individual afflicted with it is far more elaborate on the Rand than at any other place in the world. Following a suggestion made by the Transvaal Chamber of Mines and with the generous assistance of this Chamber, the International Labour Office is therefore convening a conference of experts on silicosis to be held in Johannesburg in August of this year. Those taking part will include, besides the men who have acquired unparalleled experience in coping with miners' phthisis in the gold-mines of the Rand, delegates from Australia, Belgium, Canada, Germany, Great Britain, Italy, the Netherlands, and the United States. The conference, which will be under the official patronage of the South African Government, will open on August 13th and will conclude on August 27th. One delegate from each of the countries represented will be asked to prepare a short statement explaining the situation in his country as regards silicosis and closely related dust diseases, the researches made and the results achieved, including particulars of compensation where it is granted. For the rest, the draft programme consists mainly of communications from workers on the Rand, whose papers will be printed and distributed in advance, so that visitors from other countries will be in a position to comment on the information provided and critically examine the statistics and the material collected in South Africa. The communications to the conference will include a historical review of mining conditions on the Witwatersrand from the point of view of dust and ventilation. Mr. Hans Pirow, D.Sc., government mining engineer, Mr. A. E. Payne, general manager of one of the mines, and Mr. F. G. A. Roberts, technical adviser to the Transvaal Chamber of Mines, will describe the conditions in the mines in the early days of the Rand and the changes which have since taken place. Mr. A. F. Macewen and Mr. J. Buist will discuss the nature and source of dust in mine air. Mr. James Boyd will give an account of methods for the determination of the amount of dust in mine air, and Mr. Malcolm Fergusson, chief inspector of mines, and Mr. Walter Scott will describe methods

for preventing the formation of dust and precautions designed to prevent the inhalation of such dust as may be formed, with the regulations designed to this end. Prof. G. A. Watermeyer and Mr. J. P. Rees will discuss the general question of mine ventilation and air renewal, including references to the heat and humidity problems. The medical aspect of miners' phthisis will be dealt with first by Dr. L. G. Irvine, who will describe the functions and working of the Miners' Phthisis Medical Bureau, over which he presides. Dr. A. Mavrogordato will discuss the aetiology of silicosis and its experimental production, Dr. A. Sutherland Strachan and Dr. F. W. Simson its pathology, and other members of the South African Institute for Medical Research will expound the symptomatology and radiology of silicosis as it affects South African gold-miners. Dr. A. I. Girdwood will describe the medical examination of native labourers on engagement, with a demonstration, and Dr. A. D. Pringle the sanatorium treatment of miners' phthisis. Dr. Andrew H. Watt will speak of silicosis as seen in the days before the establishment of the Miners' Phthisis Bureau. The statistics collected in connexion with the work of this Bureau will be reviewed, also the functions and experience of the Medical Board appointed to hear appeals from its decisions, and the efforts made to provide employment for the sufferers from silicosis and for their dependents. Visits to mines and demonstrations of material and radiograms will be arranged, and the last few days of the conference will be devoted to round-table discussion of questions arising from the previous sessions. The Rand gold-mining industry must inevitably come to an end after a few more decades, since all the reef near enough to the surface to be mined with profit will have been extracted. It would have been most unfortunate if the experience so expensively gained had not been put at the disposal of other nations whose industries include those involving the risk of silicosis, and the idea of convening a conference while the organisation is still at its zenith was a happy one which should have fruitful results.

INDICATIONS FOR MASTOID ANTROTOMY.

THERE is an increasing inclination among otologists to perform the mastoid operation in the later stages of an acute suppurative otitis media. When, somewhere about the fourth week of the disease, a profuse purulent discharge continues without signs of diminution, the majority of aural surgeons now advise antrotomy, even in the absence of other local or general symptoms. If treated conservatively, such cases usually go on to chronic suppurative or, at best, to a scarred fibrosed tympanum and impaired hearing; on the other hand, after the mastoid operation, a soundly healed drum and perfect, or nearly perfect, hearing may be expected. It is surprising what extensive disease may be found under these circumstances, despite the absence of symptoms, though it is possible that careful examination may reveal a fleeting rise of temperature, or a, perhaps very slight, bulging of the postero-superior wall of the meatus. Such is the opinion of Prof. Gustav Alexander, who has recently contributed an interesting exposition¹ of his views of the indications for operation in acute otitis. In the early stage of acute aural suppuration, on the other hand, opinion is hardening against operation. Prof. S. J. Kopetzky, of New York, whose work on "Otologic Surgery" was reviewed in our columns on March 15th (p. 577), believes that the danger of extension to the lateral sinus is increased by operation within the first three days, and that the best results are obtained if operation is performed at the end of this period. Prof. Alexander has long been convinced that the subsequent course of an otitis media is unsatisfactory when the mastoid has been opened in the first week of the disease. In

¹ Wien. Klin. Woch., May 8th, p. 577.

his opinion the surgical form of mastoiditis makes its appearance in the third week, just at the time when, in the normal course, the otitis should have healed. He states categorically that there is no such thing as otitis and meningitis beginning simultaneously, and that sinus-thrombosis, like other intracranial complications, occurs at the earliest at the end of the third week. It is true that the duration of the otitis may occasionally appear to be shorter but, on careful inquiry into the history of pain in the neck, or feeling of fullness in the ear, before the onset of actual earache, one finds that the case is really one of otitis in its third week. But, Prof. Alexander maintains, acute otitis produces no genuine complications in the first few days; in severe cases, especially in children, there often appears in the early stage, while the drum is still intact, or before a profuse unobstructed flow of pus has followed paracentesis or spontaneous rupture, a series of symptoms—acute mastoid pain and tenderness with high fever—which imitates, but is distinct from, surgical mastoiditis. This condition is distinguished by the absence of the signs of true mastoiditis; in the latter the soft parts over the mastoid are diffusely thickened, less movable, and warmer than on the opposite side, the tip is obscured by œdema and, above all, there is bulging of the posterior-superior mental wall. He terms this condition "mastoidismus," but, as he acknowledges that the symptoms are due to an underlying inflammation, the word is open to criticism; it may be better to agree that the mastoid antrum and cells participate in the inflammation of a severe otitis in the early stage. The fact remains that these symptoms disappear when free discharge from the ear is established, that such cases do badly if the mastoid is opened at this stage, and therefore that no operation should be performed beyond incision of the drum-membrane when perforation is absent or insufficient.

THE RESEARCH DEFENCE SOCIETY.

THE report of the Committee of the Research Defence Society is a brief document, reflecting there the fact that the business of the year has been relatively quiet, in spite of the large increase in the numbers of Members of Parliament and public persons whom we hear of as being opposed to the work of the Society. There has been an increasing demand for lecturers and speakers for debates, and a large amount of literature, expounding the benefits to mankind and to animals as well resulting from research, has been distributed gratuitously to the public. But there is one point which emerges from the report which should be brought to the attention of our readers and that is the difficult financial position of the Society. Increased expenditure on publicity has meant, and must mean, a depletion of funds unless the propaganda meets with an increasing number of subscribers. This Society exists for the benefit of the public, its object being to defend medical and scientific research in order that the public may receive benefits therefrom. The attacks of the opponents of scientific progress are directed, of course, not against laymen, whose particular proclivities may not be known, but against the medical profession and institutions like the Medical Research Council. It is therefore particularly to the medical profession that the committee appeal for members, feeling that from this quarter full support should be given to their energies. The support given is disappointing.

At the annual meeting of the Society, held at the rooms of the Medical Society of London on June 3rd, Lord Lamington presiding, Sir Leonard Rogers, as honorary treasurer, pointed out that during the last four years expenditure had exceeded income by over £400. Mrs. May Mellanby delivered the fourth Stephen Paget memorial lecture on "Diet and Dental Disease: what we have learned from Animal Experiments." She showed that all fundamental facts upon which current hypotheses concerning correct feeding

had been based were discovered by animal experimentation. The average human being in this country was fed, especially during childhood, on just those diets which had been found to produce defective teeth and defects in related tissues in animals—i.e., large amounts of cereals, with comparatively little whole milk, egg yolk, and other foods which contained fat-soluble vitamins. The profession was now aware of some of the worst errors committed in feeding, and in feeding children especially, and so long as these errors were persisted in, so long, she submitted, would the teeth of civilised man remain in their present deplorable state. In the course of the discussion Col. F. E. Fremantle, M.P., said that he had asked the Minister of Education in the House of Commons whether he would bring to the notice of children in schools the researches of Mrs. Mellanby, and the reply was a copy of the handbook issued on diet. He suggested that this handbook might require some modification in view of recent researches, and Mrs. Mellanby concurred. The difficulty in regard to public propaganda at the present time was that much appeared in the lay press which was untrue, and that made it even more difficult for those who had not scientific habits of thought to discern the accepted facts. She might have added that even in scientific circles there is not yet agreement on the theoretical significance of dietary experiments and still less on the precise way in which their lessons could be translated in didactic advice in handbooks. It is just at this stage that the patient work of a body like the Research Defence Society, whose sole object is to impress the public with the need of further experimental research, is valuable. Its work is neither pleasant nor easy, and should not be further hampered by lack of financial support.

It is announced that the Rockefeller Foundation has offered £100,000 to the University of Sydney for provision of laboratory facilities in the departments of surgery, pathology, bacteriology, and allied subjects.

THE Cavendish lecture of the West London Medico-Chirurgical Society will be given at 8.15 P.M. on Tuesday, June 17th, by Prof. Fritz de Quervain, of Berne, who will speak on Cretinism and its Relation to Thyroid Physiology.

THE Croonian lectures will be delivered at the Royal College of Physicians of London at 5 P.M. on June 12th, 17th, and 19th, by Sir Charles Martin, F.R.S., Director of the Lister Institute. His subject will be the Thermal Adjustment of Man to External Conditions, more particularly those pertaining to Warm Countries. Members of the medical profession will be admitted on presentation of their cards.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Courses have been arranged in the following subjects: Gynaecology, at the Chelsea Hospital for Women, certain mornings and afternoons from June 16th to 28th; dermatology, at the Hospital for Diseases of the Skin, Blackfriars, each afternoon, between same dates; medicine, surgery and the specialties, daily, 10.30 A.M. to 5.30 P.M., between same dates; proctology, at St. Mark's Hospital, City-road, daily, from June 30th to July 3rd. Detailed syllabuses of all courses can be had from the Fellowship at 1, Wimpole-street, London, W. 1.

LONDON TEMPERANCE HOSPITAL.—Re-building operations have been begun at this hospital. Four additional storeys will be added to the out-patients' department, and the pathological and massage departments will be housed in better quarters. There will also be a new radiological department, a lecture room, private wards for paying patients, and new quarters for nurses. The cost of rebuilding will be £45,000, towards which £11,000 is in hand or promised. During the week ending May 31st, 21 new in-patients were admitted and over 1340 attendances were made at the out-patients' departments.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles Contributed by Invitation.

LXXV.—CHEMICAL TESTS OF PANCREATIC EFFICIENCY.

PART I.*

As in the case of the kidneys (see THE LANCET, 1928, ii., 1092) certain general principles must be considered when testing the functional efficiency of the organ. The tests yield abnormal results only when the disease of the organ is extensive. The gland possesses a large "reserve power" and in interpreting the results of tests the possible influence of non-pancreatic factors must be considered, and in particular the likelihood of coincident disease of the liver or bile-passages.

Functions of the Pancreas.

The functions of the pancreas include (1) the formation of the internal secretion ("endogenous insulin"), and (2) the formation of the external secretion (pancreatic juice), which contains enzymes (or zymogens) acting on each of the three classes of foodstuffs—viz., amylase or diastase (carbohydrates), trypsin (proteins), and lipase or steapsin (fats). It is difficult to examine these secretions because of the inaccessibility of the gland; examinations must of necessity be conducted on the duodenal contents, gastric contents, faeces, blood, or urine.

Tests of Deficiency of Internal Secretion.

Hyperglycemia and glycosuria.—Glycosuria is uncommon in diseases involving the pancreas as a whole, and particularly in chronic lesions. In acute hemorrhagic pancreatitis, slight transient glycosuria and hyperglycemia are fairly often found and are valuable in diagnosis, but there is rarely time to make estimations of blood-sugar. In chronic diseases of the pancreas, it is worth while to obtain data for a blood-sugar curve, but the result is often within normal limits, because hyperglycemia does not occur till a very large proportion of the islets of Langerhans is damaged. A normal curve, therefore, does not exclude pancreatic disease, and when an abnormal curve is obtained it is necessary to consider the possible influence of other factors.

Luciw's test.—The pupils of both eyes are carefully examined, noting their size and their reaction to light and accommodation. Two drops of 1 in 1000 adrenaline are instilled into one eye, the other being left untreated for comparison. The pupil of the treated eye is examined at intervals of about 15 minutes for the next hour, and compared with that of the untreated eye. Normally the adrenaline causes no change in the pupil. The reaction is positive if the pupil dilates. In positive cases the pupil is often oval and the dilatation eccentric. Several attempts to explain this observation have been made, of which two may be noted: (1) The "hypoinulinism" produces a relative hyperadrenalism which increases the sensitivity of the sympathetic system, wherefore the pupil reacts to the instillation of adrenaline. (2) Inflammation of the pancreas causes irritation of the solar plexus, wherefore the autonomic system is hypersensitive.

The test is not specific because positive results have been obtained in hyperthyroidism, and in diseases of the gall-bladder or of the bile-duct. The latter observation might be "explained" on the basis of coincident pancreatic disease, but obviously limits the clinical value of the test. Negative results have been obtained in typical examples of acute pancreatitis. Some writers speak highly of this

reaction in acute disease, others have discarded the test. It is so simple that it is worth performing in parallel with other tests, so long as its limitations are remembered. It is very rarely positive in diabetes mellitus.

Tests of Deficiency of External Secretion.

Theoretically tests might be applied for the different enzymes, or evidence might be sought of incomplete digestion of foodstuffs owing to deficiency of these enzymes. Examination of gastric contents, of duodenal contents, of faeces, of blood or of urine might be utilised. In practice many of these points of attack are of limited or no value, as will readily be understood if the presence of other enzymes in the alimentary tract, the action of bacteria, the influence of diarrhoea, and so forth are remembered. It is convenient to discuss the methods under the heading of each enzyme in turn.

Carbohydrate-spitting ferment.—Examinations of gastric or duodenal contents are useless owing to the presence of salivary ptyalin. Examination of the faeces has also proved disappointing, owing to the action of bacteria, or the presence of diarrhoea. Estimation of diastase in the blood is of limited value. Normally, tested by Wohlgemuth's method (see below), the blood contains 3 to 10 units of diastase. In acute pancreatic disease the amount is increased, but owing to its rapid excretion urine examination is much more satisfactory.

Estimation of diastase in urine has proved a useful test of pancreatic efficiency, although it is still not decided whether the diastase is derived solely from the pancreas. Wohlgemuth's is the method usually employed.

A Wohlgemuth unit is the amount of diastase which will digest 1 c.cm. of 0.1 per cent. soluble starch (1 mg.) in 30 minutes at 37° or 38° C. to such a degree that no blue colour is obtained on adding iodine. The diastatic index is the number of units in 1 c.cm. of urine. It is important to adjust the reaction (pH) of the urine to the optimum for the enzyme. In health the concentration of diastase in the urine, or the diastatic index, is 6.7 to 33.3 units. Occasionally when the urine is concentrated the index may rise as high as 50 units. The day's output of diastase is the product of the volume of the 24 hours' urine in cubic centimetres and the index. Normally the day's output varies from 8000 to 30,000 units.

An index of 50 is suspicious, and of 100 is almost always definitely abnormal. In acute pancreatitis values of 100, 200, and even up to 2000 may be found. In chronic pancreatitis and in carcinoma of the pancreas the diastatic index is usually normal or low, but sometimes in carcinoma the index may rise to about 100. In severe trauma of the pancreas the urine not uncommonly contains an increased concentration of diastase (up to about 200 units), and the finding of high indices in the urines of patients who have had a blow in the abdomen is useful clinically. It has been claimed that the index is often high in the toxemias of pregnancy, and it has been suggested that the cause of this is an increased permeability of the kidney. In many cases, however, the index is normal (though rarely, if ever, low). In eclampsia indices of 50 to 100 are fairly common, and very occasionally even higher values are obtained. It is possible that these figures are mainly, if not entirely, due to oliguria. In diabetes the diastatic index is almost always normal or low.

Estimations of diastase should be made on the 24 hours' urine, except in acute pancreatitis. Normally, owing to polyuria (drinking, cold, and so on), or oliguria (sweating, restricted fluid intake), there are considerable variations in the diastatic index of specimens taken at different times of the day, though this range of variation rarely exceeds 2 to 50 units. For this reason the 24 hours' sample is employed, and when this is done the variations in different healthy individuals usually fall to the figures (between 6.7 and 33.3 units)

* Part II. will appear next week.

already indicated. In acute pancreatitis, diagnosis is so urgent that 24 hours cannot be allowed for collecting the urine, and the first obtainable sample is used. Fortunately, in genuine cases of the disease such a sample usually contains 100 or more units per 1 c.cm., but lesser concentrations of diastase are obviously not significant.

The increase of diastase in the blood and urine in pancreatic lesions may be due to obstruction of the ducts, or to increased permeability of the pancreatic cells due to inflammation. These hypotheses fit in with the clinical observation that the urinary diastase is increased when the ducts are obstructed or when inflammation is acute, and is normal or low in chronic sclerosing conditions. I. Cohen and E. C. Dodds have shown that the same variations in the diastatic index are found in starvation as after food, so that presumably diet has no influence on the output of the enzyme.

There may be a transient increase of the concentration of diastase in the urine when a salivary duct is obstructed or a salivary gland is acutely diseased, but such a cause is readily recognised from the clinical examination of the patient.

If there is a deficiency of the external secretion of the pancreas, it might be expected that a certain amount of starch might escape digestion and be recognisable in the faeces, but microscopical examination of the stools for starch granules has been found of no value as a test of pancreatic function. Starch granules are often absent in proved pancreatic disease, and are not uncommon when there is gross diarrhoea or the subject is ingesting large quantities of starchy foods.

Protein-splitting ferment.—Either the gastric or the duodenal contents may be examined for trypsin. A positive result excludes complete obstruction of the pancreatic ducts, but a negative result in either fluid is not conclusive. It is unlikely that quantitative estimations will be of any value owing to the unknown degree of dilution. Regurgitation of duodenal fluid into the stomach is uncertain, but it has been suggested that the reflux might be provoked by administering 0.4 per cent. hydrochloric acid. Generally, however, direct duodenal intubation is employed. When examining the gastric contents for trypsin it is, of course, essential to make the reaction alkaline.

Examination of the faeces for protein-splitting ferments has proved disappointing. In a certain number of healthy individuals no such enzyme can be detected, and in the rest, when quantitative methods are employed and the results are expressed in terms of the dried faeces, a wide range of variation is obtained. It would appear, therefore, that results characteristic of pancreatic lesions do not exist. Examination of the blood and urine for trypsin is of little or no value.

If the external secretion of the pancreas is deficient it might be expected that the faeces would contain more protein and protein-products than normally, though the action of intestinal erepsin, and of bacteria, and the influence of the rate of passage of the intestinal contents are all obvious complicating factors. Whilst it is true that the total nitrogen expressed as a percentage of the dried faeces is increased in gross pancreatic disease, such a wide range of variation is found in other pathological conditions—gastro-intestinal disease often giving quite as high values as pancreatic disease—that the estimation is of little or no value. A proper metabolism experiment in which the intake and output of nitrogen are measured gives more information, but is not a practical proposition in routine clinical work.

Microscopical examination of the faeces for undigested muscle-fibres is a simple qualitative test of some value, but it is important to realise what constitutes "creatorrhoea," or the passage of undigested meat fibres. The connective tissue binding the fibres together is digested by the gastric juice, so that pancreatic trypsin acts on individual muscle-fibre fragments. There results seriatim the disappearance of the nuclei, the rounding of the ends of each fragment, and the disappearance of the

transverse striations, leaving round yellow-brown fragments, which may either show a faint longitudinal striation or may appear quite homogeneous, and finally the complete disappearance of muscle-fibres. Fibres with rounded ends, but visible transverse striations are not uncommon in simple diarrhoea. The discovery of numerous fibres with irregular ends and well-marked striations ("true creatorrhoea") almost always points to a deficiency of pancreatic trypsin, but their absence does not exclude a gross lesion of the pancreas, since other protein-splitting ferments (intestinal or bacterial) may cause partial or complete digestion of muscle. The only things likely to be mistaken for muscle-fibres are the woody fibres of certain vegetables. There is rarely any serious difficulty, however, because the striations of the woody fibres are much coarser, more irregular, and more refractile. Naturally, when the observations are made, the patient must be consuming meat or poultry. Some investigators have claimed that better results may be obtained with special test diets, but for routine clinical work an ordinary hospital diet, containing meat, is generally satisfactory.

Fat-splitting ferment (lipase).—Tests for lipase in gastric contents, blood, or urine are of little or no value clinically, but examination of the duodenal contents for lipase is sometimes useful. As in tests for trypsin in duodenal fluid, a positive result excludes a complete obstruction of the pancreatic ducts, but a negative result is not conclusive evidence of the presence of such obstruction. Tests for the two ferments should be run in parallel. Tests for lipase in the faeces are of no value, because the lipase is destroyed by trypsin, but microscopical examination of the stools and a differential estimation of fat in faeces are generally recognised as of value in pancreatic disease.

General Appearance and Microscopical Examination of Faeces.

The passage of bulky stools is a well-recognised clinical feature of pancreatic disease, though other conditions may cause bulky stools—e.g., obstructions of the bile-duct, coeliac disease, sprue, congenital steatorrhoea, gastro-colic fistula, and mesenteric tuberculosis involving the lacteals. Bulky, watery stools, due to diarrhoea are easily differentiated. The stools in the above diseases are not only bulky, but fatty in appearance, owing to the presence of an excess of fat. The passage of fatty stools, which are liquid when passed and set solid on cooling, constitutes "true steatorrhoea," though the term steatorrhoea is often applied to the passage of any fatty stool, even though it does not solidify on cooling. True, steatorrhoea is apparently diagnostic of pancreatic defect (except possibly in congenital steatorrhoea). The fresh stool consists of faecal material floating in molten oil, and on cooling the faecal matter forms a plate.

Microscopical examination is useful, not only to check the macroscopical appearance of fat, but also to give a rough idea of the type of fat (neutral fat globules, fatty acid crystals, soap flakes) present. When there is a deficiency of the pancreatic juice, it is the splitting of the fats which is defective. Hence the excess of fat is chiefly in the form of neutral fat. On microscopical examination, therefore, oily globules, but not an excess of fatty acid crystals or of soap flakes, may be found in a typical uncomplicated case. In clinical work, however, cases of combined pancreatic and liver disease are commoner than those of pure pancreatic disease, wherefore the microscopical findings are often not "typical." Moreover, the neutral fat is often so finely divided that it is not readily seen under the microscope, and when oily globules are visible it is important to exclude liquid paraffin and other oily drugs as their source. The results of microscopical examination therefore can only be interpreted in the light of the clinical examination. Lastly, even in the complete absence of pancreatic juice the neutral fats may be hydro-

lysed lower in the gut by bacteria, for which reason the absence of a "typical" microscopical picture by no means excludes the existence of pancreatic disease.

In the laboratory, one of the chief reasons for making a microscopical examination is to decide whether or not the laborious analysis of faeces for fat is worth undertaking. If, macroscopically, the faeces are nor bulky and not fatty-looking, and if microscopically, no fat globules, no fatty-acid crystals, and only occasional soap plaques are seen, then chemical analysis is certainly a waste of time.

Fat in faeces.—Normally, of the dried faeces, not more than one-fourth to one-third is fat, and of the faecal fat not more than one-fourth to one-third is unsplit. In typical pancreatic cases the total fat percentage is excessive, often over 50, and the splitting is defective, the unsplit neutral fat being 40 to 70 per cent., or even more, of the faecal fat. But, as indicated in the last section, such typical results are the exception rather than the rule, and the finding of a high percentage of total fat of which the greater proportion is "split" (free fatty acids and soaps) does not by any means exclude pancreatic disease. Differentiation between free fatty acids and soaps is of no value, since the reaction of the faeces is the chief factor influencing the proportion of fatty acids which is combined as soaps.

G. A. HARRISON, M.D. Camb.,

Reader in Chemical Pathology in the University of London;
Chemical Pathologist to St. Bartholomew's Hospital.

IN Dr. John Freeman's article on the Significance of Idiopathic Skin Reactions (Part II.), which appeared on page 1197 of THE LANCET last week, the first paragraph, which preceded the list of asthma-group diseases, should have read as follows:—

"In Part I. of this article it was made clear that we can produce a long list of symptoms by applying grass pollen to the hay-fever subject in various ways. Let us make a list of these hay-fever 'symptoms,' for they are identical with the 'diseases' (produced by various protein irritants) which we are to test for by skin reactions."

DONATIONS AND BEQUESTS.—Mr. Clement A. Ravenscroft left, among other bequests, £30,000 upon trust for his brother Leonard for life, with remainder on his decease equally between St. Mary's Hospital, King's College Hospital, St. George's Hospital, Charing Cross Hospital, and the London Hospital.—Colonel Arthur Bray, T.D., of Church Lane House, Adel, Leeds, left £1000 each to the Leeds University and Leeds General Infirmary.—Mr. P. Breda Vander Byl left £1000 to the London Hospital, among other bequests.—Mr. George Strachan, of Ellisland, Pollock-shields, Glasgow, left, among other bequests, £2500 each to the Glasgow Royal Infirmary, the Glasgow Western Infirmary, the Glasgow Victoria Infirmary, and £2000 to the Glasgow Royal Hospital for Sick Children; £1500 to the Elder Cottage Hospital, Govan; £500 each to the Glasgow Eye Infirmary, the Princess Louise Scottish Hospital for Lameless Sailors and Soldiers, the Ralston Auxiliary Hospital, the Royal Samaritan Hospital for Women, Glasgow, the Glasgow Royal Cancer Hospital, the Glasgow Ear, Nose, and Throat Hospital, the Glasgow St. Andrew Ambulance Association, and St. Dunstan's Hospital for Blind Soldiers and Sailors.—Sir Ralph Collingwood Forster, Bart., of Sutton, left £5000 to the Sutton Hospital for such part as he had not given since the date of his will, Feb. 28th, for general purposes, and £1000 each to the Surrey Convalescent Home for Women at Bognor, the Surrey Convalescent Home for Children at Bognor, and the Surrey Convalescent Home for Men at Seaforth.—Colonel Sir William E. O. Ounrie, of Ilton Court, Chestport, among other bequests left £1000 to the Newport Hospital and £1000 to Chestport Hospital.—Mr. Clement Arrol Ravenscroft, of Westbourne-terrace, Paddington, left £500 to St. Dunstan's Hostel for the Blind; £30,000 on trust for his brother Leonard for life, with remainder on his decease equally between St. Mary's Hospital, King's College Hospital, St. George's Hospital, Charing Cross Hospital, and the London Hospital.

Special Articles.

NATIONAL INSTITUTE FOR THE DEAF.

THE annual meeting of the National Institute for the Deaf was held at the Church House, Westminster, on Friday, May 30th, the President, Lord Charnwood, in the chair. After welcoming Mr. Stanley Baldwin, who had promised to address the meeting, and who was present at great personal inconvenience, the chairman referred to the progress of the Institute. It had, he said, been steadily growing in influence since their last meeting, while efforts which had been made to get the importance of the cause sufficiently realised by the public had begun to tell. During the last 12 months, for example, a scheme had been framed, and was now ready to be launched, for supporting a school for the higher education of congenitally deaf people, and promises of financial support to it had already been received. Plans had also matured for starting in London a centre for social intercourse, and once these were under weigh the deaf, first in London and thence elsewhere, would help themselves and one another, and the necessary financial support, he thought, would soon be found. Much headway had been made in promoting local organisations, and such work could only be done thoroughly by the Institute itself. As to the result of pressure upon the last administration, it was entirely due to the Institute that anything was done; now the Minister of Health agreed with the Minister of Education, and would make an inquiry for himself through an experienced official in whom there was complete confidence. The conditions of the deaf and the measures necessary for the removal of some of their difficulties would follow, he thought, on the sort of public inquiry which was desirable being held. The problem of the deaf was now before the minds of our rulers in a way and to an extent which it was not when the annual meeting of the Institute was held last year.

Mr. Baldwin's Appeal.

Mr. Baldwin said he would try to put in a few words what were the disabilities of the deaf, and at the same time to arouse the sympathy of the outside public, so that they would be ready to help the Institute in its admirable work. The outside public had very little realisation of the tragic fate of the deaf. He was not thinking so much of those who were born so, tragic as their case was, but the public should be careful not to confuse the special teaching, given to those born deaf, with the requirements of the ordinary deaf.

The first thing that struck him—it was most unfair and he did not know the reason—was the complete difference in the treatment of those who were blind and those who were deaf by the outside world. Blindness was a most terrible affliction, but from the dawn of history it had been met by those who were not blind with a consideration and kindness which went far in the alleviation of the lot of the sufferers. Every allowance was made for them; everyone was ready to help them across the road; everybody was ready to talk to them and tell them of things; and they had open to them all the resources that modern science could bring to their delectation in the way of speech and music. If the blind had lost their sight in later life they had the recollection that nothing could take from them: the beautiful sights of this earth and the faces of their friends who could talk with them, while they could hear the voices of their fellow creatures. There was a gulf of isolation between their fate and the fate of the deaf. There seemed to be very little natural sympathy for deafness, and that arose from want of thought and want of imagination. One never heard a joke made at the

expense of the blind; pantomimes and ordinary conversation were full of jests at the expense of the deaf. If people were short-sighted and wished for a book or a picture to be brought nearer to them in order that they might see better, one did not shout at them "Can't you see? Are you blind?" But if people were asked to repeat a remark, the reply might often be "Can't you hear? Are you deaf?" This lack of sympathy could be found in every place, in every country, and at all times. Mr. Baldwin said he was thus calling attention to the obvious in the hope that his words might lead to a little more consideration, and a little more courtesy being shown to those who suffered from deafness. With the totally deaf the prospect was appalling. It would be indecent on the part of anyone who still had command of his faculties to ask which was the greater deprivation, sight or hearing. Both were terrible, but he had often thought that there could be no more awful fate than to be completely cut off from ordinary daily intercourse with human beings, and that of course was what complete deafness meant. Those who were not deaf ought to realise that deafness did not always mean just complete silence and oblivion; it was often accompanied with distressing noises in the head and troubles which anyone who had suffered from temporary deafness would never forget. When the deaf could hear by the aid of appliances, how different again was their fate from that of the blind. Everyone was eager to help and converse with them. There was not one person in a hundred who would go voluntarily to speak to a deaf person by the aid of an instrument. People made for the other side of the room, which must cause the deaf a great deal of unnecessary pain. People, when they talked to the deaf, became, as it were, paralysed; their conversation became unnatural and stilted. The moment that deaf people got to the point when artificial aids must be employed, they were in a slow process of being immured alive; they were cut off completely from contact with their kind. That was a very terrible fate, and everything should be done to lighten it for them. There was no better way to begin than by altering our behaviour towards deaf people, assimilating it to our behaviour towards the blind. As with the blind, very often the sense of hearing and the power of memory became more acute; he imagined that with the deaf, the sense of sight and the power of memory grew. To those who became deaf late in life that which came to them through the eye must be of growing importance all through their lives. With such training as Lord Charnwood had alluded to, the deaf subject could be taught an appreciation of the beautiful things of this world; and if music should be cut off from them, why should they not learn to derive an equal pleasure from the sight of beautiful things, of books, works of art, and the scenes of nature? "The deaf and the blind alike need our help," he said, "and to remedy the deficiency let us try to open for them, as far as we can, those deeper and permanent spiritual possessions which would never fail, and which would last to the end of their days."

Major Bonn, the son of the late Mr. Leo Bonn; the virtual founder of the Institute, then proposed a vote of thanks to Mr. Baldwin, which was seconded by Sir Squire Sprigge, and briefly replied to.

Report and Formal Resolution.

The report and statement of accounts which showed a deficit of £115 for the year ending March 31st, 1930, had been circulated to the meeting, but they were summarised by Mr. A. J. Story, the hon. secretary, and Mr. W. G. Yates, the hon. treasurer, respectively. On being put to the meeting by the President and seconded by Mr. M. Birley, chairman of the executive committee, the report and statement of accounts were carried unanimously.

Sir Harry Stephen proposed and Mr. Yates seconded an amendment to the articles of Constitution enlarging the composition of the executive committee with the

object of giving greater representation to Counties Associations. This having been agreed to, on the motion of Admiral Sir Edward Bradford, the thanks of the meeting were given to the honorary officers of the Institute, who were confirmed in their several capacities.

Mr. Myers, one of the honorary auditors, submitted a resolution acknowledging the services of the executive committee, and suggesting the following names for election to that body:—Sir Harry Stephen, Rev. F. W. G. Gilby, Rev. A. Smith, The Hon. Mrs. John Tennant, Miss H. Davids, Miss M. Hare, Miss B. Neville, Miss F. M. Townsend, Dr. C. Heath, Dr. D. A. H. Moses, Major F. J. Wegg Prosser, Mr. E. Ayliffe, Mr. S. A. N. Oxley, Mr. C. Shaw, and Mr. A. W. Taylor be elected for the ensuing year.

In seconding this resolution, Col. F. E. Fremantle emphasised the need for keeping the welfare of the deaf constantly before the Government, while there remained the necessity for medical research into the causes of deafness and the means for its prevention.

The proceedings closed with a vote of thanks to the chairman.

IRELAND.

(FROM OUR OWN CORRESPONDENT).

The Sweepstakes Bill.

THE "Sweepstakes Bill" has now passed both Dail and Senate, and only awaits the signature of the Governor-General to become the law of the land. While the opposition to the Bill failed to have any effect in either house, it cannot be claimed that there is any enthusiasm for the measure, or any genuine hope that it will remove the difficulties of the Dublin hospitals. The real financial position of the several hospitals is unknown except to those in the inner circle of each institution. Most of them exhibit overdrafts, but few exhibit as openly a statement of their assets. This may be good propaganda, but it makes understanding of the hospital problem impossible. Suggestions were made in the debates in the Dail and Senate that a thorough investigation of the financial position of the several hospitals is desirable. If this is to be done it would be preferable that it should be undertaken by the hospitals themselves rather than by any external authority. It would seem that even a preliminary survey would be helpful, before any sweepstakes are promoted. If the several hospitals which are in genuine need were to pool their influence in promoting a joint sweepstake, it is possible that their immediate needs might be satisfied. If half a dozen institutions promote sweepstakes independently, none will benefit to an appreciable extent, and the general problem will be unchanged. Moreover, the common belief that sweepstakes are an unfailing resource is certain to interfere with what must remain the chief normal source of hospital income—the charity of the benevolent.

Royal College of Surgeons in Ireland.

Mr. Richard Atkinson Stoney has been elected President of the Royal College of Surgeons in Ireland. He had been vice-president for the past two years. Mr. Stoney is a graduate in medicine and surgery of Dublin University, and has been a Fellow of the Royal College of Surgeons in Ireland since 1900, and a member of the Council of the College for several years. He is senior visiting surgeon to the Royal City of Dublin Hospital, and is at present President of the Section of Surgery of the Royal Academy of Medicine in Ireland. Mr. Frank Chetwode Crawley has been elected Vice-President of the College. He is a graduate in arts of Cambridge University and in medicine and surgery of Dublin. He has been a Fellow of the Royal College of Surgeons in Ireland since 1900. He is ophthalmic surgeon to the Royal City of Dublin Hospital, and surgeon to the

Royal Victoria Eye and Ear Hospital. He held the post of surgeon dentist in ordinary to the Lord Lieutenant during the Vice-Royalty of Lord Aberdeen. He is at present president of the Ophthalmological Society of the United Kingdom.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Bacterial Aftergrowth in Water.

SOME cities in this country are suffering from what appears to be a growth of bacteria in the water-supply after it has passed through the plant for filtration and/or chlorination. When the multiplying organism happen to be the colon bacillus a difficult situation arises. The possibility that pollution is occurring is naturally the first thought, but even when this possibility appears to be rigorously excluded at any given time, the sanitary engineer is still faced with the difficulty that his most trustworthy method of detecting pollution at any subsequent date is removed so long as the bacterial aftergrowth continues. In an attempt to investigate the extent, and, if possible, the cause of this phenomenon, a questionnaire was recently sent out by the American Public Health Association to 90 cities with a total population of 30 millions. Replies were received from 48 cities representing a total population of 25 millions. Fourteen cities with an estimated population of nearly 16 millions reported that they had had or were having trouble with bacterial aftergrowths. Among these cities there are 48 open reservoirs in use. The Committee on Water Supply of the A.P.H.A. recommends that water departments apply themselves to a study of these reservoirs with the hope that their number may be reduced to a minimum. However, there is evidence that open reservoirs are not the sole source of multiplying colon bacilli. Five cities state that there is increase in these organisms in the distribution system from sections where there is no possibility of the water coming from an open reservoir. Obviously there is need for more intensive investigation, and now that the problem has been defined such investigation will soon follow.

The Falling Death-rate.

The record in low mortality established in the first three months of this year by the Metropolitan Life Insurance Company is attributed in their statistical bulletin in part to the absence of any epidemic, but also to an all-round reduction with especial improvement for such important diseases as influenza, tuberculosis, pneumonia, diarrhoea, and chronic nephritis. The drop in tuberculosis has been so pronounced as to make it almost certain that a new minimum will be reached for this disease in 1930. The rate for white policy-holders for the first quarter is 65.3 per 100,000, and this is 10 per cent. lower than the previous lowest period for the first quarter. The death-rate from alcoholism shows a marked drop and for once cancer deaths are on the decline. Accidents as a whole remain in statu quo but automobile fatalities continue to increase steadily. Among the contagious diseases measles has been very prevalent of late, but fortunately the death-rate does not yet show a marked increase. Epidemic cerebro-spinal fever is more prevalent than it has been for some time.

Maternity in Dollars.

The present fashion for medical cost-accounting has produced two studies recently in the expense involved in childbirth. A professor in the Ohio State University finds that the cost of a baby in Columbus, Ohio, varies from nothing at all to \$602. The average expense to parents with an income of \$3000 or more is \$270; for those with an income

of \$1200 to \$3000 it is \$120; and for those whose income is less than \$1200 it is \$64. The investigator concludes that only the well-to-do and the dependent have medical care at childbirth that approaches modern standards of obstetrics. Others would purchase competent medical care if they had the means to do so.

Another study¹ comes from Berkeley, California, both of them covering the year 1928. The average cost in Berkeley was \$213 per baby. In half of the cases the cost was \$179 or less. Almost 10 per cent. were charged no physician's fee. The mean cost of the physicians' services was \$92, and the mean cost of midwives \$33, while the mean cost of trained nurses amounted to \$116. The other important item in the bill is hospital room \$82, or ward \$62.

SURGERY IN AUSTRALASIA.

EXAMINATIONS AND ETIQUETTE.

THE annual general meeting of the College of Surgeons of Australasia was held in Melbourne from March 24th to 27th. About 170 Fellows from all parts of the Commonwealth and New Zealand attended.

The Australasian and English Fellowships.

In his inaugural address, the President, Sir Henry Newland, of Adelaide, referred to the qualifications for admission to Fellowship of the college. It was probable, he said, that in the future, the ranks of the Fellows of the college would be replenished chiefly by young men who, soon after graduating, decided to undergo special training for the practice of surgery, which was insisted upon in the constitution of the college. Such candidates would be required to have one year's training as house surgeon or house physician, one year's training as senior resident officer at a special hospital, a general surgical qualification recognised to be of senior standing by the Council, and surgical experience gained by assisting the surgical members of the honorary staffs of the large public hospitals at operations and in the out-patient department. It was obligatory that the course should last at least five years after graduation.

It was probable, he said, that the primary Fellowship examination of the Royal College of Surgeons of England would be held in Australia in August or September, 1931, provided that not less than 25 eligible candidates offered themselves for examination. If this experiment proved successful, it would forge a link in the chain binding Australia to England, and would bring more Australian graduates intimately under the traditions of British surgery.

Two examiners in anatomy and two examiners in physiology, who shall be present or past members of the board of examiners in anatomy and physiology for the Fellowship, will be sent by the college from England. A professor of anatomy and a professor of physiology, or such other persons as may be agreed upon, shall be appointed by the council from names submitted by the College of Surgeons of Australasia, to act as assessors for the examiners. The expected deficit on the examination shall be borne equally by the two colleges. The Royal College of Surgeons emphasises the fact that the proposed scheme will be provisional and experimental only, and that it shall be free to decline to hold another examination in Australia without laying itself open to any suggestion of a breach of faith.

The suggested scheme has been circulated to all members of the council, and the replies are unanimously in favour of its adoption. The honorary secretary has therefore sent a reply to the Royal College of Surgeons, accepting the scheme, with the proviso that, if this trial Fellowship examination in Australia proves unsatisfactory for any reason, either college is free to refuse to repeat the experiment.

¹ Bolt, H. A.: Jour. Amer. Med. Assoc., 1930, xciv., 1561.

The Surgeon's Fee.

The following rules for the conduct of Fellows have been drawn up and approved:—

1. The patient, or the person legally responsible for him, must consent in the choice made of a surgeon to perform the operation. It is to be noted that such a consent would be an essential factor in the successful suit by a surgeon for the recovery of his fee.

2. Having been selected by the patient, or the person legally responsible for him, the surgeon is personally responsible to him for the operation. He is also responsible for, and shall conduct, the post-operative treatment, except by special arrangement with the patient, or the person legally responsible for him.

3. The surgeon must render his account direct to the patient, or to the person legally responsible for him.

4. The surgeon must not accept his fee for an operation from the practitioner in charge of the patient, unless the surgeon forwards a receipt for the fee received direct to the patient, or to the person legally responsible for him.

5. If circumstances compel the surgeon to delegate the post-operative treatment of a patient to another practitioner, the latter must collect the fee for so doing direct from the patient, or from the person legally responsible for him. The surgeon must not pay the practitioner in charge of the patient a fee for conducting the post-operative treatment.

6. Separate accounts for the assistant, anaesthetist, or for other necessary services—e.g., the pathologist—must be sent to the patient, or to the person legally responsible for him, or the surgeon must state on his account form the exact amounts due for these services.

7. The assistant's standard fee shall be not more than one-eighth of the operation fee, or, alternatively, not more than five guineas. When, owing to special circumstances, the assistant's fee is larger than this amount, the assistant must render his own account on his own account form.

8. The anaesthetist's standard fee shall be not more than one-eighth of the operation fee, or, alternatively, not more than five guineas. When, owing to special circumstances, the anaesthetist's fee is larger than this amount, the anaesthetist must render his own account on his own account form.

9. It is desirable that the practitioner in charge of the patient should be present at an operation on his patient. Should he have to travel any considerable distance for this purpose, the patient must be informed beforehand of the extra fee involved.

Affairs of the College.

The President reported that there are now 353 Fellows of the college (two of them honorary) and 14 junior Members. The balance-sheet showed that the finances were in a sound state, and though the *Journal* showed a deficit of about £133, the executive expressed its congratulations on the high standard maintained. The only nominations for the council were E. D. Adhern, A. L. Kenny, Sir Henry Newland, R. Hamilton Russell, and F. P. Sandes, the retiring members, who were accordingly re-elected. It is proposed that the college shall be incorporated under The Companies Act of one of the Australian States, and Victoria has been chosen. If it is decided later to apply for a Royal Charter, there will be nothing to prevent a dissolution of the incorporation.

At the inaugural meeting Prof. F. Wood Jones gave a lecture on Physical and Biological Concepts in Science, and at the conclusion of the meeting Mr. R. Hamilton Russell was presented with his portrait, painted by Mr. G. W. Lambert, A.R.A. In thanking the President and the college, Mr. Hamilton Russell recalled the association in his student days with Lord Lister, at whose feet, he said, he laid this tribute.

The last evening of the conference was devoted to scientific papers in the several sections.

LONDON FOOT HOSPITAL.—It is proposed to purchase the new freehold building at 33, Fitzroy-square for £18,000, but at present only £7000 is available. Last year's income on general accounts was £2461, but the expenditure was nearly £900 more, chiefly by reason of bank interest. A recent annual meeting was reminded that the hospital was the only one of its kind in Europe until similar work was undertaken in the provinces.

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, MAY 27TH–31ST, 1930.

PENAL CASES REPORTED BY THE DENTAL BOARD.

A FURTHER report of the Dental Board on the *Case of James Edgar Nelson* was considered in camera. The President announced that the Registrar had been instructed to erase Mr. Nelson's name from the Register.

The Case of Joseph Limbrick, registered as of 8, High-street, North Woolwich, "Dentist 1921." The Dental Board recommended that Mr. Limbrick's name be erased from the Register after consideration of the following facts, established before them by evidence:—

Limbrick was on Nov. 21st, 1920, at the Central Criminal Court, convicted on indictment for that he, on Oct. 23rd, 1920, married Dora Kates during the life of his wife Emily Jane, in respect of which he was sentenced to six months' imprisonment in the second division. He had been a Welsh miner and local preacher. He was married to his present wife on Dec. 31st, 1909, at the Congregational Chapel, Talbot-street, Oldbury. There were three children of the marriage. In June, 1910, Limbrick deserted his wife, who later in the same year obtained a separation order against him.

He went to Southampton, and there in August, 1926, met Dora Kates. Representing himself to be a widower he proposed, and they went through a form of marriage at Brentford Registry Office on Oct. 23rd, 1926. They resided at various addresses until 1928, when they moved to 8, High-street, North Woolwich.

In September, 1929, Limbrick became friendly with a patient named Alice Church, and at his suggestion she came to reside at 8, High-street, North Woolwich. He mis-conducted himself with the said Alice Church, and on Oct. 15th, 1929, left Woolwich with her in a car which he had and returned on the 18th. Meanwhile Miss Kates, having learned that his wife was still alive, had written to Limbrick saying so. On his return he taunted her about the letter and stated that she was no better than Alice Church.

Dora Kates, when she met Limbrick, had £1000. This has all gone. Alice Church had money which was used in part payment for the motor-car. The arrears of maintenance for the legal wife of Limbrick amounted to about £550.

Limbrick stated that he was being divorced, that he wished to marry Miss Kates as soon as possible, and to go with her abroad to practise dentistry. He had already obtained a passport.

The Dental Board's solicitor, Mr. C. J. Harper, and Mr. Limbrick addressed the Council. After deliberation in camera, the President announced that the Council had directed the Registrar to erase Mr. Limbrick's name.

The Case of Frederick William Osborn, registered as of 22A, Regent-street, Rugby, "Dentist 1921." The Dental Board found that the name of Mr. Osborn ought to be erased from the Register owing to the following facts, established before them by evidence:

Osborn had been convicted on Feb. 18th, 1930, at Rugby Petty Sessions, of feloniously stealing a banker's cheque value £4, the property of Harry Seal-Wilson, and had been fined £3 19s. and £1 1s. costs. He had pleaded guilty. Osborn had been employed by Mr. Seal-Wilson, a dentist, whose principal surgery was in Bloomsbury, but who had several branches about the country. Osborn had been manager of the Rugby branch at a salary of £5 10s. with commission. He had opened a letter addressed to Seal-Wilson which contained a cheque, endorsed it without authority, and used it for his own purposes. There were other cases, but only the one above-mentioned had been proceeded with.

In 1927–28 Osborn had embezzled the sum of £64 belonging to Mr. Seal-Wilson by taking letters containing cheques and endorsing them in Seal-Wilson's name. The latter, at Osborn's earnest request and solemn assurance that it should never occur again, overlooked the matter. Osborn had, however, again stolen his cheques, and the prosecution followed.

Mr. Osborn did not attend, and after deliberation in camera the President announced that the Council

had directed the Registrar to erase his name from the Dental Register.

PENAL CASES REFERRED FROM 1929.

The Case of Elizabeth Caroline Mudie, registered as of 3 Windsor-quadrant, Kelvinside, Glasgow, W., L.R.C.P. Edin. 1925, L.R.C.S. Edin. 1925, L.R.F.P.S. Glasg. 1925, who had been referred from the summer session, 1929.²

Mr. Harper said that the Medical Defence Union had received copies of the testimonials provided by Dr. Mudie and did not wish to prefer any further charge. Dr. Mudie said that she had no further connexion with the business in question and no longer derived any benefit from it. After deliberation in camera the President announced that the Council had decided not to erase Dr. Mudie's name from the Register.

The Case of William Mulhall Corbet, registered as of 66, Finsbury-pavement, E.C.2, M.B., B.Ch. 1915, N.U.Irel. who had been referred from the summer session, 1929. Mr. Corbet appeared. Mr. Harper announced that the Medical Defence Union had been furnished with a copy of the testimonials supplied by Mr. Corbet and had no further complaints to offer. The Legal Assessor read the testimonials, and Mr. Corbet gave assurances of regret and promises to refrain in future from the conduct proved against him. After deliberation in camera the President announced that the Council had not seen fit to erase Mr. Corbet's name from the Register.

NEW PENAL CASES.

The Case of Frederick Wyndham Chamberlain, registered as of Aylsham-road, Norwich, L.M.S.S.A. Lond. 1915, M.R.C.S. Eng. 1920, L.R.C.P. Lond. 1920, who had been summoned to appear before the Council on the following charge:—

"That you were at the Essex County Assizes, commencing on Feb. 10th, 1930, convicted of indecently assaulting two male persons under the age of 16 years, and were sentenced to 16 months' imprisonment in the second division."

Mr. Harper laid the facts before the Council and read the judge's summing-up at the trial. Mr. Chamberlain did not appear and was not represented. After deliberation in camera the President announced that the Council had found the charge proved to their satisfaction and had directed the Registrar to erase Mr. Chamberlain's name from the Register.

Alleged Adultery with a Patient.

The Case of Frederick William Barton (senior), registered as of 218, Stockwell-road, London, S.W. 9, M.R.C.S. Eng. 1889, L.R.C.P. Lond. 1889, L.S.A. Lond. 1889, who had been summoned to appear before the Council on the following charge:—

"That, being a registered medical practitioner, you abused your position by committing adultery with Mrs. Lizzie Catherine Thomas, a widow, with whom you stood and with whose deceased husband you had stood in professional relationship, of which adultery you were found guilty by the decree of the Probate, Divorce and Admiralty Division (Divorce) of the High Court of Justice, dated Jan. 10th, 1930, in the case of Barton v. Barton, in which you were the respondent. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

Mr. Barton did not appear and was not represented. Mr. Harper laid the facts before the Council and put in evidence the record of divorce proceedings. Mr. Barton admitted, he said, that Mr. Thomas had been a patient of his and that there had been a liaison, but said it had not occurred until some years after Mr. Thomas's death, when professional relationship had ceased. There was a declaration from Dr. Barton's son describing the relationship between respondent and Mrs. Thomas and the professional attendance of Dr. Barton on Mr. Thomas.

Mr. Harper called in evidence Mrs. Emily Allen Claydon, Mrs. Thomas's landlady, who testified to her statutory declaration, describing professional relationship between Dr. Barton and Mrs. Thomas, although she understood that Dr. Barton had made no charge.

Miss Alice Ellis, a church nurse, testified to her statutory declaration in which she said that Mrs. Thomas had told her that Dr. Barton had been their doctor for many years. She stated that he had actually attended Mrs. Thomas after her husband's death in 1925.

After deliberation in camera the President announced that the Council had adjourned the case for six months, in order that the respondent might appear.

Mr. Harper drew attention to the fact that this case concerned Frederick William Barton senior, of 218, Stockwell-road, and not the younger practitioner of the same name of 182, Stockwell-road.

A Conviction for Drunkenness.

The Case of Percy Bateman, registered as of 423, New Cross-road, London, S.E. 14, L.R.C.P. & S. Edin. 1909, L.F.P.S. Glasg. 1906, who had been summoned to appear before the Council on the following charge:—

"That you were on April 2nd, 1930, convicted at the Woolwich Police-court of the following misdemeanour—namely, of being drunk, and were fined 5s. or five days' imprisonment in default."

Mr. Harper explained that this single conviction followed on four similar convictions in 1927 and another in 1928. In the latter year the respondent had appeared before the Council and given an undertaking that conviction should never occur again. Six months later he had again been summoned for drunkenness, but had been admitted to a mental home in Camberwell before sentence had been passed. The story was in many ways a tragic one. Dr. Bateman had left the home too soon and his nerves had again given way. Mrs. Bateman had then secured a small house on the Deconcrete estate and there the doctor had obtained an appointment on the panel. The present conviction arose out of a meeting with a publican friend on the day the respondent had received a small cheque for panel fees. The doctor had remembered no more until he had gone up to a policeman and invited arrest. Next day he had been convicted, and admitted into the Nunclon home of the C.E.T.S. on a specially reduced charge which Mrs. Bateman was now struggling to pay, week by week. Mr. Harper read two letters from the respondent, one from the superintendent of the home, and one from the police commissioner. Dr. Bateman's letters expressed no regret and admitted no drunkenness but spoke only of loss of memory and overwork; he undertook to remain in the home for 12 months. The superintendent said that the doctor was suffering from nervous breakdown, but was improving; he hoped ultimately to do medical work in more congenial surroundings. Mrs. Bateman confirmed the facts set out by Mr. Harper.

After deliberation in camera the President announced that the Council had postponed judgment on the conviction proved against Mr. Bateman for 12 months.

Removal of Name.

The Registrar reported that the three degrees held by Mr. William Wolfe Glucksman had been withdrawn, the L.R.F.P.S. Glasg. 1929, having been recalled in February last. The committee reported that they were satisfied that Mr. Glucksman had not been deprived of his qualifications on the ground of the adoption of any theory of medicine or surgery, and the Council directed the Registrar to remove Mr. Glucksman's name from the Register under Standing Orders, Chap. 13, ii., 7.

Alleged Convancing and Alienation of Patients: the Case Dismissed.

The Case of Arnold Fletcher Doyle, registered as of Highbury, Old Hill, Staffs., M.R.C.S. Eng. 1923,

¹ THE LANCET, 1929, I., 1213.

² THE LANCET, 1929, I., 1216.

L.R.C.P. Lond. 1923, M.B.; B.S. 1924, U. Lond., who had been summoned to appear before the Council on the following charge:—

"That, being a registered medical practitioner, and while engaged as assistant in his practice to Thomas Ellis Mitchell, M.B., and subsequently, you endeavoured to attract to yourself the patients of the said Thomas Ellis Mitchell, and in one instance of Dr. A. McQueen, by various improper means and in particular: (1) By canvassing such patients either directly yourself or by means of an agent. Patients so canvassed were Mrs. Daisy Homer, Mrs. Florence Plant, Samuel Jackson (a patient of Dr. A. McQueen), Mrs. Emmie Willetts, Mrs. Clara Tommey, Mrs. Kate Maguire, and Miss Lucy Coley. (2) By substituting without authority your name for that of the said Thomas Ellis Mitchell on the medical cards of certain patients of his—namely, Norman Leslie Clark, Horace Priest, and Mrs. Lily Sidaway. (3) By asking the secretaries—viz., Dan Adams Priest and Benjamin Troman, of the Women's Clubs of the said Thomas Ellis Mitchell for lists of members and for their help in getting you the members as patients. (4) By depreciating to patients of the said Thomas Ellis Mitchell the capabilities of himself and of his dispenser, Miss Mary Constance Wilkinson. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

The complainant was Dr. T. E. Mitchell. Dr. Mitchell was represented by Mr. T. C. Carthew, counsel, instructed by Messrs. Taylor, Jelf and Co. Dr. Doyle was represented by Mr. Ward, instructed by Messrs. Jeffrey, Wild and Lovatt.

Mr. Carthew, opening the case for the complainant, said that in September, 1923, Dr. Mitchell had advertised for an assistant in the *British Medical Journal* and Dr. Doyle had been appointed, but no agreement had ever been signed. An agreement in the usual form had been put forward by complainant in April, 1929, but respondent had then refused to sign it. Respondent had taken over the panel patients of his predecessor, acting as deputy for him until the end of 1928, and at the beginning of 1929 the patients had been transferred. In August, 1929, complainant had found respondent "storming at" the dispenser, and said that complaints should be brought to him in the first place. Respondent had said he had been very dissatisfied with the dispensing and had set traps for her; he had added that for "two pins he would twist her blinking neck." Thereafter he had made up his own prescriptions. Soon after respondent had demanded that Dr. Mitchell should sell him a share of the practice. Dr. Mitchell had refused, having a son qualifying at Guy's. He had then taken proceedings in the County Court to terminate the assistantship, as respondent refused to accept the sum offered in lieu of notice. The new assistant had found that in several panel cards Dr. Mitchell's name had been scratched out with pen or knife, and that Dr. Doyle had signed his name in its place. Respondent claimed that this was done with complainant's knowledge because his panel was full; complainant denied this. In September or October Dr. Doyle had started a women's club in the same town and had approached secretaries attempting to secure members from other clubs. Patients would testify to respondent's canvassing. There was evidence that respondent had gone into a patient's house the day after complainant had called and prescribed, and had advised the mother to throw the medicine down the sink.

Dr. Mitchell testified to his statutory declaration, and in reply to cross-examination confirmed the facts as set forth by his counsel. There had been no discussion whatever of possible partnership at the first interview with respondent. He could not say how many panel patients had been allocated to Dr. Doyle by the Allocation Committee on Jan. 1st, 1929. It might have been over 1500, but he did not admit that that proved that the committee regarded Dr. Doyle as a partner or prospective partner. His own panel list had never been full or complete and he was prepared to prove it: the figure of 2503 was the "reputed" and not the "actual" figure.

In reply to the Legal Assessor, he said that when cards were brought to his surgery with the name

of a doctor on them he had never given any authority to Dr. Doyle to erase the name, and he had never seen it done, nor known of its being done. Two of the cases had been discovered before Dr. Doyle left, but he had not personally taxed Dr. Doyle with them. When cards were brought in with no name on them complainant usually signed them, but in his absence cards were usually handed to the panel clerk for subsequent discussion between the two doctors. All panel cards had—or should have—passed through complainant's hands. If numbers were exceeded the onus was on the panel committee to give notice to reduce; he had never received such notice.

Three panel cards were put in evidence, two showing erasures, and complainant declared that he had never given authority for the erasures.

In answer to Dr. H. B. Brackenbury, through the chair, complainant said that Dr. Doyle had signed cards in his own name, not "pro Dr. Mitchell." He did not know at all whether Dr. Doyle's name had appeared on the county medical list as an assistant or a separate practitioner.

Horace Priest and Mrs. Lily Sidaway testified to their statutory declarations and insurance cards, on which Dr. Doyle's name had been substituted for Dr. Mitchell's.

Mr. Dan Adams Priest and Mr. Benjamin Troman, secretaries of women's clubs, testified to their statutory declarations, and stated that Dr. Doyle had asked them for lists of club members. Mr. Troman said that respondent had said he had already 200 members out of that club and had added "You'll see what you can do," presumably implying a desire to be appointed doctor of the club.

Miss Daisy Homer appeared as a witness on behalf of her mother, who was ill. She had been present throughout the whole interview between her mother and Dr. Doyle. Dr. Doyle had called and said he and Dr. Mitchell had split partnership and he had started a club on his own which her mother might join; she might also tell other people in the house and other panel patients.

Mrs. Florence Plant and Mr. Samuel Jackson testified to their statutory declarations. Mrs. Plant said she had got the impression from Dr. Doyle that Dr. Mitchell was retiring and had called at the latter's house to ask if it were true. Mr. Jackson said that Dr. Doyle had told him to get transferred to his panel list and he could cure him. He had paid for three bottles of medicine from Dr. Doyle but had been Dr. McQueen's panel patient all the time.

Mr. Norman Leslie Clark and Mrs. Sarah Ann Hill testified to their declarations. Mrs. Hill stated that Dr. Doyle had asked her if she had any medicine from Dr. Mitchell for her son; she had never at any time complained about the medicine. Dr. Doyle had told her it was no good and told her to throw it down the sink and she had done so.

Mrs. Kate Maguire recounted an argument in her presence between the two doctors as to whose panel patient she was. She had never at any time been on Dr. Doyle's panel. Dr. Doyle had said "Take no notice of him; the old man's going off his head." He had not said "going off the deep end."

Miss Mary Constance Wilkinson, the dispenser, confirmed the material facts. She had heard Dr. Doyle say to a patient (Frederick Rock) that Dr. Mitchell would soon have him stiff and cold. She had dispensed for Dr. Mitchell about three years before Dr. Doyle arrived, and neither Dr. Mitchell nor his former assistant had ever made any complaints.

In reply to the President, she said that Dr. Doyle's complaint had been that she had omitted some magnesium sulphate from a bottle of medicine; no steps had been taken to test for magnesium sulphate. She maintained that this drug had never been put on the prescription.

In reply to the Legal Assessor, she identified Horace Priest's panel card and denied absolutely having made the erasure and substituting Dr. Doyle's

name. She had not seen the card before the erasure had been made.

Mrs. Mary Evans testified to her statutory declaration describing canvassing by Dr. Doyle.

Dr. T. F. Tibbetts, chairman of the Dudley Panel Committee, testified that a panel doctor, at the relevant period, was allowed 4000 patients, 2500 for the principal and 1500 for the assistant. It was not true that the number for an assistant was limited to 1000.

In answer to the President, he said that the numbers were estimated by the amount paid quarterly; it was not an absolute number of names. In answer to Sir Robert Bolam, through the chair, he thought that a panel of 3000 would probably mean a number of credits of about 2800. In answer to Dr. H. B. Brackenbury, through the chair, he agreed that it was the practice in Staffordshire to allow the principal to increase his panel from 2500 to 4000 if he took an assistant, and there was no ruling as to how many belonged to each.

Dr. Doyle, examined by Mr. Ward, declared that he had taken the assistantship with a view to partnership and had signed forms for the insurance committee, with Dr. Mitchell's knowledge, stating that he was in partnership. At that time Dr. Mitchell had said that this was stretching the regulations slightly, but that, as Dr. Doyle was going to buy a share, it did not matter. The allocations had been made to respondent personally and his name had appeared as a separate doctor on the medical list. On Norman Clarke's card Dr. Mitchell's name had been crossed out by him as part of the routine of the practice; he had signed some hundred cards, some blank and some with Dr. Mitchell's name on them. No complaint or comment had ever been made and Dr. Mitchell had had all the fees. He emphatically denied ever erasing anything from Horace Priest's card and was certain that the handwriting of the name of "Dr. Doyle" was not his writing, though the signature "A. F. Doyle" was. He had asked the secretaries of the clubs to put his name up as one of the doctors who might be chosen by the members as their doctor; he did not consider that he was doing anything wrong. He had been treating members of the clubs ever since he had been there. A list of members would not have been the slightest use to him and he had never asked for it. He had said to Mr. Troman that if he did not get on the club he would be forced to form a club of his own. He had no need to ask for help in getting patients; he had 2000 on his list at the present time. About 800 of the original 1500 panel patients had transferred back to Dr. Mitchell and 500 or 600 new patients had joined him from other doctors. He denied the canvassing charges. He maintained that the district was seriously under-doctored, and that Mrs. Hill had complained to him that the medicine was not doing the boy any good. He had never told her to put it down the sink, but he had known the medicines were not being dispensed correctly and had told her to send for something else. He had not blamed Dr. Mitchell for it and had not told Dr. Mitchell that he had changed the medicine. On many occasions he had watched Miss Wilkinson dispense and noticed her putting in less than he had ordered. No prescriptions were ever kept. He had never discussed Dr. Mitchell with Mr. Rock or any other patient. He had always had regard to the etiquette of his profession in all his dealings.

Cross-examined by Mr. Carthew, respondent said that he had been a stranger to the district before he went as Dr. Mitchell's assistant. He asserted that every one of the doctors in the neighbourhood was against him. He knew that Dr. Mitchell had a son a medical student, not that he had always had a salaried assistant. If he had complained to Dr. Mitchell about the dispenser she might have got into more trouble; he was not in the habit of going behind people's backs.

The Legal Assessor asked if respondent thought she was misdispensing from incompetence or wilfulness,

as he had said he thought she might improve if he spoke to her direct. Dr. Doyle replied that he did not wish to make any suggestion. Mr. Carthew quoted respondent's evidence "I do not know whether she did it carelessly or from some other reason" and asked what reason. Dr. Doyle suggested laziness, as the magnesium sulphate was in a heavy bottle on a high shelf. Pressed by Mr. Carthew, he said he did not wish to give any other explanation. Complainant had promised him an appointment, but had put off the preparation of the agreement from day to day until he had sprung the bombshell of instant dismissal, leaving him with a panel of 1000 on his hands and nowhere to go. He had no recollection of Horace Priest among his many patients, but could only suggest as likely to erase a name those people who handled the cards—viz., the patient, his mother, the dispenser, or Dr. Mitchell himself. He took it for granted that he had authority to cross out Dr. Mitchell's name and substitute his own.

Mr. Carthew established that the usual arrangement in the district was for each club to have one doctor, appointed by a two-thirds majority of the members, and the club was known as "Dr. So-and-So's club." Two doctors were only found in combination on a club if they were in partnership. Dr. Doyle explained his request to be appointed medical officer to Dr. Mitchell's clubs as due to his ignorance of their rules and customs at that time; he would not so apply now, but did not admit that such an action was an improper one and an attempt to flich away patients. He would have no objection to any other doctor applying to his club, because he knew the application would have no chance. He had prescribed for and charged Jackson, knowing that he was Dr. McQueen's patient; he had disliked doing it but Jackson had urged it. Dr. Mitchell knew about it and took the money; respondent assumed that Dr. Mitchell knew Samuel Jackson was Dr. McQueen's patient. He had said "Here's two shillings for a bottle of medicine from Samuel Jackson"; he flatly denied that Dr. Mitchell was ignorant of the whole transaction.

In answer to the Legal Assessor, respondent agreed that the letter written by Dr. Mitchell to him after the interview contained no reference whatever to any idea of partnership. He would never have considered going but for the verbal promise of a partnership and had accepted the position on that letter because he relied on Dr. Mitchell's word. He had signed Priest's card with the erasure on it, but had not mentioned the erasure to anybody. He did not remember whether he had had other cards with erasures on them.

In reply to members through the chair, Dr. Doyle said that all the patients of whom he had spoken to the club secretaries had come to him in the five or six weeks after he had broken with Dr. Mitchell. He had worked on the panel for about three years and when he had written to the clerk of the insurance committee he had believed that the clerk could give the patients a chance to return to Dr. Mitchell. The clerk had called about three days later and explained, and suggested that a card of change of address be sent to all patients on Dr. Doyle's list. No other information had been given, and there had been nothing in the notice to suggest any breach with Dr. Mitchell. Dr. Mitchell ran an insurance practice of 4000 with the assistance, successively, of Dr. Roberts, Dr. Clark, and Dr. Doyle, and each of these gentlemen obtained their patients from Dr. Mitchell's practice. Dr. Doyle declared that Dr. Clark had personally transferred the practice to him, but for no consideration. He knew that there was a definition of a partner in the National Health Insurance Act; he had never been allowed to bring himself within that definition. He had offered to pay Dr. Mitchell for his share of the panel. He considered that if he had left the district he could have transferred his panel to someone else for a consideration.

Dr. Eason, through the chair, asked who had made the statement to the Staffordshire official that

Dr. Doyle was a partner. Mr. Ward replied that the documents had been asked for and refused by the Insurance Committee.

Re-examined by Mr. Ward, Dr. Doyle said that the contract with the National Health Insurance made him stay in the district or provide a deputy for three months after giving notice. He had had a letter from Dr. Mitchell on Oct. 4th, 1928, saying that as the joint panel slightly exceeded the number allowed for one practitioner and an assistant, Dr. Doyle would have to act as a salaried partner, on which an agreement would have to be signed. In April Dr. Mitchell had put forward a form of agreement offering the status of partner but with a clause saying that there should be no claim on the goodwill of the practice. This Dr. Doyle had refused to sign. After the split Dr. Doyle had taken his solicitor to see the clerk of the Insurance Committee to see what should be done, and he had followed the clerk's instructions precisely.

Mr. Alfred Lovatt, Dr. Doyle's solicitor, testified to being present at the interview between his client and the clerk to the Insurance Committee.

Mrs. Florence Doyle confirmed Dr. Doyle's account of the interview with Dr. Mitchell, stating that Dr. Mitchell had promised a two-fifths share in 12 months. This was their first interview.

Cross-examined, she could not remember Dr. Mitchell's words, but he had said that he had been considering taking a partner and that he would offer a partnership. The 12 months might have been to give Dr. Mitchell time to consider whether he liked Dr. Doyle or not. The offer had not been made until after an hour and a half's conversation, and Dr. Doyle had repeatedly said that he would not go to Old Hill without the promise of a partnership.

Sir Robert Bolam asked through the chair if the price of the partnership had been discussed. Mrs. Doyle replied that she did not think so, but that she had not been present the whole time.

Arthur Harvey Cole, a hairdresser and a patient of Dr. Doyle's, confirmed Dr. Doyle's account of the complaint about his third bottle of medicine. Cross-examined, he said he did not know whether the mistake was in the prescribing or in the dispensing. Dr. Bone pointed out that witness had said he had put the medicine down the sink, whereas his statutory declaration said that Dr. Doyle had taken it back to the surgery. Witness said the declaration was right.

Mrs. Ellen Davis testified to complaining of the medicine to Dr. Doyle. Cross-examined, she said she had no idea what was wrong, but one bottle had smelt after a day or two; the first few doses had been all right. In reply to the President, there had been nothing wrong when she had received it.

Frederick Rock testified to his statutory declaration, saying that his wife had obtained relief from some bottles of medicine and not from others. He had never discussed Dr. Mitchell with Dr. Doyle.

Mr. Ward and Mr. Carthew then addressed the Council. After deliberation in camera the President announced that the facts alleged against Dr. Doyle had not been proved to the satisfaction of the Council.

The Case of Hans-Raj, registered as of 40, Clifton-street, Bilston, Staffs., M.R.C.S. Eng. 1925, L.R.C.P. Lond. 1925, who had been summoned to appear before the Council on the following charge:—

"That, being a registered medical practitioner, you have canvassed patients of Fakir Chand, M.B., for whom you formerly acted as assistant, with a view to their transferring from his panel to yours, and in particular the following patients—viz.: (1) In or about the month of February, 1929, Florrie May Watts. (2) In or about the month of March or April, 1929, Arthur Jeavons. (3) In or about the month of May, 1929, Joseph Caddick. (4) In or about the month of May, 1929, William Lewis. (5) In or about the month of June, 1929, Thomas Blevitt. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

The complainant was Mr. Fakir Chand, M.B.; Mr. Hans-Raj was represented by Mr. Freibusch, solicitor. Mr. Chand conducted his own case. He

related his medical history and his association with the respondent, and put in five statutory declarations from patients supporting the charge of canvassing. He was unable to produce witnesses. After cross-examining complainant, Mr. Freibusch submitted that he had no case to answer. After deliberation in camera the President announced that the Council agreed with this submission, and the case was therefore dismissed.

Alleged Seduction of a Patient: the Case Dismissed.

The Case of Abraham Hipwell, registered as of 1, Homefield-place, Heavitree, Exeter, L., L.M. 1906, R.C.P. & S. Irel., D.P.H. Liverp. 1909, who had been summoned to appear before the Council on the following charge:—

"That you abused your position as a medical man by seducing a patient—namely, Mrs. Hilda Annie Spike—whom you were attending professionally, and also by behaving or attempting to behave improperly to her on divers occasions subsequently while she was still your patient. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

The complainant was Mrs. H. A. Spike; who was represented by Mr. F. S. Laskey, counsel, instructed by Mr. J. C. M. Dyke.

Dr. Hipwell attended in answer to his summons, and was represented by Mr. H. A. Singleton, K.C., and Mr. T. C. Carthew, counsel, instructed by Messrs. Le Brasseur and Oakley.

Mr. Laskey said that Mrs. Spike was a widow whose husband had been killed in 1917; she had two sons, aged 15 and 17 respectively. Respondent had been her regular medical attendant. Until 1927 she had enjoyed good health, but in that year she had had a vulval cyst which had been removed in August in a nursing home. She had to return for further operative procedures in September. Respondent had attended her after she had left the home once before Oct. 27th, but had not examined her. About a week before that date she had asked for an examination to be sure everything was all right. On that day he had called and seen her in bed. A servant was present in the house, but Mrs. Spike had not been anxious to have her in the room, and neither party pressed the suggestion. The doctor had held her on the bed with his left hand and had connexion with her. She had made no effective resistance, but she maintained that at this time her will had been entirely dominated by that of the doctor. It had all happened very quickly. In consequence she had become pregnant, of which fact she had become certain in January, 1928. Respondent had then four times supplied her with medicines; she had kept the three last bottles, which were in evidence. Of these the first had contained Epsom salts, the second contained ergot, and the third was innocent, containing a mild tonic and Epsom salts. At the end of January she had again assured the doctor that she was pregnant; the doctor had performed some operation from which she had suffered intense pain, and there had been an abortion. Since then her health had been seriously affected, and she had attended several doctors, including respondent. Her explanation was that her illness was due to the doctor's actions, and he ought to cure her. In March, 1928, she had asked definitely if she could be cured, and told him he ought to help her; he suggested paying a sum of money towards her expenses, and in April or May a solicitor acting on the doctor's behalf had called on her, offered her a loan—which was refused—and finally handed her £30 unconditionally. In March a series of X ray photographs had been taken after a bismuth meal. The photographs handed to Mrs. Spike by Dr. Hipwell were not complete; she had seen the negative of the one missing one, which showed the uterus. Subsequently, when she had asked for this picture, respondent had said that he did not possess it. The photographs had been handed to complainant's medical adviser. Her brother, in August, 1929, had interviewed respondent with her; he had said, "This

will be a very serious thing for me." In December complainant's adviser had written to respondent threatening proceedings; his advisers had repudiated liability and suggested that complainant's motive was blackmail. Her advisers had then stated that she only wished to be cured, by respondent if necessary, but at all events to have her expenses paid.

The complainant, examined by Mr. Laskey, testified to her statutory declaration. She had known Dr. Hipwell since 1920 or 1921. On Oct. 27th, 1927, respondent had examined her internally, and said that the womb was a little lower than it should be. He had told her to get out of bed, and she had obeyed. He had put his hand under her nightdress, an action which at the time she had thought was for examination. He had directed her to lie on her back on the bed; then assaulted her. After the assault he had said, "I am sorry, it is all my fault." He had instructed her to use a syringe. She had not screamed, as she had been under his power. Respondent had leant over her, fixed his eyes on hers, and she had felt she had no power to resist. He had then left the house. Subsequently, in December, respondent had treated her for a boil. She confirmed counsel's account of her pregnancy and the consultation in January. Respondent had given her the medicine referred to in counsel's opening, and subsequently had examined her at his surgery and performed the operation which had led to the abortion. In showing her the skiagram now alleged to be missing, respondent had said that it was a photograph of the stomach, but witness thought it represented the uterus. She had taken respondent the bill for the photographs, and he had paid her the amount in notes. In January she had gone to another medical attendant who had dropped her case after a short time, and she had returned to respondent. In March she had threatened to claim damages, and he had offered £20. She had asked that compensation be paid through a solicitor, and £30 had been paid. She had given no receipt. On another occasion, in the summer of 1928, respondent had asked her to lie on the sofa in his surgery, and she had refused. On other occasions when he had been examining her he had undone his clothing, and she had told him to behave himself. Her illness in 1928 and 1929 had consisted chiefly of repeated vomiting and pain in the left side. Respondent had never sent an account for his services.

Cross-examined by Mr. Singleton, witness admitted having written a letter to respondent on May 10th, 1928, asking for a loan and for a consultation. She admitted having asked for more money from respondent's adviser in April, 1929. In December, 1929, after the visit with her brother, she had visited respondent's surgery again with her son and had asked to see his wife; he had telephoned or pretended to telephone to the police.

The doctor had put his arm round her waist, before October, 1927, just once; he had not had the chance to do it again. She had not complained to respondent that the surgeon had ruined her or disfigured her. She considered that respondent had exercised hypnotic influence; she presumed that the seduction was due partly to that and partly to her weak state after the operation. She had not visited the surgery on Oct. 27th. The medicines were all in the bottles she had received them in; the doctor had given her prescriptions which she had taken to a chemist. The medicine in the bottles was the original medicine. He had said, "Take this for my sake." She had kept the bottles for over two years, but had never taken any. She had not kept them for any special reason, and had not changed the contents of the bottles. She had not kept any more. She had visited the surgery on Jan. 27th, when he had performed some operation; he had then told her to go away at once as she would be very ill. She did not visit the surgery next day. She admitted that in January, before the 27th, she had been having slight three-weekly periods. She had asked respondent if at that time it was possible to have periods when pregnant, and he had

said it was not. Respondent had suggested the X-ray examination "to clear himself"; she had threatened. In March to take her life if she suffered much more pain. She denied having ever been treated for her nervous temperament—which she admitted. She denied that she had continually asked respondent for money to go away for a rest, according to a second doctor's advice. She alleged that a short time before her letter asking for money respondent had offered her £25 in his surgery; she had refused, but her expenses had increased and so she had written the letter. She could not give any details of this expense. The money paid by the solicitor had not in any way been given as hush-money. She had continued attending respondent regularly until September, 1929. She had gone to his solicitor again in April, 1929, to discuss her expenses. In spite of her solicitor's letter threatening proceedings unless respondent suggested some form of compensation, she denied that her object was money "in the way Dr. Hipwell put it."

Re-examined, she said that she had been ordered two abdominal belts, one in 1928 and one in 1929; she had gone to see respondent's solicitors just after receiving the second account, in response to their invitation to inform them if she incurred any further expense. Witness stated that respondent had himself handed the medicines to her, and that she had not obtained them from a chemist.

Mr. Frank Edward Street, brother of the complainant, examined, stated that her health had been good until the end of 1927. In the early part of the summer of 1929 he had interviewed respondent with his sister. Cross-examined, he admitted that he had said twice that he had not come for blackmail, but had said at the end of the interview that he was very dissatisfied and would put the matter in other hands. He had gone to respondent to hear his account of the matter. He said that, from his sister's account, he thought that respondent could only have been attempting to procure abortion, but admitted that he had not said this in his statutory declaration. Respondent had denied performing an operation, and had shown an object which he had said was a torch, which he said he had used. In reply to a question through the Chair, witness said that he had not known that his sister was at all in want of money.

Mr. Singleton addressed the Council before calling witnesses for the respondent. He said that, but for the payment of the £30, the case would obviously be unproved. Respondent's solicitor had made the payment on his own initiative. If he had made no payment, the charge would never have been brought. Moreover, respondent had acted unwisely in continuing to attend the complainant. The medicine containing ergot had been prescribed for frequent periods, and counsel proposed to show that the bottle produced was not that in which it had been dispensed.

Dr. Hipwell, giving evidence on his own behalf, stated that complainant's record showed attendance since 1922. She had complained that she had been "ruined" by the second operation at the nursing home, and he had examined her on that occasion, about Oct. 10th, in his consulting-room. He had not visited her on the date of the alleged assault; she had visited him, and he had prescribed bromide and arsenic for nervousness. He had never had intercourse with her at any time, nor had he put his arm round her waist. The labels on the bottles were all in his writing. The ergot prescription had been one for a chemist, as he had stocked no ergot. All the labels on bottles dispensed by him were numbered in series, corresponding to the date; all the three bottles produced were dated June, although they contained medicines prescribed in January. The object of the ergot mixture had been to check flooding. On Jan. 23rd, 1928, complainant had been suffering from metrorrhagia and fortnightly periods, according to a note made at the time. She had not been pregnant, and had not suggested she was pregnant until March just after he had made an internal examination.

He had not examined her in January, and had never operated for any purpose at all. Her first suggestion against him had been on March 8th or 10th; she had then said that he must have used some instrument, "because he had hurt." She had also accused him at that time of causing her pregnancy. She had then been rather hysterical and suffering from a certain amount of pain; witness had suggested a second opinion or an X ray. No photograph was missing; he had paid for the films. No photograph had ever been taken of the uterus. The second opinion had prescribed a rest and change. Complainant had then said she was worried about money matters, but witness had never offered her £25. He had visited his solicitor, Mr. F. P. Cottey, after receiving complainant's letter, and Mr. Cottey had paid her money with witness's knowledge in May, 1928. Respondent had continued attending her as a patient until September, 1929. She had asked him for more money in May, 1929. She had collected and paid him a small sum from some sickness club, but had paid him no other fees. At the interview with the brother the only suggestion had been that of hurting complainant; seduction had not been mentioned. Witness had pointed out that he could have performed no operation; no preparation had been made, and no instrument used, and the couch was an unsuitable one, covered with chintz. He had shown an electric torch that he had used. On Dec. 2nd, 1929, Mrs. Spike and her son had visited him. She had first said that she wanted witness to cure her, and he had refused. She had then refused to go without seeing his wife, and he had telephoned to the police. She had then gone away, but had come to his door on Dec. 7th and handed him an empty envelope, with the address of the General Medical Council written on the back. Witness had occasionally helped patients by advancing them money. He had allowed complainant to have £30 because her financial worry had been making her condition worse. He had helped her in every way throughout.

Cross-examined, witness admitted that he was not a rich man, and that complainant had not asked for money or assistance before 1928. He had not regarded her demands at first as directed to obtaining money, but had thought she wanted to be cured. She had blamed him for her illness earlier, and he had walked out of her house and refused to treat her; she had retracted her accusation after going into a nursing home and being treated by Dr. Roper. She had not made the accusation to him personally in May, whatever she had said to Mr. Cottey. Asked why he had put the matter into Mr. Cottey's hands, he said he had wanted her to get mentally better, but that if he had handed her money he would have admitted himself liable for some injury. He had chosen the solicitor as a means of helping her to get better; she had not then been making accusations, but had threatened to do herself an injury. He had never helped other patients through a solicitor, but they had not been hysterical or invalid. He had often advised her to go to another doctor. He had no record nor recollection of seeing her in her room at any time. He had never shown her any X ray negatives. He had never told Mr. Cottey to tell complainant to come back if she had any further expenses. At the interview he had told complainant that her statements were a figment of the imagination. He had not taxed her with lying, although she had demanded money more than a year before, and he had paid it; he had tried to prove that the injury was an imaginary one. He had not sent in an account after the end of 1927, because he had been giving her money to carry on.

Re-examined, he said he had never made up an ergot medicine. To a question through the chair, he said that the accusations had preceded the payment of money, having been made in March.

Mrs. Winifred Kate Hipwell, wife of respondent, said that her relations with her husband had always been happy and normal in every way. Complainant

had accosted her in the street and accused respondent of "nearly killing" her.

Mr. F. P. Cottey stated that he knew of other cases in which respondent had advanced money to patients. On May 11th, 1928, respondent had seen him in his office and produced the letter from complainant asking for a loan, and described the charges she had made against him. In the afternoon witness had seen the records of the case. The payment had been left absolutely to him. When he had left the surgery he had not decided whether or how much to pay her. He had drawn £30 from his office and, after seeing Mrs. Spike, had paid her, and had informed respondent by telephone. No sum had been discussed between him and respondent, but only certain expenses complainant would probably incur. At his interview with her she had said she would need money for her rest, and did not like to touch her sons' money or some she had had from her father. He had not asked for a note of acknowledgment, and had prepared no document of any kind. He had acted for respondent on his own advice. Complainant had not made any accusation on that occasion. Witness took entire responsibility for the payment. He had known that a suggestion of accusation had been made in March, but should never have paid any money if a charge had been made at the interview. He would never pay money for the withdrawal of a charge. In April, 1929, complainant had come to his office to ask for more money. He had met her a second time that day, coming out of his office with some third party. On a later occasion he had visited complainant's solicitors at their request, and they had suggested a sum of £300 or £400 as compensation. He had immediately advised respondent to consult Messrs. Le Brasseur and Oakley. Mr. Street, in visiting him, had complained of "injury" to his sister, and had not mentioned damages; he had advised him to see respondent personally. Later in the year complainant's solicitors had informed him that they had dropped the case, and that another firm had been instructed and had sent for the medicine. Cross-examined, he assured counsel that he would not have touched this matter if he had had the slightest suspicion that anything was wrong. With the exception of one reference by complainant to an illegal operation, no charge had ever been made. The surgery was only about 10 ft. by 10 ft.; every sound made in it could be heard outside, and anyone was liable to come in at any moment. He had thought that he was merely dealing with a genuine application for a loan.

The Council, after deliberation in camera, decided that they did not desire to hear any further evidence in defence. Mr. Laskey thereupon addressed the Council. After further deliberation in camera, the President announced that the Council had not found the facts proved to their satisfaction.

Adultery Proved in the High Court.

The Case of Andrew Alexander Fyffe, registered as of Martham, Great Yarmouth, M.R.C.S. Eng. 1912, L.R.C.P. Lond. 1912, who had been summoned to appear before the Council on the following charge:—

"That you abused your position as a medical man by committing adultery with Doris Esperanza Rosemary Chicheley Ferrier, a married woman, with whom you stood in professional relationship, of which adultery you were found guilty by the decree of the Probate, Divorce and Admiralty Division (Divorce) of the High Court of Justice, dated Dec. 3rd, 1929, in the case of Ferrier v. Ferrier, Thorp and Fyffe in which you were co-respondent. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

There was no complainant in this case.

Mr. Harper, solicitor to the Council, outlined the facts as stated in the charge. He put in the transcript of the shorthand note taken at the trial, the evidence in which had occupied eight days. This showed that a special jury had found after five minutes' deliberation that adultery had been committed; also that respondent had been in professional relationship with Mrs. Ferrier. He read extracts from the summing-

the numerous applications for admission received from the United States had been from students who, from the educational and personal point of view, deserved admission.

"In addition to applicants who have not entered upon their medical curriculum in America, but have passed examinations with that object, there are some who, after a period in an American university or school have received 'honourable dismissal.' In view of the fact that those who obtain the qualifications of the Conjoint Boards in England, Scotland, and Ireland are entitled to take the examination of the National Board of Medical Examiners and, if this is passed, to obtain registration in the majority of the United States, it is highly desirable that no American students, who for one reason or another have not been considered satisfactory in their own country, should be admitted to medical schools here."

With reference to students who wish to study abroad, not because they cannot gain admission in America, but because they wish to enjoy the benefits of education abroad, the Registrar suggested that there should be no difficulty. The letter concluded by stating that the whole question would come before the Education Committee of the Council, and inviting information as to what documents American students who wish to study here should be asked to produce: (1) if they have never obtained admission to an American medical school, (2) if they have received "honourable dismissal" from an American school, and (3) if they have been satisfactory students in America and desire to enjoy the benefits of education abroad.

Dr. W. C. Rappleye, the Director of Studies of the Commission on Medical Education organised by the Association of the American Medical Colleges, who was present at the meetings of the Council held in May last, was also asked for his views, and replied as follows:—

"Thank you very much for your last letter telling about the action of the Council regarding applications from American students. I notice that the statement required is 'from the dean of a medical school which is a member of the Association of American Universities.' Only 55 of the 70 approved medical schools are in universities which are members of that Association, but all of the approved medical schools (formerly designated as Class A) are members of the Association of American Medical Colleges. I mention this because you may get a statement from one of the 15 schools which does not belong to the University Association, but which is in equally good standing and a member of the Medical School Association.

"The most common cause for not accepting applicants for admission to medical schools here is designated 'class full.' Many students rejected for that reason have met all the requirements for admission to that school, it is the least objectionable designation by which students can be rejected for personal or racial reasons. I mention this, also, because you may get statements from some of the deans over here that they would have accepted a given student if the class had not been filled.

"Possibly the best way to deal with this problem of American students in the British schools would be for you to accept no students except those who have had one or more years in an American school, and then only on evidence that the work here had been entirely satisfactory. I suppose it would be necessary to make some exceptions. As you know, there are quite a number of American students who have failed in their medical courses here that are now studying in Europe. We are very anxious to have good students from America spend time in the British schools either as a part of their undergraduate training or later in graduate work, and everyone wants to be sure that it is our good students that go over and not those who have done poorly here."

On April 22nd a reply was received from the National Board of Medical Examiners to the letter sent to them, in which they said that the matter would be brought before their executive committee which would meet on April 15th, after which they would write again. In the meantime the circular letter by the Council sent to applicants was modified by substituting the words "the dean of a medical school which is a member of the Association of American Colleges" for "the dean of the faculty of medicine of a university which is a member of the Association of American Universities."

The Registrar's memorandum closed by quoting a letter received from the National Board of Medical Examiners on May 3rd expressing appreciation of the efforts made to admit only well-qualified candidates into the medical schools of Great Britain. The difficulty was admitted of deciding in this country as to a student's eligibility who had not applied for admission to any school of medicine in the United States.

Memorandum on the Registration of Students.

A memorandum on this subject was submitted to the committee by Sir Norman Walker, the first portion of which dealt with the forms which applicants for registration as medical students are enjoined to fill up. Sir Norman Walker pointed out that the form did not receive the proper consideration by the person signing it. For example, it is not unusual to find that the parts which the teacher was unable to certify were none the less certified to by the omission to strike out certain lines in the certificate. But the gist of Sir Norman Walker's memorandum was to point out that the applications now being received from students in the United States makes the need of looking into the matter more urgent.

"The preliminary examination in general education," wrote Sir Norman, "is quite clearly within the sphere of the Council's duty under the Medical Act, but the preliminary examination in chemistry and physics is not quite so clear, and it is common knowledge that many of the universities have a marked preference for the plan of conducting the whole of the teaching in these subjects within the curriculum. The American applications are raising some difficult points, and there is a danger lest the Council should seem to interfere with the rights and prerogatives of the British medical schools. These rights, however, carry with them duties and responsibilities, and there are matters which should be seriously considered by their deans. It is presumably within the power of any school to impose any conditions it likes, even with reference to race, colour, or creed. The Medical Council has no such powers; if an applicant has passed a recognised general education preliminary, and a further recognised preliminary in elementary chemistry and physics, and has been accepted as a student by any recognised school of medicine in this country, his application for registration must be acceded to. But the deans should give very careful consideration to the international difficulties that may arise. It is well known that in the last 30 years there has been a remarkable elevation of the standard of medical education in the United States, and that the numbers applying for admission to their medical schools are straining their capacity to its limits. Thus, in 1927-28 there were 11,282 applicants, of whom only 6495 were accepted. If a student from some other country desires to study medicine in this country, and is accepted by one of our medical schools, the licensing bodies by custom accept the certificates of their teachers and admit the student to their examination. But the question is complicated by the fact that, in the American colleges, a great deal of critical attention is directed to the class work of the students, and those who, in their first or second year of work, are found deficient, receive an intimation that they will not be allowed to proceed, and a certificate that they have been 'honourably dismissed.' Persistent inquiry has elicited that the meaning of this is that they are not up to the scholastic requirements of the particular school, though there is nothing against their character, and it is this group of students that is responsible for the difficulties with which we are faced.

"As all such students have fulfilled the conditions of the approved (by the Council of Medical Education of the A.M.A.) medical colleges, which are that they must have a minimum two years (some require three or even four) in biology, chemistry, physics, and other subjects, one of which is a foreign language, they may quite properly be regarded as having fulfilled our conditions of general education, and the preliminary

the numerous applications for admission received from the United States had been from students who, from the educational and personal point of view, deserved admission.

"In addition to applicants who have not entered upon their medical curriculum in America, but have passed examinations with that object, there are some who, after a period in an American university or school have received 'honourable dismissal.' In view of the fact that those who obtain the qualifications of the Conjoint Boards in England, Scotland, and Ireland are entitled to take the examination of the National Board of Medical Examiners and, if this is passed, to obtain registration in the majority of the United States, it is highly desirable that no American students, who for one reason or another have not been considered satisfactory in their own country, should be admitted to medical schools here."

"Audi alteram partem."

AVERTIN ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—The strong commendations of avertin by Dr. James Young in your issue of May 31st (p. 1177) are most welcome and refreshing, whilst his equally strong condemnation of the usual methods of procuring anæsthesia should provoke reflection, if not discussion, and stimulate the search for new anæsthetic drugs. It cannot be denied that the present position is and has long been very unsatisfactory, and that anæsthetists who have tried each new drug and each new method as it has come out would receive with delight the advent of a drug which would possess all the advantages and none of the disadvantages of those in daily use. Perhaps in our endeavours to extract the best qualities and reject the worst of the common anæsthetics we have concentrated too much upon improvements in technique and not enough upon the necessity—the urgent necessity—of search for new drugs. There are, in other words, too few anæsthetics and too much apparatus. It has even been whispered, Sir, that there are too many "stunts" (if this word may appear in your columns), too little science, but this is just malicious gossip, the product of envy and uncharitableness. Whatever the truth, it would seem that little real scientific advance can be noted. Improvements in the technique of spinal analgesia, of local anæsthesia, the more frequent use of local anæsthesia combined with nitrous oxide and oxygen are all steps in the right direction, but we should not rest satisfied until a new drug or drugs have been found which will eliminate the dread and discomfort of the onset of unconsciousness, provide a safe induction, and procure adequate anæsthesia, and a recovery free from post-operative sickness and complications, whether toxic or irritant.

Avertin marks a great advance. It possesses in high degree most of these properties, and when combined with nitrous oxide and oxygen or a reduced ether anæsthesia very closely approaches the ideal. I hope sincerely that its use will increase. Its advantages are immense, and it is easy to give, easy to take. As regards the actual administration, I find that in cases of urgency the preliminary enema can be withheld; further, that I give morphine less frequently than I did, reserving its use for selected cases. Perhaps Dr. Young will find that the fall of blood pressure will be at times less pronounced if morphine is not given as a routine. Avertin by itself procures in most cases the desired deep sleep, and if the dosage has been accurately estimated (and in making this estimation the temperament and not the physique of the patient appears to be the important factor) the resulting depression of respiration never causes anxiety. It can be given more quickly than Dr. Young recommends—I find that half an hour is ample time in which to prepare the solution, supervise or at any rate initiate its injection, and have the patient ready for operation.

Due credit must be given to its distributors, Messrs. Bayer Products, Ltd., who wisely suggested to Dr. H. H. Dale that the drug should be tested by an experienced body of anæsthetists before it was placed upon the market. The control of it was therefore handed over to the Joint Committee of the Medical Research Council and the Section of Anæsthetics who issued it to authorised workers, including Mr. F. J. Morrin, of Dublin, on the condition that they reported their results to the Committee.

I am, Sir, yours faithfully,

York-terrace, N.W., May 31st. FRANCIS E. SHIPWAY.

To the Editor of THE LANCET.

SIR,—I have read Dr. Young's article with much interest and am glad to find another disciple of

avertin. He mentions in his paper Morrin, of Dublin, Blomfield and Shipway, of London, as the introducers of this drug. He omits to mention the Municipal General Hospital at Bradford, which I think I am right in stating was one of the pioneers. This drug was seen in Berlin in 1927 by one of our staff who moved heaven and earth to get it. We were one of the first to receive it and to try it out. One of us saw it used by Prof. Katzenstein in his private clinic, and immediately saw its good properties. It has been used in this institution from its inception combined with only light ether application, also with regional anæsthesia, and is still being used to-day. It has been employed in several hundreds of cases and its remarkable contrast to chloroform and ether narcosis with their invidious leaveings have rendered its use a routine procedure at this hospital for the past two years. I hope this hospital may be claimed a pioneer in this respect. Perhaps as a provincial hospital we have been overlooked, but we should give credit where credit is due.

I am, Sir, yours faithfully,

BASIL HUGHES, D.S.O., F.R.C.S.

Bradford, May 31st, 1930.

THE CAUSATION OF ECLAMPSIA.

To the Editor of THE LANCET.

SIR,—May I reply to the three points raised by Mr. Paramore on p. 1209 of your last issue? "Eclampsia," he says, "either is due to toxins absorbed from the gut—or it is not." It is my belief that the symptoms of the syndrome of eclampsia are usually expressions of disturbed physiological functions resulting from a damaged liver. At the outset of the disease there is no excess of toxins in the general circulation. Once the liver is unable to carry out its detoxicating functions, toxins absorbed from the gut will be carried in the blood stream to poison the tissues of the body—the kidneys as well as the heart. I stated some of the reasons why I believe that "it is abundantly clear that the kidneys are not concerned in the ætiology of eclampsia." I do not believe that there is any excess of toxins or poisons in the maternal blood for the kidneys to excrete—until the liver fails. The third question, as to whether the failure of the liver is due to overwork, I will answer in the negative. I believe it fails because the foetus requires 8 g. of calcium, and relatively large supplies of sugar, iron, and iodine during the last four weeks of pregnancy. Prof. J. Russell Greig, of Edinburgh, has been kind enough to send me reprints of papers he has published this year in the *Veterinary Record* and elsewhere, showing that milk fever in cattle, so like eclampsia in many ways, is associated with a hypocalcæmia, and may be cured by intravenous injections of calcium gluconate. Injection of saline or air into the udder raises the blood calcium.

Mr. Paramore says I have burned my boats, but I have not done so without building a bridge. There is less room in the abdominal cavity of a primipara than of a multipara, and the intestines are more awkwardly displaced, so that the weight of the uterus is more likely to press on certain parts of them. I added two other reasons why primiparae suffered more frequently from eclampsia—the fixing of the foetal head at the thirty-sixth week, and last but not least the psychological traumata and anxieties associated with marriage, pregnancy, and the fear of labour. I ought to have said that my observations on the pressure in the abdomen were made with the woman flat on her back and under an anæsthetic.

I was much interested to read of Dr. Chalmers's experience with Chinese women, and am glad that he emphasised the fact that they have such unhealthy gastro-intestinal tracts. I think that sunlight is a profoundly important factor in preventing the toxæmias, and in this country it is essential, especially in Glasgow and manufacturing areas, to provide the women with vitamins by mouth. The parathyroids

Customs and Excise registered to doctors; how many were sent out, and at what cost for registration alone; and what was the object of registering this leadlet.—Mr. SNOWDEN (Chancellor of the Exchequer) replied: The Commissioners were advised that it was desirable to ensure that the contents of the notice, to which the hon. and gallant Member refers, were effectively brought to the knowledge of the persons concerned, and they were therefore either delivered personally, where this was practicable, or were sent by registered post. Particulars of the numbers delivered by post and, in consequence, the cost of registration, cannot be ascertained without undue labour.

Robbins, Dr. B. E. Schlesinger, Sir John Thomson-Walker, Dr. Lennox Wainwright, Mr. C. P. G. Wakeley, Dr. F. M. R. Walshe, and Mr. F. A. Williamson-Noble.

MENTAL AFTER-CARE ASSOCIATION.—Prince George presided at the jubilee meeting of this association on June 2nd, and stated that nearly 10,000 patients had been helped since the work began in 1879. Only lack of funds prevented the further expansion which was desirable. Sir Maurice Craig said that ex-patients found in the association a group of people who were willing to help not only with money but with understanding. Valuable work was also done in preventing first breakdowns, and cases of this kind were often sent from general hospitals and elsewhere. Mr. L. G. Brock, chairman of the Board of Control, said it was because the association provided the right kind of help that it was one of the few organisations to which his department was able to subscribe. He hoped that local authorities would support such work financially.

ROYAL VISITS TO HOSPITALS.—On Thursday last week Princess Beatrice laid the foundation-stone of the new Kensington, Fulham, and Chelsea General Hospital in Richmond-road, Earl's Court, which, when completed, will contain 112 beds. At first two-thirds only of the scheme will be carried out, with 76 beds and an out-patients' department. The cost of this will be about £70,000, of which over £30,000 has been raised. A promise of £10,000 has been made anonymously on condition that five beds are endowed at a cost of £1000 each.—On the same day Prince and Princess Arthur of Connaught were present at the "house warming" given by the lady superintendent and the nursing staff of the Middlesex Hospital to view the new nurses' home in Foley-street. The first section of the building is already occupied, and the second is nearing completion. The building contains 225 bedrooms in four schemes of colour—blue, blue and cream, green, and orange. Among the amenities are a swimming pool, a roof lounge, badminton courts, reading room, and smoking room.—On Saturday Prince George opened the Orthopaedic Hospital at Redland, Bristol, and the patients of the Bristol Crippled Children's Society are being removed. The building, which is the nucleus of a larger scheme providing for 160 children, will accommodate 60 patients. It consists of an administrative block, a treatment block, a large open pavilion divided into two wards with a broad concrete terrace in front; in the treatment block there are an operating theatre, an X ray room, and the necessary appurtenant buildings. The hospital has been erected at a cost of £62,000 on a spur of the Mendip Hills.

Customs and Excise registered to doctors; how many were sent out, and at what cost for registration alone; and what was the object of registering this leaflet.—Mr. SNOWDEN (Chancellor of the Exchequer) replied: The Commissioners were advised that it was desirable to ensure that the contents of the notice, to which the hon. and gallant Member refers, were effectively brought to the knowledge of the persons concerned, and they were therefore either delivered personally, where this was practicable, or were sent by registered post. Brock, chairman of the Board of Control, said it was because the association provided the right kind of help that it was one of the few organisations to which his department was able to subscribe. He hoped that local authorities would support such work financially.

ROYAL VISITS TO HOSPITALS.—On Thursday last week Princess Beatrice laid the foundation-stone of the new Kensington, Fulham, and Chelsea General Hospital in Richmond-road, Earl's Court, which, when completed, will contain 112 beds. At first two-thirds only of the scheme will be carried out, with 76 beds and an out-patients' department. The cost of this will be about £70,000, of which over £30,000 has been raised. A promise of £10,000 has been made anonymously on condition that five beds are endowed at a cost of £1000 each.—On the same day Prince and Princess Arthur of Connaught were present at the "house warming" given by the lady superintendent and the nursing staff of the Middlesex Hospital to view the new nurses' home in Foley-street. The first section of the building is already occupied, and the second is nearing completion. The building contains 225 bedrooms in four schemes of colour—blue, blue and cream, green, and orange. Among the amenities are a swimming pool, a roof lounge, badminton courts, reading room, and smoking room.—On Saturday Prince George opened the Winford Orthopaedic Hospital, to which the inmates of the Orthopaedic Hospital at Redland, Bristol, and the patients of the Bristol Crippled Children's Society are being removed. The building, which is the nucleus of a larger scheme providing for 100 children, will accommodate 60 patients. It consists of an administrative block, a treatment block, a large open pavilion divided into two wards with a broad concrete terrace in front; in the treatment block there are an operating theatre, an X ray room, and the necessary appurtenant buildings. The hospital has been erected at a cost of £62,000 on a spur of the Mendip Hills.

Customs and Excise registered to doctors; how many were sent out, and at what cost for registration alone; and what was the object of registering this leaflet.—Mr. SNOWDEN (Chancellor of the Exchequer) replied: The Commissioners were advised that it was desirable to ensure that the contents of the notice, to which the hon. and gallant Member refers, were effectively brought to the knowledge of the persons concerned, and they were therefore either delivered personally, where this was practicable, or were sent by registered post. Particulars of the numbers delivered by post and, in consequence, the cost of registration, cannot be ascertained without undue labour.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointment has been made: Surg. Lt. T. L. Cleave to *Beaufort*.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. (D) J. E. Daniels to be Surg. Lt. (D).

ROYAL ARMY MEDICAL CORPS.

Capt. D. Crellin, *M.C.*, to be Maj.
Lt. J. W. Eames to be Capt.

ARMY DENTAL CORPS.

Capt. T. Edwards to be Maj.

ARMY RESERVE OF OFFICERS.

Lt.-Cols. F. J. Palmer, J. Tobin, and H. A. Davidson, having attained the age limit of liability to recall, cease to belong to the Res. of Off.

Lt. G. R. A. de M. Rudolf to be Capt.

TERRITORIAL ARMY.

Capt. D. Lamont to cmd. 5th (Scottish) Hygiene Co., vice Capt. J. A. Bingham, vacated.

To be Lts.: A. Glen (late R.G.A., Spec. Res.), P. Malpas (late Offr. Cadet, Liverpool Univ. Contgt., Sen. Div., O.T.C.), W. H. Dowell (late Cadet, Oundle Sch. Contgt., Jun. Div., O.T.C.), and H. W. Bambridge.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt. R. N. Kinnison, from Active List, to be Lt.

INDIAN MEDICAL SERVICE.

Lt.-Col. G. C. L. Kerans to be Col.

Lt.-Col. J. Husband to be Col.

The undermentioned officers retire: Lt.-Cols. G. H. Fielding and C. B. McConaghy.

The following command changes of R.A.M.C. officers in India are notified: Lt.-Col. P. J. Hanafin to the British Military Hospital at Bangalore; Maj. F. S. Gillespie to the British Military Hospital at Madras (temporary), relieved by Lt.-Col. C. J. Wyatt; Col. J. C. Kennedy, officiating D.D.M.S., Southern Command; Lt.-Cols. C. White, officiating commandant of the Colaba Hospital; and E. A. P. Brock to the Poona Hospital; Maj. H. P. Rudolf, specialist, Madras District; A. D. Fraser, to the British Military Hospital at Kamptee; and R. W. D. Leslie to the British Military Hospital at Pachmarhi.

HONORARY SURGEONS TO THE KING.

Maj.-Gen. H. Ensor, C.B., C.M.G., C.B.E., D.S.O., late R.A.M.C., vice Maj.-Gen. R. S. Hannay, C.B., C.M.G., D.S.O. (ret.), and Lt.-Col. (temp. Col.) G. de la Cour, O.B.E., R.A.M.C., promoted Bt.-Col., vice Maj.-Gen. J. S. Gallie, C.B., C.M.G., D.S.O. (ret.), have been appointed Honorary Surgeons to the King.

MANFIELD HOSPITAL CONVALESCENT HOME.—Mrs. Shipman has given her residence, Templemore, and the two acres in which it stands, as a convalescent home for Manfield Orthopedic Hospital, Northampton.

A PLAGUE OF ANTS.—The Queen Victoria Hospital, Morecambe, is said to be suffering from a plague of ants which crawl about the floors and infest the patients' lockers. Some of the flooring is being taken up in the hope of tracing the trouble to its source, and the advice of an insectologist is being sought. There was similar trouble about this time last year, and it was hoped that a recurrence of the visitation had been prevented.

Medical News.

UNIVERSITY OF CAMBRIDGE.—On May 31st the following degrees were conferred:—

M.D.—L. S. Fry, L. P. L. Firman-Edwards, Reginald Hilton, J. V. Fielden, and E. E. Schlesinger.
M.B. & B.Chir.—Charles Hill, G. E. Parker, and J. E. Semple.
M.B.—J. C. C. Poole.

UNIVERSITY OF LONDON.—The Senate invite applications for the Graham Scholarship in Pathology (£300 per annum for two or more years, tenable at University College Hospital) and for the Laura de Saliceto Studentship for Cancer Research. Particulars will be found in our advertisement columns.

AUSTRALIAN AND NEW ZEALAND MEDICAL ASSOCIATION IN ENGLAND.—The summer dinner of this association will be held at the Trocadero Restaurant, Piccadilly, on Friday, June 13th, at 7.45 for 8 p.m. Mr. T. P. Dunhill will preside and Sir Neville Howse, V.C., will be present as the official guest of the association. All medical visitors from Australia and New Zealand, whether members of the association or not, are invited to attend. The hon. secretary's address is 26, Queen Anne-street, London, W. 1.

MEDICAL SOCIETY OF LONDON.—The officers of this society elected for the forthcoming session are as follows: President: Dr. R. A. Young. Vice-Presidents: Dr. F. J. Poynton, Mr. Herbert Tilley, Mr. V. Zachary Cope, and Dr. J. Seymour Maynard. Hon. treasurer: Mr. H. W. Carson. Hon. librarian: Dr. A. F. Voelcker. Hon. editor: Mr. T. P. Legg. Hon. secretaries: Dr. A. Hope Gosse, Mr. W. E. Tanner, and (for foreign correspondence) Dr. Herbert Spencer. Council: Mr. Donald Armour, Mr. Carter Braine, Mr. W. R. Bristow, Dr. Walter Carr, Mr. R. Davies-Colley, Mr. Tudor Edwards, Dr. Anthony Feilding, Mr. Eric Pearce-Gould, Dr. F. E. Larkins, Dr. J. D. P. McLatchie, Mr. L. E. C. Norbury, Dr. B. T. Parsons-Smith, Mr. J. E. H. Roberts, Mr. F. H. Robbins, Dr. E. E. Schlesinger, Sir John Thomson-Walker, Dr. Lennox Wainwright, Mr. C. P. G. Wakeley, Dr. F. M. R. Walshe, and Mr. F. A. Williamson-Noble.

MENTAL AFTER-CARE ASSOCIATION.—Prince George presided at the jubilee meeting of this association on June 2nd, and stated that nearly 19,000 patients had been helped since the work began in 1870. Only lack of funds prevented the further expansion which was desirable. Sir Maurice Craig said that ex-patients found in the association a group of people who were willing to help not only with money but with understanding. Valuable work was also done in preventing first breakdowns, and cases of this kind were often sent from general hospitals and elsewhere. Mr. L. G. Brock, chairman of the Board of Control, said it was because the association provided the right kind of help that it was one of the few organisations to which his department was able to subscribe. He hoped that local authorities would support such work financially.

ROYAL VISITS TO HOSPITALS.—On Thursday last week Princess Beatrice laid the foundation-stone of the new Kensington, Fulham, and Chelsea General Hospital in Richmond-road, Earl's Court, which, when completed, will contain 112 beds. At first two-thirds only of the scheme will be carried out, with 70 beds and an out-patients' department. The cost of this will be about £70,000, of which over £30,000 has been raised. A promise of £10,000 has been made anonymously on condition that five beds are endowed at a cost of £1000 each.—On the same day Prince and Princess Arthur of Connaught were present at the "house warming" given by the lady superintendent and the nursing staff of the Middlesex Hospital to view the new nurses' home in Foley-street. UNIVERSITY OF CAMBRIDGE.—On May 31st the following degrees were conferred:—

M.D.—L. S. Fry, L. P. L. Firman-Edwards, Reginald Hilton, J. V. Fiddian, and B. E. Schlesinger.
M.B. & B.Chir.—Charles Hill, G. E. Parker, and J. E. Semple.
M.B.—J. C. C. Poole.

UNIVERSITY OF LONDON.—The Senate invite applications for the Graham Scholarship in Pathology (£300 per annum for two or more years, tenable at University College Hospital) and for the Laura de Saliceto Studentship for Cancer Research. Particulars will be found in our advertisement columns.

AUSTRALIAN AND NEW ZEALAND MEDICAL ASSOCIATION IN ENGLAND.—The summer dinner of this association will be held at the Trocadero Restaurant, Piccadilly, on Friday, June 13th, at 7.45 for 8 p.m. Mr. T. P. Dunhill will preside and Sir Neville Howse, V.C., will be present as the official guest of the association. All medical visitors from Australia and New Zealand, whether members of the association or not, are invited to attend. The hon. secretary's address is 26, Queen Anne-street, London, W. 1.

MEDICAL SOCIETY OF LONDON.—The officers of this society elected for the forthcoming session are as follows: President: Dr. R. A. Young. Vice-Presidents: Dr. F. J. Poynton, Mr. Herbert Tilley, Mr. V. Zachary Cope, and Dr. J. Seymour Maynard. Hon. treasurer: Mr. H. W. Carson. Hon. librarian: Dr. A. F. Voelcker. Hon. editor: Mr. T. P. Legg. Hon. secretaries: Dr. A. Hope Gosse, Mr. W. E. Tanner, and (for foreign correspondence) Dr. Herbert Spencer. Council: Mr. Donald Armour, Mr. Carter Braine, Mr. W. R. Bristow, Dr. Walter Carr, Mr. R. Davies-Colley, Mr. Tudor Edwards, Dr. Anthony Feilding, Mr. Eric Pearce-Gould, Dr. F. E. Larkins, Dr. J. D. P. McLatchie, Mr. L. E. C. Norbury, Dr. B. T. Parsons-Smith, Mr. J. E. H. Roberts, Mr. F. H. Robbins, Dr. B. E. Schlesinger, Sir John Thomson-Walker, Dr. Lennox Wainwright, Mr. C. P. G. Wakeley, Dr. F. M. R. Walshe, and Mr. F. A. Williamson-Noble.

MENTAL AFTER-CARE ASSOCIATION.—Prince George presided at the jubilee meeting of this association on June 2nd, and stated that nearly 19,000 patients had been helped since the work began in 1879. Only lack of funds prevented the further expansion which was desirable. Sir Maurice Craig said that ex-patients found in the association a group of people who were willing to help not only with money but with understanding. Valuable work was also done in preventing first breakdowns, and cases of this kind were often sent from general hospitals and elsewhere. Mr. L. G. Brock, chairman of the Board of Control, said it was because the association provided the right kind of help that it was one of the few organisations to which his department was able to subscribe. He hoped that local authorities would support such work financially.

ROYAL VISITS TO HOSPITALS.—On Thursday last week Princess Beatrice laid the foundation-stone of the new Kensington, Fulham, and Chelsea General Hospital in Richmond-road, Earl's Court, which, when completed, will contain 112 beds. At first two-thirds only of the scheme will be carried out, with 76 beds and an out-patients' department. The cost of this will be about £70,000, of which over £30,000 has been raised. A promise of £10,000 has been made anonymously on condition that five beds are endowed at a cost of £1000 each.—On the same day Prince and Princess Arthur of Connaught were present at the "house warming" given by the lady superintendent and the nursing staff of the Middlesex Hospital to view the new nurses' home in Foley-street. The first section of the building is already occupied, and the second is nearing completion. The building contains 225 bedrooms in four schemes of colour—blue, blue and cream, green, and orange. Among the amenities are a swimming pool, a roof lounge, badminton courts, reading room, and smoking room.—On Saturday Prince George opened the Winford Orthopaedic Hospital, to which the inmates of the Orthopaedic Hospital at Redland, Bristol, and the patients of the Bristol Crippled Children's Society are being removed. The building, which is the nucleus of a larger scheme providing for 160 children, will accommodate 60 patients. It consists of an administrative block, a treatment block, a large open pavilion divided into two wards with a broad concrete terrace in front; in the treatment block there are an operating theatre, an X ray room, and the necessary appurtenant buildings. The hospital has been erected at a cost of £62,000 on a spur of the Mendip Hills.

Customs and Excise registered to doctors; how many were sent out, and at what cost for registration alone; and what was the object of registering this leaflet.—Mr. SNOWDEN (Chancellor of the Exchequer) replied: The Commissioners were advised that it was desirable to ensure that the contents of the notice, to which the hon. and gallant Member refers, were effectively brought to the knowledge of the persons concerned, and they were therefore either delivered personally, where this was practicable, or were sent by registered post. Particulars of the numbers delivered by post and, in consequence, the cost of registration, cannot be ascertained without undue labour.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

The following appointment has been made: Surg. Lt. T. L. Cleave to *Beaufort*.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. (D) J. E. Daniels to be Surg. Lt. (D).

ROYAL ARMY MEDICAL CORPS.

Capt. D. Crellin, M.C., to be Maj.
Lt. J. W. Eames to be Capt.

ARMY DENTAL CORPS.

Capt. T. Edwards to be Maj.

ARMY RESERVE OF OFFICERS.

Lt.-Cols. F. J. Palmer, J. Tobin, and H. A. Davidson, having attained the age limit of liability to recall, cease to belong to the Res. of Off.

Lt. G. R. A. de M. Rudolf to be Capt.

TERRITORIAL ARMY.

Capt. D. Lamont to cmd. 5th (Scottish) Hygiene Co., vice Capt. J. A. Bingham, vacated.

To be Lts.: A. Glen (late R.G.A., Spec. Res.), P. Malpas (late Off. Cadet, Liverpool Univ. Contgt., Sen. Div., O.T.C.), W. H. Dowell (late Cadet, Oundle Sch. Contgt., Jun. Div., O.T.C.), and H. W. Bambridge.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt. R. N. Kinnison, from Active List, to be Lt.

INDIAN MEDICAL SERVICE.

Lt.-Col. G. C. L. Kerans to be Col.

Lt.-Col. J. Husband to be Col.

The undermentioned officers retire: Lt.-Cols. C. H. Fielding and C. B. McConaghy.

The following command changes of R.A.M.C. officers in India are notified: Lt.-Col. P. J. Hanafin to the British Military Hospital at Bangalore; Maj. F. S. Gillespie to the British Military Hospital at Madras (temporary), relieved by Lt.-Col. C. J. Wyatt; Col. J. C. Kennedy, officiating D.D.M.S., Southern Command; Lt.-Cols. C. White, officiating commandant of the Colaba Hospital; and E. A. P. Brock to the Poona Hospital; Maj. H. P. Rudolf, specialist, Madras District; A. D. Fraser, to the British Military Hospital at Kamptee; and R. W. D. Leslie to the British Military Hospital at Pachmarhi.

HONORARY SURGEONS TO THE KING.

Maj.-Gen. H. Ensor, C.B., C.M.G., C.B.E., D.S.O., late R.A.M.C., vice Maj.-Gen. R. S. Hannay, C.B., C.M.G., D.S.O. (ret.), and Lt.-Col. (temp. Col.) G. de la Cour, O.B.E., R.A.M.C., promoted Lt.-Col., vice Maj.-Gen. J. S. Gallie, C.B., C.M.G., D.S.O. (ret.), have been appointed Honorary Surgeons to the King.

MANFIELD HOSPITAL CONVALESCENT HOME.—Mrs. Shipman has given her residence, Templemore, and the two acres in which it stands, as a convalescent home for Manfield Orthopaedic Hospital, Northampton.

A PLAGUE OF ANTS.—The Queen Victoria Hospital, Morecambe, is said to be suffering from a plague of ants which crawl about the floors and infest the patients' lockers. Some of the flooring is being taken up in the hope of tracing the trouble to its source, and the advice of an insectologist is being sought. There was similar trouble about this time last year, and it was hoped that a recurrence of the visitation had been prevented.

Lt. G. R. A. de M. Rudolf to be Capt.

TERRITORIAL ARMY.

Capt. D. Lamont to cmd. 5th (Scottish) Hygiene Co., vice Capt. J. A. Bingham, vacated.

To be Lts.: A. Glen (late R.G.A., Spec. Res.), P. Malpas (late Offr. Cadet, Liverpool Univ. Contgt., Sen. Div., O.T.C.), W. H. Dowell (late Cadet, Oundle Sch. Contgt., Jun. Div., O.T.C.), and H. W. Bambridge.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt. R. N. Kinnison, from Active List, to be Lt.

INDIAN MEDICAL SERVICE.

Lt.-Col. G. C. L. Kerans to be Col.
Lt.-Col. J. Husband to be Col.

The undermentioned officers retire: Lt.-Cols. C. H. Fielding and C. B. McConaghy.

The following command changes of R.A.M.C. officers in India are notified: Lt.-Col. P. J. Hanafin to the British Military Hospital at Bangalore; Maj. F. S. Gillespie to the British Military Hospital at Madras (temporary), relieved by Lt.-Col. C. J. Wyatt; Col. J. C. Kennedy, officiating D.D.M.S., Southern Command; Lt.-Cols. C. White, officiating commandant of the Colaba Hospital; and E. A. P. Brock to the Poona Hospital; Maj. H. P. Rudolf, specialist, Madras District; A. D. Fraser, to the British Military Hospital at Kamptee; and R. W. D. Leslie to the British Military Hospital at Pachmarhi.

HONORARY SURGEONS TO THE KING.

Maj.-Gen. H. Ensor, C.B., C.M.G., C.B.E., D.S.O., late R.A.M.C., vice Maj.-Gen. R. S. Hannay, C.B., C.M.G., D.S.O. (ret.), and Lt.-Col. (temp. Col.) G. de la Cour, O.B.E., R.A.M.C., promoted Bt.-Col., vice Maj.-Gen. J. S. Gallie, C.B., C.M.G., D.S.O. (ret.), have been appointed Honorary Surgeons to the King.

MANFIELD HOSPITAL CONVALESCENT HOME.—Mrs. Shipman has given her residence, Templemore, and the two acres in which it stands, as a convalescent home for Manfield Orthopaedic Hospital, Northampton.

A PLAGUE OF ANTS.—The Queen Victoria Hospital, Morecambe, is said to be suffering from a plague of ants which crawl about the floors and infest the patients' lockers. Some of the flooring is being taken up in the hope of tracing the trouble to its source, "and the advice of an insectologist is being sought." There was similar trouble about this time last year, and it was hoped that a recurrence of the visitation had been prevented.

Medical News.

UNIVERSITY OF CAMBRIDGE.—On May 31st the following degrees were conferred:—

M.D.—L. S. Fry, L. P. L. Firman-Edwards, Reginald Hilton, J. V. Fiddian, and B. E. Schlesinger.

M.B. & B.Chir.—Charles Hill, G. E. Parker, and J. E. Semple.

M.B.—J. C. C. Poole.

UNIVERSITY OF LONDON.—The Senate invite applications for the Graham Scholarship in Pathology (£300 per annum for two or more years, tenable at University College Hospital) and for the Laura de Saliceto Studentship for Cancer Research. Particulars will be found in our advertisement columns.

AUSTRALIAN AND NEW ZEALAND MEDICAL ASSOCIATION IN ENGLAND.—The summer dinner of this association will be held at the Trocadero Restaurant, Piccadilly, on Friday, June 13th, at 7.45 for 8 P.M. Mr. T. P. Dunhill will preside and Sir Neville Howse, V.C., will be present as the official guest of the association. All medical visitors from Australia and New Zealand, whether members of the association or not, are invited to attend. The hon. secretary's address is 26, Queen Anne-street, London, W. 1.

MEDICAL SOCIETY OF LONDON.—The officers of this society elected for the forthcoming session are as follows: President: Dr. R. A. Young. Vice-Presidents: Dr. E. J. Poynton, Mr. Herbert Tilley, Mr. V. Zachary Cope, and Dr. J. Seymour Maynard. Hon. treasurer: Mr. H. W. Carson. Hon. librarian: Dr. A. F. Voelcker. Hon. editor: Mr. T. P. Legg. Hon. secretaries: Dr. A. Hope Gosse, Mr. W. E. Tanner, and (for foreign correspondence) Dr. Herbert Spencer. Council: Mr. Donald Armour, Mr. Carter Braine, Mr. W. R. Bristow, Dr. Walter Carr, Mr. R. Davies-Colley, Mr. Tudor Edwards, Dr. Anthony Feilding, Mr. Eric Pearce-Gould, Dr. F. E. Larkins, Dr. J. D. P. McLatchie, Mr. L. E. C. Norbury, Dr. B. T. Parsons-Smith, Mr. J. E. H. Roberts, Mr. F. H. Robbins, Dr. B. E. Schlesinger, Sir John Thomson-Walker, Dr. Lennox Wainwright, Mr. C. P. G. Wakeley, Dr. F. M. R. Walshe, and Mr. F. A. Williamson-Noble.

MENTAL AFTER-CARE ASSOCIATION.—Prince George presided at the jubilee meeting of this association on June 2nd, and stated that nearly 10,000 patients had been helped since the work began in 1879. Only lack of funds prevented the further expansion which was desirable. Sir Maurice Craig said that ex-patients found in the association a group of people who were willing to help not only with money but with understanding. Valuable work was also done in preventing first breakdowns, and cases of this kind were often sent from general hospitals and elsewhere. Mr. L. G. Brock, chairman of the Board of Control, said it was because the association provided the right kind of help that it was one of the few organisations to which his department was able to subscribe. He hoped that local authorities would support such work financially.

ROYAL VISITS TO HOSPITALS.—On Thursday last week Princess Beatrice laid the foundation-stone of the new Kensington, Fulham, and Chelsea General Hospital in Richmond-road, Earl's Court, which, when completed, will contain 112 beds. At first two-thirds only of the scheme will be carried out, with 76 beds and an out-patients' department. The cost of this will be about £70,000, of which over £30,000 has been raised. A promise of £10,000 has been made anonymously on condition that five beds are endowed at a cost of £1000 each.—On the same day Prince and Princess Arthur of Connaught were present at the "house warming" given by the lady superintendent and the nursing staff of the Middlesex Hospital to view the new nurses' home in Foley-street. The first section of the building is already occupied, and the second is nearing completion. The building contains 225 bedrooms in four schemes of colour—blue, blue and cream, green, and orange. Among the amenities are a swimming pool, a roof lounge, badminton courts, reading room, and smoking room.—On Saturday Prince George opened the Winford Orthopaedic Hospital, to which the inmates of the Orthopaedic Hospital at Redland, Bristol, and the patients of the Bristol Crippled Children's Society are being removed. The building, which is the nucleus of a larger scheme providing for 160 children, will accommodate 60 patients. It consists of an administrative block, a treatment block, a large open pavilion divided into two wards with a broad concrete terrace in front; in the treatment block there are an operating theatre, an X ray room, and the necessary appurtenant buildings. The hospital has been erected at a cost of £62,000 on a spur of the Mendip Hills.

UNIVERSITY OF EDINBURGH.—Sir James Barrie, O.M., has been elected Chancellor of the University in succession to the late Lord Balfour.

PADDINGTON MEDICAL SOCIETY.—The inaugural meeting of this society will be held at 9 p.m. on Tuesday, June 10th, at the Paddington Town Hall. The acting hon. secretary is Dr. J. Cohen, 23, Westbourne Park-road, London, W.2.

INFANTS HOSPITAL.—Over £100,000 has now been subscribed towards the extension of this hospital in Vincent-square, Westminster. Last year the hospital's convalescent home at Burnham received 119 patients, who stayed an average of 50 days.

LONDON SMALL-POX HOSPITALS.—The Public Health Committee of the London County Council has agreed to continue until the end of the year the agreements made by the Metropolitan Asylums Board with certain extra-metropolitan authorities for the reception of cases of small-pox occurring in their districts into the Board's small-pox hospitals. The agreement with the Middlesex County Council is to be reviewed in November next.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The sixteenth annual conference of this association will be held from July 3rd to 5th at the British Medical Association's house in Tavistock-square, London, W.C. It will be opened on July 3rd by Mr. Arthur Greenwood, Minister of Health, and Sir George Newman and Dr. J. Parlane Kinloch will introduce a discussion on the effects on the Tuberculosis Campaign of the Local Government Act, 1929. On the following day Major Walter Elliot, M.P., will open the conference and the discussion will be continued.

MEMORIAL TO A MEDICAL MAN.—A fund has been raised in memory of Dr. William Andrew MacWilliam, who practised for 15 years at Norbury, and died last February. It has been decided to allocate the money as follows: £100 for a memorial shelter on Pollards Hill recreation ground, Norbury; £100 for a bed in St. Mary's Maternity Hostel, Croydon; £50 for a cot in the same institution; and the remainder (about £200) for radium for Croydon General Hospital.

POOR-LAW MEDICAL OFFICERS' ASSOCIATION.—The annual meeting of this association will be held at 6 p.m. on Thursday, June 12th, in the Holborn Restaurant, and will be followed by an informal dinner. Sir Arthur Newsholme will preside and Prof. Major Greenwood, F.R.S., will introduce the subject of post-graduate education for the local government medical service. Poor-law or local government medical officers are invited to attend, and further particulars may be had from the hon. treasurer, Mr. F. Greenwood, Bank Chambers, High-street, Stoke Newington, N. 16.

ELDERLY NURSES' PERMANENT HOME FUND.—A scheme has been prepared with the object of providing a home for elderly nurses who are no longer able to earn a living by the practice of their profession. The site chosen for the home is Bournemouth, whose mayor and mayoress are supporting the movement, but the home is not to be confined only to those who have worked or lived in the town. Contributions should be sent to the Hon. Treasurer of the Fund, Mr. F. Cobley, Westminster Bank, Southbourne, Bournemouth.

AN ABERDEENSHIRE COTTAGE HOSPITAL.—Colonel Farquharson, of Invercauld, Provincial Grand Master of Aberdeenshire, recently laid, with masonic honours, the foundation-stone of the Nicoll Hospital in the village of Rhynie, in north-western Aberdeenshire. The late Dr. P. J. S. Nicoll, a native of the parish, who practised in London and died in 1926, bequeathed £5000 towards its erection, a sum subsequently augmented by the gift of £3000 from his friend, Mr. Theodore Godlee. The hospital contains six beds.

MEDICAL GOLFING SOCIETY.—The annual summer meeting was held at Walton Heath on May 28th. Over 100 members competed, and enjoyed the hospitality of Lord Riddell. The various competitions resulted as follows: **THE LANCET Challenge Cup:** W. Rowley Bristow, after a tie with C. Max Page, at 1 down. **Milsons Rees Challenge Cup:** M. G. Mayou, after a tie with J. W. Harrison, at 6 down. **Henry Morris Challenge Cup:** A. Don, 3 up. **Veterans' Cup:** A. Don, 3 up; George Dawson, 2 up. **Handicap prizes:**—Class 1: C. Max Page, after a tie with W. Rowley Bristow, at 2 up. Best last 9: H. G. Apperley, 1 up. Class 2: (1st) A. Don, 3 up; (2nd) George Dawson, 2 up. Best last 9: J. W. Harrison, 3 up. **Fouromes:** (1st) T. J. Kelleher and J. Grace; (2nd) Lindsay Rea and W. McCullagh.

STRANGEWAYS RESEARCH LABORATORY, CAMBRIDGE.—A course of instruction in the technique of tissue culture will be given at this laboratory from July 1st to 26th. Only a limited number of applicants can be received, and those wishing to take the course should communicate with Dr. H. B. Fell at the laboratory.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The College is to be closed on Saturday, June 7th, and Monday, the 9th.

CONFERENCE ON CREMATION.—The ninth annual conference of the Federation of Cremation Authorities will be held at Edinburgh and Glasgow from July 4th to 8th. The federation's address is 37, York-street, Manchester.

A LONG WAITING LIST.—The Cumberland Infirmary's waiting list now exceeds 700, and the public assistance committee is being urged to prepare its scheme under the Local Government Act as speedily as possible.

VENTNOR CONSUMPTION HOSPITAL.—Of the 168 beds at the Royal National Hospital for Consumption, at Ventnor, 165 were, on the average, in constant occupation last year. The annual report states that in nearly every case in which early treatment had been sought there was an improvement.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE. 1, Wimpole-street, W.
FRIDAY, June 13th.—5 p.m. **OPHTHALMOLOGY.** Election of Officers and Council. Paper: Mr. Tudor Thomas: An Experiment in Keratoplasty.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.
ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
THURSDAY, June 12th.—5 p.m. Sir Charles Martin: The Thermal Adjustment of Man to External Conditions, more particularly those pertaining to Warm Climates. (First Croonian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, June 10th, to SATURDAY, June 14th. **MEDICAL SOCIETY OF LONDON,** 11 Chandos-street, Cavendish-square, W. Special M.R.C.P. lectures at 8.30 p.m. Tues. Dr. H. Gardiner-Hill: Recent Work on the Ductless Glands. Fri. Prof. Hugh McLean: Recent Research on Gastric Physiology and Pathology and its Bearing on Treatment. Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
WEDNESDAY, June 11th.—2.30 to 5 p.m.: Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 a.m.: Dental Clinics. 2.30 to 5 p.m.: Medical, Surgical, Throat, and Ear Clinics. Operations.
FRIDAY.—10.30 a.m.: Ear, Nose, and Throat Clinics. 2.30 to 5 p.m.: Medical, Surgical, and Children's Diseases Clinics. Operations.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

TUESDAY, June 10th.—10 a.m. Medical Registrar: Medical Wards. 2 p.m. Mr. Hamblen Thomas: Throat, Nose, and Ear Dept. 3 p.m. Sir Henry Simson: Gynaecological Ward.

WEDNESDAY.—10 a.m. Dr. Burnford: Medical Wards. 2 p.m. Mr. Simmonds: Surgical Wards. Dr. Scott Finchin: Medical Out-patients.

THURSDAY.—10 a.m. to 1 p.m. Neurological Department. Demonstration of Fractures. 2 p.m. Medical, Surgical, Eye and Genito-Urinary Departments.

FRIDAY.—10 a.m. Dr. Pritchard: Medical Wards. 2 p.m. Mr. Vlasto: Throat, Nose, and Ear Department.

SATURDAY.—9 a.m. Mr. Vlasto: Throat, Nose, and Ear Operations. 9.30 a.m. Dr. Burnford: Bacterial Therapy Department. 10 a.m. Dr. Owen: Medical Children's Department.
Daily, 10 a.m. to 5 p.m. Medical, Surgical, and Special Out-patients, Operations, Wards Visits, Anesthetic Courses.

NATIONAL HOSPITAL, Queen-square, W. C.
TUESDAY, June 10th.—2 p.m. Dr. Walche: Out-patient Clinic. 3.30 p.m. Dr. Martin: Cerebral Vascular Disease.

THURSDAY.—2 p.m. Dr. Kinnler Wilson: Out-patient Clinic. 3.30 p.m. Dr. Riddoch: Neurosophills.

FRIDAY.—12 noon. Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 p.m. Dr. Adie: Out-patient Clinic. 3.30 p.m. Dr. Symonds: Minor Mental Disorders.

ST. MARY'S HOSPITAL INSTITUTE OF PATHOLOGY, W.

THURSDAY, June 12th.—5 p.m. Col. L. W. Harrison: The Development of the Modern Treatment of Syphilis.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.4.
TUESDAY, June 10th.—5 p.m. Dr. H. C. Lucey: Clinical Pathology of Pregnancy.

Appointments.

BAMBER, G. W., M.B., B.Ch. Camb., M.R.C.P. Lond., has been appointed Dermatologist to the Metropolitan Hospital, Kingsland-road, E.
 PARRY, R. H., L.R.C.P. Lond., M.R.C.S., Medical Officer of Health for Bristol.
 WOOD WALKER, G. B., M.B. Camb., F.R.C.S. Eng., Assistant Surgeon to the West London Hospital.

Vacancies.

Applications should be reach the Private Secretary, Home Office, Whitehall, London, not later than 21st June, 1930.

Births, Marriages, and Deaths.

BIRTHS.

BUIST.—On May 30th, at Dundee, the wife of Major T. P. Buist, R.A.M.C., of a son.
 COOKE.—On May 29th, 1930, at the Stoneboro Nursing Home, to Betty, wife of Robert V. Cooke, F.R.C.S., 9, The Green, Llandaff—a son.
 COTTER.—On May 22nd, the wife of Major E. Cotter, I.M.S., Eglantine, Cork, of a son.
 HANSON.—On May 23rd, at Welbeck-street, the wife of David C. Hanson, M.C., M.B., New King's-road, Hurlingham, S.W., of a daughter.
 HAWARD.—On May 22nd, at a nursing home, the wife of Dr. F. C. Haward, of a daughter.
 SABONADIÈRE.—On May 25th, at Harver House, Watton, Norfolk, the wife of R. W. Sabonadière, M.R.C.S., L.R.C.P., of a daughter.

MARRIAGES.

DAVIES—FANING.—On May 24th, at Holy Trinity Church, Exmouth, D. S. Davies, M.D., to Mary, widow of the Rev. J. F. E. Fanning, M.A.
 GREENWOOD—JONES.—On May 31st, at Maze Hill Congregational Church, Greenwich, Eric John Greenwood, M.B., B.Ch., to Dorothy Helen Jones, elder daughter of Mr. and Mrs. W. G. Jones, of Greenwich.

DEATHS.

BROCK.—On June 1st, 1930, at Bloemfontein, O.F.S., South Africa, Benjamin George Brock, L.R.C.P. & S., D.P.H. Edin., aged 76 years.
 CAMPBELL.—On May 26th, at Beech-hill-road, Eltham Park, London, Dr. Susan Campbell, of Ajmer, India.
 GASTER.—On May 31st, at Devonshire-place, Anghel Gaster, M.D., M.R.C.P. Lond., aged 66.
 JOHNSTON.—On June 1st, at a nursing home in Edinburgh, Robert McKenzie Johnston, M.D., F.R.C.S.E., of Lansdowne-crescent, Edinburgh.
 MAELED.—On May 30th, at Craven-hill, W., Herbert William George Maled, M.D., B.Sc., M.R.C.P. Lond., Barrister-at-Law, late Captain I.M.S., aged 69 years.
 SANDALL.—On May 31st, at Springfield, Montalt-road, Woodford Green, Colonel Thomas Edward Sandall, C.M.G., T.D., M.D. Camb.
 WINTER.—On May 28th, at Holne Brake, West Malvern, Dr. George Mitchell Winter, O.B.E., J.P., late of St. Marychurch, Torquay.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Notes, Comments, and Abstracts.

INFANT WELFARE WORK IN HOLLAND.

The town council of Amsterdam undertook the work of municipal infant welfare in 1920, at a time when the Society for Infant Welfare felt unable to carry on the task. It was thought that this work offered remarkable opportunities not only for the prevention of disease and the reduction of infant mortality, but as a means of raising the cultural level of the population. The young mother with her first baby is faced with so serious a responsibility that she is peculiarly ready to accept advice, and the rules of hygiene instilled at a welfare centre will stand her in good stead in subsequent pregnancies. The report of the Municipal Health Service of Amsterdam for the five years between 1922 and 1926 records a steady increase in the number of centres, and mentions that 72 infant welfare conferences are now held weekly in various parts of the city. The staff of each welfare division consists of a chief, or leader, who is a full time officer, and of medical officers who do part-time work at the centres. Each centre has, in addition, a full time trained nurse, and 18 partly trained women, called *kraamverzorgsters* are attached to each division. The municipal midwives carry out their antenatal work in the building containing the welfare centre, and create a link between the expectant mothers and the welfare workers. Propaganda visits are made to young mothers and pregnant women, but if it is learned in any case that the family doctor has undertaken the care of the child, the clinic does not attempt to interfere further. Sick children are not treated at the centres, but the mothers are advised to go at once to their own doctors. At present the work of the clinic ends when the child passes its first birthday, but it is hoped that supervision will shortly be extended up to three years, when the child passes into the hands of the school doctor.

Statistics collected over the five years show that the average duration of supervision at the centre for each child increased from 21 weeks in 1922 to 29 weeks in 1926; in other words, the interest of the mothers is becoming more persistent as the value of the clinics becomes more widely appreciated. The number of children attending the centres, moreover, had increased from 4873, or 34.1 per cent. of live-born children in 1922, to 6337, or 40.7 per cent., of live-born children in 1926. Some interesting statistics have been compiled on infant feeding from information supplied by the various centres, and it is even possible to compare the results at individual centres by an analysis of these statistics. On the whole, almost three-fifths of the children attending the centres are breast-fed, at any rate for the first three months of life. One-fifth of infants are partially breast-fed, and the remainder are artificially fed, or the feeding is unknown. It is found that the proportion of breast-fed infants varies very little from year to year. It is yet too early to draw conclusions, but there is some evidence that the infant mortality-rate under one month is considerably lower among children attending the centres than among the general population.

RHEUMATISM IN CHILDHOOD.

In his annual report on the St. Marylebone Children's Rheumatism Supervisory Centre for 1929, Dr. J. F. Halls Dally, the medical director, says that at this centre such therapeutic measures as may be found necessary are subsidiary to an inquiry into the nature of the constitution of rheumatic children. "Recent findings," he says, "tend to confirm previous conclusions that the rheumatic constitution can be detected by biochemical means. The most common abnormality is a chemical constitution of the rheumatic soil" is faulty metabolism of calcium, phosphorus, magnesium, and sulphur. Corresponding with different clinical types which manifest different rheumatic symptoms, two biochemical groups can be differentiated. One group presents either no deviation of the acid-base equilibrium of the body, or a slight deviation to the alkaline side; this group does not, as a rule, suffer from cardiac rheumatism. The second group shows a deviation of the acid-base equilibrium to the acid side, and so far there has been no exception to the rule that cases of cardiac rheumatism fall into this latter class. It is significant that a very large proportion of all children investigated up to date yields no evidence whatsoever of any acute or chronic infective process. It would thus seem that most of the subjective symptoms can be accounted for by metabolic abnormalities alone."

Dr. Halls Dally says that an attempt is being made to interpret both clinical and biochemical findings in terms of endocrine function. The work of the centre is, in this way, being correlated with recent developments in research

elsewhere, which, he believes, point to lack of balance or inadequacy of the glands of internal secretion as one of the primary causes of rheumatism.

SMOKE AND HEALTH.

The joint committee of the Manchester and District Regional Smoke Abatement Committee and of the National Smoke Abatement Society have done well to include in their propaganda the lecture recently delivered at the College of Technology by Dr. J. S. Taylor, assistant medical officer of health for Manchester. Dr. Taylor deals with the subject in a clear and convincing manner. Charts illustrate the effect of fogs in Manchester in causing an increase in the deaths from respiratory diseases. The excess in infant and young child mortality in the towns, when compared with the country and in the northern industrial towns as compared with the southern towns, is shown in tabular form, and reasons are adduced to support the view that a smoky and dusty atmosphere is a prime cause in producing this relative excess. We have often called attention to the greater mortality from respiratory diseases in dirty-air as compared with clean-aired towns, a greater mortality which falls especially on the young children. Dr. Taylor deals adequately with the biological action of light, and the facts and references in the pamphlet should prove of value in arousing a demand among town-dwellers for a purer atmosphere in which to live.

The pamphlet (price 2d.) can be obtained from the office of the Societies, Civic Buildings, 1, Mount-street, Manchester.

HINDU MEDICAL TREATMENT.

This little book¹ is founded, as the author, Miss Dorothea Chaplin states, on the verbal and written teaching of the late Mr. S. M. Mitra, a lawyer and well-known publicist, whose views on many international and social questions found expressions at congresses and in the columns of the press. He became a psychotherapist, and in that capacity wrote a volume for the use of neurosthenic members of the public who consulted him, and in this he dealt specially with the treatment of nervous disorders by Hindu remedies. The Hindu practice, it appears, includes a form of psychoanalysis, in which specially prepared tales are read to the patient after which questions are asked which are calculated to elicit the various mental symptoms. These notes on Hindu medical treatment are too disjointed to give a coherent idea of what is being aimed at or what definite results have been obtained.

BRISTOL HOMOEOPATHIC HOSPITAL.

This institution, which last year received nearly 1000 in-patients, and treated 1095 out-patients, had a deficit of £3360 on its ordinary expenditure. The President, Mr. Melville Wills, has given £5000 to reduce the bank overdraft and £20,000 to the endowment fund. The work of the hospital, which has now been recognised as a training school for nurses, has so greatly increased that it is rapidly becoming impossible to carry it on in the present premises.

ABSINTHE DRINKING IN ENGLAND.

We have received from Messrs. Gancia and Co., Ltd., Canelli, Italy, who are among the largest producers of vermouth, a letter traversing some of the facts contained in an article published in THE LANCET of April 26th under this heading. The Italian firm protest against the implication that the absinthe in vermouth forms an introduction to absinthe-drinking in England through the medium of cocktails. They write:—"We will at once confess that our brand of vermouth does contain the essential oil of absinthe, but to the negligible extent of three milligrammes of absinthe to one litre vermouth or, expressed in plain English, about one 350,000th part by weight or volume. Why such a small proportion? Because we too know that many stimulants, taken in excess, are harmful, and because vermouth does not depend on any one herb for its special taste and aroma, but on prolonged maceration of many different plants in fortified wine. We believe that vermouths of other makes would also show much the same results, if analysed. We submit that such a small amount of absinthe in vermouth cannot be considered injurious; quite on the other hand, these few milligrammes form a valuable stimulant, besides improving the taste of the vermouth. However, should the British public, acting on Dr. Brashers' advice, disapprove of the presence of absinthe in vermouth at all, then we are quite prepared to eliminate it from our brand altogether, substituting other herbs which will give much the same effect without possessing the lethal properties which your doctor fears so much. We are afraid that the absinthe question in England has been confounded with the pure 70 per cent.

¹ Some Aspects of Hindu Medical Treatment. By Dorothea Chaplin. London: Luzac and Co. Pp. 71. 3s. 6d.

alcohol absinthe which was once upon a time allowed in France. We agree with Dr. Brasher that this beverage is injurious, unless drunk in exceedingly small quantities. What is required is moderation in these things. We scarcely think that the author of the article in question eschews tea and coffee completely, simply because they are injurious to the human system when drunk in excess, or that he refuses to ride in a motor-car because it is possible to drive it too fast!

A CELEBRATED MEDIUM.

THE investigations into the phenomena produced in this country by Mrs. Piper, the American medium, are to be found in the Proceedings of the Society for Psychical Research, but those who are interested in the abnormal mental states known as mediumship will welcome an account of the life of this medium as recorded by her daughter. The father and mother of Mrs. Piper were of English ancestry, deeply religious, and "strong, healthy, normal people," while the medium herself, the fourth of six children, seems to have heard voices and seen visions as early as her eighth year. Subsequently, Mrs. Piper further developed her unusual psychic qualities. After her mediumship had been investigated in America by Prof. William James of Harvard, and others, she was the subject of inquiry by the Society for Psychical Research in this country, and the book describes these investigations besides giving some account of the medium's home life. The volume is illustrated with reproductions of portraits of Mrs. Piper at various ages and of William James, F. W. H. Myers, Richard Hodgson, and Sir Oliver Lodge, as well as with specimens of automatic writing.

"BANTAM" COFFEE.

THERE is much waste in the making of coffee in the ordinary way, while the care necessary for properly preparing it takes up much time. These things are designed to be obviated by the use of "Bantam" coffee, a sample of which has been sent to us by the Bantam Products, Ltd., of Wortley, Leeds, with London offices at 9, Queen Victoria-street, E.C. 4. This consists of a brown granular powder which contains the soluble portion of the coffee bean. The powder can be completely dissolved in hot water, in cold water more slowly, and as there are no "grounds" left the beverage may be drunk to the last drop. It can be made in the cup at the table, or for large parties in an urn. The product should not be classed with "coffee essences," for on the palate it has the flavour of freshly roasted coffee prepared in the usual manner. If protected from moisture it is claimed that the powder will remain unchanged for a long time, and certainly the preparation is economical in use.

THE DOCTOR'S JOB.

THIS small book¹ is introduced to medical readers in a few words by Sir Donald MacAlister, who commends it to the careful perusal of medical students. Undoubtedly every medical student will be better "qualified" for his profession if he is able to look at the general problems of social life in the clear manner that Dr. Lloyd-Williams employs for their elucidation. A chapter on the problems of medical practice is added for the consideration of the qualified, where the remarks on birth control are thoughtful

CABBAGES.

MR. A. W. Hill, F.R.S., Director of Kew Gardens, who delivered a Chadwick lecture in the open air at the Chelsea Physic Garden on May 20th, said that the original cabbage was supposed to have arisen from the tears of Lyeurgus whom Dionysus had bound to a vine; botanically every cabbage was descended from the indigenous *Brassica oleracea*, now to be seen covering the cliffs at Dover. It was a plant with a stem, leaves and many racemes, which men had altered to suit their own needs. The stem is developed in kohlrabi (*caulis*, cole, kale, the stalk). The leaves had been grown into heads in the spring cabbage, in the curly savoy, in the red cabbage (which should never be pickled, but cut in slices and stewed in its own juice), and in the thousand-leaved kale grown for the winter food of sheep. The axillary buds become Brussels sprouts, which are anatomically bulbs. The inflorescence had been developed in the broccoli or cauliflower. No other plant has had so much advantage taken of its opportunities. Theophrastus mentions three kinds, Pliny six, de Candolle (1834) 30; now there are a hundred kinds.

A STOKER'S LOG.

GENERALLY when people talk about ventilation on board ships it is to complain of draughts. It is the more satisfactory to learn from the account given by Mr. H. Vincent¹ of his time as a stoker in the Navy in the war, that when he moved from an old cruiser to the new flagship of the Harwich force, he found the new ventilation a comfort, fresh air being driven into every compartment, however small. As a stoker in the tropics he was never ill; on the contrary, he was always in good condition, and hungry for the hot and greasy dishes he had in his mess. He never heard a word against the quality of the "pusser's" provisions, though they would have been better without cockroaches. He drank water freely when "on the fires," and against advice, but never suffered from cramps; but then he does not tell us what quantity of salt he took in his mess. Stokers are, he thinks, the hardest working men in the ship, very kind to one another, even to the author when he had just joined. The worst crime in this branch of the service is to let the fire out; the next bad, to admit an allotted job too hard, or to look exhausted. The night runs from Harwich were made in constant anxiety, and it was at such times leave was most welcome, though at all times a luxury to men off a crowded, severely conditioned lower deck. This book contains many good and dramatic stories, and some excellent silhouettes.

HOSPITAL AND AUXILIARY SERVICES AT LIVERPOOL.

THE Merseyside Hospitals Council has issued a handy little "Guide to Hospital and Auxiliary Services" within the scope of that body. These services are many and of great variety, ranging from convalescent treatment and the loan of invalid furniture to the follow-up of out-patients and home nursing. The booklet forms an admirable conspectus of the auxiliary services which are being developed rapidly by this enterprising council. It should be of real and suggestive value to the similar organisations which are springing up all over the country.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 24TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 304 (last week 324); scarlet fever, 1887; diphtheria, 1167; enteric fever, 89; pneumonia, 1034; puerperal fever, 44; puerperal pyrexia, 103; cerebro-spinal fever, 15; acute poliomyelitis, 2; acute poliomyelitis, 1; encephalitis lethargica, 10; dysentery, 2; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the infectious hospitals of the London County Council on May 27th–28th was as follows: Small-pox, 462 under treatment, 13 under observation (last week 513 and 22 respectively); scarlet fever, 2036; diphtheria, 2376; enteric fever, 29; measles, 797; whooping-cough, 68; puerperal fever, 21 (plus 18 babies); encephalitis lethargica, 121; poliomyelitis, 1; "other diseases," 19. At St. Margaret's Hospital there were 17 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London there was no death from small-pox, 1 (6), from enteric fever, 45 (16) from measles, 6 (2) from scarlet fever, 28 (1) from whooping-cough, 29 (6) from diphtheria, 42 (12) from diarrhoea and enteritis under two years, and 30 (6) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred at Ilford. Deaths from measles are rapidly sinking, the highest figures being Liverpool, 4; Manchester and Salford, each 3 (Edinburgh has 8). Four deaths from whooping-cough are reported from Birmingham, and 3 from diphtheria. Liverpool is credited with 7 deaths from diarrhoea; Manchester with 5.

The number of stillbirths notified during the week was 287 (corresponding to a rate of 40 per 1000 births), including 57 in London.

Lectisomian Lectures

ON

ENLARGED PROSTATE AND
PROSTATECTOMY.

Delivered before the Medical Society of London

By **SIR JOHN THOMSON-WALKER, O.B.E.,**
M.B. EDIN., F.R.C.S. ENG.,CONSULTING UROLOGIST TO KING'S COLLEGE HOSPITAL; SURGEON
TO ST. PETER'S HOSPITAL.LECTURE III.—THE OPERATION OF SUPRAPUBIC
PROSTATECTOMY.

(Delivered on March 6th.)

The operations for the removal of the enlarged prostate are divided into those performed by the perineal route and those, following McGill, by the suprapubic route. At the present time, largely as the result of Freyer's advocacy, the suprapubic route is almost universally practised. The popularity of the suprapubic route depends upon the ease of approach and the readiness with which the enlarged prostate can be shelled out by the finger. All enlarged prostates can be removed by the suprapubic route, and it is generally believed that the late results of the operation are better than those of the perineal operation. Space does not permit of a full discussion of the merits of the two operations. Only suprapubic prostatectomy will be described. Two types of procedure are at present in use, a closed operation which has been called Freyer's method¹ and an open operation that has been practised by Judd² and myself.³

Freyer's Method of Suprapubic Prostatectomy.—The bladder is approached and opened by a suprapubic incision two and a half inches in length. The forefinger of one hand is introduced into the rectum and pushes up the prostate. The forefinger of the other hand is introduced into the bladder, ruptures the mucous membrane covering the intravesical portion, and—keeping in close contact with the capsule—enucleates first one and then the other lateral lobe. The urethra is torn across and the prostate removed. The surfaces at the neck of the bladder are pressed together, between the finger in the rectum and that in the bladder in order to reduce bleeding. The bladder is irrigated with hot boric lotion (110° F.) through the catheter. A stout drainage-tube with two lateral eyes at the vesical end is placed in the bladder. The edges of the parietal wound are brought together and the tube kept in place by silkworm-gut sutures. The catheter is removed, and a voluminous dressing of gauze and wool applied. The bladder is irrigated twice daily with antiseptic lotion. The tube is replaced by a smaller one on the fourth day, and this is retained for a few days longer. When the wound has contracted to a small size a catheter is passed along the urethra and the bladder washed out through this.

OPEN PROSTATECTOMY.

Judd's Method.—The patient is placed in the Trendelenburg position, the bladder opened by a suprapubic incision, and self-acting retractors introduced. The prostate is then dissected out by forceps and scissors. A catgut suture is placed on any bleeding vessel, and if necessary the cavity is packed. Drainage is either by catheter (and the bladder closed), or by suprapubic tube.

Thomson-Walker's Open Method.—The aim of this method is to avoid sepsis, to control bleeding, and to prevent post-operative obstruction. A median suprapubic incision, five inches long, is made, and the bladder is opened. The forefinger of the right hand

is introduced into the bladder, the whole hand sinking between the recti muscles so that the hand moves freely. Enucleation commences by rupturing the mucous membrane at the posterior lip of the internal meatus, or on the far side of a projecting lobe. The finger separates the upper part of the lobes and easily finds the line of cleavage. After enucleation of each lobe, assisted by the longer second finger, the anterior commissure is separated from above downwards, the urethra severed on the catheter, and the prostate removed. No finger has been placed in the rectum. A catgut sling is placed in each lip of the bladder wound and the patient is raised into the Trendelenburg position. My self-retaining retractors are introduced, the catgut sling being twisted round the wings of the flynut on each arm. The blades are separated and the wound in the bladder extended so as to allow of free separation. The bladder base is freely exposed, clots are removed from it and the prostatic cavity, and a careful inspection is made.

There is usually some hæmorrhage and sometimes spouting vessels are seen. Arterial bleeding comes almost invariably from an artery lying below the torn mucous membrane at the outlet of the bladder about the mid-coronal line. Venous bleeding comes from the lateral or anterior walls of the prostatic cavity. Long artery forceps are placed on the bleeding points. With a short, strong, fully curved needle on a special holder, a catgut ligature is passed round the bleeding point and tied. There is usually no difficulty in this, but sometimes in the deeper part of the prostatic cavity it may not be easy. A continuous hæmostatic suture is introduced in most cases. This serves the double purpose of controlling bleeding and of forming a smooth edge which heals evenly at the vesico-prostatic outlet. The suture commences just in front of the mid-coronal line on the far side, and passes round the posterior two-thirds of the circumference of the opening. The stitch includes the mucous membrane, the edge of the bladder sphincter, and sometimes, at the lateral aspect of the opening, the edge of a thin layer of the false capsule of the prostate. If the bladder is contracted and deep, and there is urgent necessity for saving time, the stitch may be omitted, but it is very useful and greatly reduces the danger of hæmorrhage.

If venous bleeding persists, in spite of temporary plugging with a swab, and there is no single point readily accessible, the prostatic cavity should be packed. For this, the catheter is drawn well into the bladder, and a strip of iodoform gauze is packed round it.

Having controlled the bleeding, and before introducing the hæmostatic suture or packing, a search is made for tags, flaps, or nodules of prostatic tissue. A large variety of these may be discovered and dissected away. Loose flaps of mucous membrane at the sides of the vesico-prostatic opening are dissected away, and nodules of prostatic tissue may also be removed. A prominent semilunar ledge forms the posterior lip of the opening, which it tends to narrow. It is picked up in the middle line and a wedge cut out of it. This enlarges the vesico-prostatic opening, and prevents post-operative contraction.

Having completed the arrest of hæmorrhage, the clearing of the prostatic cavity and the opening-up of the vesico-prostatic opening, repair of the bladder and abdominal wall is undertaken. A large rubber tube is placed in the bladder and the blades of the retractor changed. The blades are inserted in the pubic end of the wound and separated, and the anterior surface of the bladder wall and the space of Retzius are fully exposed. The bladder is pulled up by the catgut slings and the bladder wound closed up to the tube by a continuous catgut suture. If the prostatic cavity has been packed with gauze, a corrugated rubber strip is placed between this and the bladder wall in front of the tube. A small tube is placed in the prevesical space. Two catgut mattress sutures are placed through the recti muscles and sphenas about an inch from the edge of the wound and the same distance apart. The rectus

¹ Lectures I. and II. appeared in our issues of May 31st and June 7th, respectively.

sheath is united with a continuous suture of fine catgut and the mattress sutures are tied. The skin wound is closed to the tubes with interrupted silk-worm-gut sutures. A many-eyed catheter is tied in the urethra with the tip in the bladder. This is closed with a spigot, and the end of the catheter and the penis are enveloped in an antiseptic dressing.

Routine Post-operative Treatment.—The treatment of cases of prostatectomy from the time of the operation to the closure of the bladder is of vital importance. Failure in the conduct of cases during this stage accounts for a large percentage of the mortality and also for imperfect late results. The following is the routine that is carried out in cases under my care.

Immediately after the operation the foot of the bed is raised 18 inches, and the patient is carefully watched for shock. If he is restless, a quarter of a grain of morphia is given hypodermically and this may be repeated at night if necessary. At the operation a dressing of gauze and wool is applied, and this is usually allowed to remain overnight, or is reapplied. Haemorrhage is the danger at this stage. An increasing pulse-rate, uncontrollable bladder spasm from clot, restlessness, and blanching are all important signs, and should lead to careful inspection. If bleeding is so severe as to produce large clots, or the general effect of haemorrhage is apparent and the blood is bright, the prostatic cavity will have to be packed. This is best carried out under a short anaesthesia; gas and oxygen is not suitable as it increases the bleeding. The tubes are taken out, clots are rapidly removed from the bladder with sponge forceps, and a full stream of weak nitrate of silver solution (1 in 20,000) is passed through the catheter. The end of the catheter is now drawn well into the bladder. The prostatic cavity is packed with iodoform gauze, the finger of the right hand being in the bladder and packing the strips of gauze snugly round the catheter. The large bladder tube and the prevesical tube are replaced. If the patient has not already had morphia he is given a hypodermic of a quarter of a grain, and the foot of the bed is well raised.

When no such accident has occurred the usual routine is carried out. The gauze and wool dressing is replaced on the morning after the operation by a Hamilton Irving suprapubic box, and the bed is returned to the horizontal. Either intermittent daily irrigation or continuous irrigation is arranged. The majority of my cases are placed on continuous irrigation, which is maintained for four or five days or even longer. An irrigation rubber bag, or better a thermos, is hung 3 feet above the level of the patient. Interrupting the rubber tube leading from this is a glass dropper. The tube passes over a rubber hot bottle, and is connected with the catheter in the urethra. The tubes of the Hamilton Irving suprapubic apparatus are carried under the thighs to a pail under the bed. The fluid (silver nitrate solution 1 in 20,000) runs at a rapid drip. In the cavity of the suprapubic box is placed a gauze bag of coarse crystals of boric acid, which is replaced every 12 or 24 hours. On the third day after the operation a dose of castor oil is given. Enemata are forbidden, as they are liable to cause haemorrhage. If the prostatic cavity has been packed the packing should be very carefully removed after 24 or 48 hours. This is assisted by a stream of fluid through the catheter, and constant irrigation is installed at once after the removal. The tubes are removed on the fourth or fifth day, but not before. A small tube replaces the large bladder tube for two days, and is then removed. Continuous irrigation may be maintained for another day or two, or omitted.

Each day the box is removed, cleaned, boiled, and replaced. A suitable ointment containing an antiseptic is smeared on the skin so that the box does not irritate it. Care and frequent inspection are required on the part of the nurse to adjust the box. At the daily dressing a full flow of fluid is passed through the catheter and tube, and all clots are removed. Care

must be taken not to raise the pressure in the bladder by too great a flush, otherwise haemorrhage may be started. If during the time the tubes are in the wound the urine becomes brightly blood-stained or a dark, venous oozing persists, constant irrigation with weak silver solution is installed at once, an injection of morphia is given, and the patient kept quiet. If the oozing persists, an injection of hæmoplastin should be given each night and morning for two days and calcium lactate by mouth in doses of ten grains every four hours for 48 hours. If at the end of this time the bleeding has not ceased or is not diminishing, the prostatic cavity should be packed. Haemorrhage sometimes occurs about the tenth or twelfth day, when the bladder is beginning to be stretched by contraction on closure of the wound or where it has been over-distended by irrigation. If the bleeding appears to be serious, the suprapubic wound should at once be opened up, and a tube introduced and a catheter placed in the urethra and continuous irrigation installed. If the haemorrhage persists in spite of this and other measures already enumerated, the prostatic cavity should be packed round an indwelling catheter.

In the usual routine the catheter is removed on the seventh day. During the time the catheter is in the urethra the most stringent precautions must be taken to prevent infection spreading up alongside it or along the column of urine in its lumen. A dressing of glycerin on iodoform gauze is placed round the glans penis, and when the catheter is not in use for irrigation it is closed with a sterile plug and the end covered with an antiseptic dressing. Washing the bladder by Janet's method of hydrostatic irrigation through the urethra and the forcible distension of the bladder to the point of micturition by the nozzle of an irrigating apparatus in an almost-closed suprapubic fistula are methods that are better avoided, as they promote bleeding. Haemorrhage at the time of the operation and during the convalescence from prostatectomy requires prompt and skilful treatment. The patient operated on for removal of the prostate should leave the operating theatre as dry as he would in any other operation. Continued leakage of dark venous blood should be looked upon as a matter of serious import demanding energetic measures for its control. The appearance of bright blood in the urine, especially when accompanied by clotting, should be regarded as a matter of grave danger. The hæmostatic bag of Hagner or Pilcher is used by some surgeons. It is a rubber bag attached to a catheter and distended with air to press on the walls of the prostatic cavity. The bag is held in position by traction on the catheter. I do not use this method as I have found the means of controlling haemorrhage already described amply sufficient if applied in proper time.

TWO-STAGE PROSTATECTOMY.

Prostatectomy as a secondary operation is a different operation from primary prostatectomy. The bladder is open and infected and it is adherent to the abdominal wall and the posterior surface of the pubic symphysis. The cavity is reduced to a small space, and the walls are thick and rigid. The abdominal wall in the suprapubic region is infiltrated with inflammatory material and is rigid. Under such conditions open prostatectomy in the manner I have described is not a satisfactory operation. In order to perform the open operation the matted inflammatory tissue and the scar tissue must be dissected away, the bladder freed from the abdominal wall and pubic bones, and the scar tissue in the bladder wall surrounding the fistula excised. This mobilisation of the bladder must take place before the enucleation begins. The contracted bladder renders exposure of the prostatic cavity far from perfect. This is a formidable addition to the ordinary open operation, and is, I believe, too severe for the majority of cases submitted to secondary prostatectomy. There are some cases where months have elapsed since the preliminary cystotomy where the scar tissue is small in amount and the condition of the patient good. In these cases an open operation

may be performed. For the majority of cases of secondary prostatectomy the technique of Freyer is more suitable. With this also the operation is more severe than a primary prostatectomy, and the probability of obtaining a clean prostatic cavity and a rapidly closing firm wound is less.

PROSTATECTOMY IN THE FIBROUS PROSTATE.

In most cases of fibrous prostate enucleation by the closed method is a difficult and unsatisfactory operation, and may be impossible to complete. The ultimate results in the majority are highly unsatisfactory. The ragged walls left after tearing out the prostate promote sepsis, and post-operative contraction of the vesico-prostatic outlet is a likely sequel. It has been suggested that these cases should be operated by the perineal route. It must be remembered that in many cases the adherent nature of the prostate is not discovered until the operation has commenced, and occasionally only when the prostate is partly enucleated. To abandon the operation and resort to a perineal dissection is a highly unsatisfactory procedure. I have found no difficulty in dissecting these prostates by the open suprapubic method. If difficulty is encountered in enucleating the prostate the patient is at once placed in the Trendelenburg position and the operation performed by dissection.

Where the adherent nature of the prostate is discovered before enucleation has been commenced the Trendelenburg position is assumed at once, and the bladder base exposed. The mucous membrane round the internal meatus is incised with curved scissors and the incision deepened. The upper part of the prostate, as it begins to appear, is grasped with forceps and gently raised while the clipping with scissors proceeds, the blades being kept rigidly to the surface of the gland. The lobes are dissected equally and some blunt dissection with the closed scissors or the forefinger may help. The anterior commissure is separated from above downwards, and the urethra cut across. A clean, roomy cavity with smooth walls can thus be obtained. There is more tendency to bleeding after the dissection than after enucleation, and I usually pack the prostatic cavity as well as introducing a hæmostatic suture.

SURGICAL ACCIDENTS AND COMPLICATIONS OF PROSTATECTOMY.

The causes of death in 269 cases of suprapubic prostatectomy for simple enlargement of the prostate at St. Peter's Hospital are stated in the following table, and give a general idea of the dangers that attend the operation.

Table showing Causes of Death after Suprapubic Prostatectomy in 269 Fatal Cases at St. Peter's Hospital from 1901 to 1929.

	Total number and Percentage.
Surgical accidents:	
Shock	25 }
Cardiac failure	32 }
Hæmorrhage	7 }
Renal failure:	
Uremia	67
Septic complications:	
Pyelonephritis	53 }
Pelvic cellulitis	3 }
Sepsicæmia	7 }
Diseases of the lungs:	
Pneumonia	23 }
Bronchitis	5 }
Diseases of the circulation:	
Cerebral hæmorrhage	4 }
Coronary thrombosis	1 }

Intoxication	10 }
Asthænia and general debility	10 (3.7)
Accidental complications:	
Acute mania	2 }
Induræcia (epidemic)	2 }
Pancreatitis	4 }
	269

It will be seen that over 70 per cent. of fatal results are due to shock, renal failure, and sepsis. Hæmorrhage

accounts for only a small number (2.6 per cent.) of deaths, but it is probably a contributory factor in other fatal cases, such as some of those from asthenia and general debility.

Shock and cardiac failure are the result of too severe an operation on an old or enfeebled patient. The most serious shock follows attempts to enucleate an adherent fibrous prostate, secondary prostatectomy with much rigidity of the abdominal wall, and the open operation where the surgeon is unpractised in bladder surgery and unsystematic in surgical technique. At St. Peter's Hospital the open method is the operation generally practised, and the mortality compares very favourably with other hospital figures. In each case the type of operation which is most suitable should be chosen, having regard to the condition of the patient and the ability and experience of the surgeon.

The avoidable causes of serious hæmorrhage after prostatectomy are numerous. They include the following:—

1. Insufficient precautions at the time of the operation.
2. Sepsis. The onset of an attack of cystitis from post-operative infection may be heralded by severe hæmorrhage. Late hæmorrhage (tenth to twelfth day) is seldom a real secondary hæmorrhage in the surgical sense.
3. Injudicious and unskilful passage of instruments along the urethra during the first week or ten days after the operation.
4. Over-distension of the urethra or bladder by attempts to wash the bladder by Janet's hydrostatic method or by forcing fluid into the bladder through a narrow suprapubic fistula.
5. Distension of the rectum by large enemata during the first week after operation.
6. Straining and undue exertion on the part of the patient.
7. Delay in treating a moderate hæmorrhage when it is commencing or when there is continuous oozing.

After the operation all patients should be encouraged to drink large quantities of fluid and especially the diuretic waters, such as Contrexéville and Vittel. If symptoms of uræmia appear (drowsiness, want of appetite, thirst, dry tongue) the diuretics should be pressed, and in addition fluid may be introduced by means of proctolysis or subcutaneous or intravenous infusion of saline solution with glucose. The prevention of septic complications begins at the operation and continues until the bladder is closed. In the open operation the rectal finger is banded, and all shreds and loose material likely to slough and become infected are carefully removed.

After the operation the following measures are adopted to prevent sepsis:—

1. The Hamilton Irving suprapubic box with a bag of boric acid crystals on the wound.
2. Continuous irrigation of the prostatic cavity and bladder with weak antiseptic solution through a catheter retained in the urethra.
3. Antiseptic dressing of the penis and catheter.
4. The routine use of urinary antiseptics such as cystazol, caprokol, and acriflavin.

Epididymitis is one of the most frequent complications of urinary infection, and many surgeons perform vasectomy at the time of the prostatectomy. I have not found this necessary, for epididymitis occurs only in a small number of my cases (0.4 per cent.), and is usually very mild.

THE MERITS OF THE DIFFERENT OPERATIONS.

The closed, blind or Freyer method has the advantage of rapidity, which in some cases that require operation is a matter of importance. The question of rapidity must, of course, depend on the habits and skill of the surgeon, but other things being equal, it is the most rapid of the suprapubic operations. This method is, moreover, easy to perform and requires no special skill in bladder surgery. Once the surgeon has learned to find the line of cleavage he will succeed, in some measure at least, in removing the obstruction.

Its disadvantages are that sepsis is more likely to be a complication of convalescence than in some other methods, that hæmorrhage is blindly and often imperfectly controlled, and that post-operative

obstruction may be expected in a certain proportion of cases.

The open operation has the advantages that many of the causes of sepsis are removed, that hæmorrhage is more efficiently controlled, and that post-operative obstruction is guarded against.

The disadvantages of the open method are that it is more difficult and needs a knowledge of bladder surgery, notably the proper exposure of the bladder base and intravesical manipulation.

Practice and team work is necessary if the time taken is not to be unduly prolonged. My usual time for the operation from the incision to the last stitch is 18 minutes, and, if the hæmostatic stitch is omitted, 13 minutes. The longer time taken by a surgeon unaccustomed to bladder work is a serious disadvantage. Enucleation with the finger in the horizontal position before exposure of the bladder base has the advantages that the method is more rapid than dissection in the Trendelenburg position, and in my experience there is less hæmorrhage when the prostate is enucleated than when it is dissected. Enucleation has the further advantage that the time during which the patient is in the Trendelenburg position is shorter.

RESULTS.

The results of suprapubic prostatectomy for simple enlargement of the prostate will be considered under two headings: mortality of the operation and failures.

Mortality.—In order to obtain a general view of the mortality of suprapubic prostatectomy, I found it necessary to collect statistics from various sources representative of the different conditions under which the operation is performed. In this country there is a sharp distinction between the arrangements that control the after-treatment of charity patients and what are called private patients. I have been fortunate in obtaining statistics from 11 of the great hospitals in different parts of the country for a period of ten years (1918 to 1928), and one for a period of seven years. I wish to express my cordial thanks to the members of the surgical staffs of these hospitals for the readiness with which they acceded to my request for information and the trouble taken to collect the statistics. I have arranged the statistics of the general hospitals in the accompanying Table, the hospital being designated by a letter and the number of beds in each hospital being indicated. The second group of statistics are those of St. Peter's Hospital, London, a hospital of 30 beds devoted entirely to surgical diseases of the urinary organs. The statistics of this hospital include all the operations of suprapubic prostatectomy from the first operation Sir Peter Freyer performed there in 1901 to the end of 1929. The third group of statistics which represent the statistics of private practice are my own cases. In order that the groups may be entirely distinct, I have excluded from my own figures all cases operated on in hospital.

In the general hospitals there were 3451 operations of suprapubic prostatectomy for simple enlargement of the prostate. Of these, 675 died, a mortality of 19.5 per cent. At St. Peter's Hospital there were altogether 2691 cases in a period of 29 years with

268 deaths, a mortality of 9.9 per cent. The fluctuation of the mortality from year to year is set out in the accompanying chart. In three of the years the mortality was below 5 per cent.—namely, 4 per cent. in 1909 and 4.9 per cent. in 1917 and 1918. In my private practice, during the 11 years 1919 to 1929 inclusive, I performed suprapubic prostatectomy on 472 patients with 25 deaths, a mortality of 5.2 per cent. The total number of my private cases was 608, with 37 deaths, a mortality of 6.08 per cent. There were series of cases of a year's duration in which the mortality fell to 1.7 per cent. (1921) and 2.1 per cent. (1923), and there were other series where the mortality rose to 9.7 (1927) and 11.4 (1920) per cent. The fallacy of considering a short period of time and a small number of cases is therefore obvious. It is, I think, the experience of all surgeons that a very considerable difference exists

between the mortality of their private practice and that of their hospital work; and there is a further difference in mortality that becomes evident in the statistics that I have collected—namely, between the mortality of prostatectomy in the wards of a general hospital and that of a special hospital.

It is evident, therefore, that there is some factor outside the immediate control of the operating surgeon that produces so

Chart of mortality of suprapubic prostatectomy at St. Peter's Hospital during 29 years.

constant a difference in the mortality. The patients in private practice are on the whole better cared for and subjected to less physical strain, and are for the most part less exposed to the effects of unsuitable diet than are those of the hospital class. Hospital patients are, as a rule, submitted to operation at a later stage of the disease than private patients, and infection of the urinary tract is more frequently present before operation. Nevertheless, it cannot be denied that a very considerable proportion of cases operated on in private practice are grave surgical risks. A glance at the figures I have given in regard to circulatory risks is convincing of this. Moreover, the cases treated in a special hospital, taking them as a whole, are slightly greater surgical risks than those treated in a general hospital, for the reason that the cases that are considered hopeless elsewhere are usually referred to the special hospital.

So far as selection of cases for operation is concerned, I can vouch for the wide range of risks that are faced in the special hospital. If there is any criticism to make it is rather on the score of occasional recklessness than of over-caution in the sifting of cases for operation. In selecting cases we have been influenced by the fact that a working man who is refused prostatectomy is condemned either to catheter life or to suprapubic drainage, and that either of these alternatives implies certain misery and very grave risk; that, doubtless, is the general feeling among surgeons at the present time. The principal cause of the difference in statistics is, I think, to be found in the different conditions under which post-operative treatment is carried out in a general hospital, a special hospital, and in private practice. In a general hospital these patients are necessarily treated in large, freely ventilated surgical wards, and the post-operative treatment is mainly in the hands of the resident

surgeon, who as a rule is recently qualified and is replaced every six months. The private patients are accommodated in private hospitals or homes in separate rooms, heated to suit their special sensibility, and attended by special nurses accustomed to deal with these difficult cases; the post-operative treatment is carried out by the operating surgeon or his permanent assistant. Between these come the special hospitals, where the grouping of cases leads to special nursing measures and the post-operative treatment is in the hands of a resident surgeon of senior grade who has held several surgical appointments and been trained as a junior in the dangers which follow operation in these cases before he assumes the full responsibility.

The treatment after operation for prostatectomy is complicated, and its success depends on scrupulous attention to detail and on early and rapid action

thinking that, if the belief in adequate preoperative examination and treatment were generally held, the time and accommodation would be forthcoming. It may well be that the adoption of a two-stage operation in some surgical centres is an attempt to meet this objection; as such it cannot be too highly commended. My own view is that the preparation in the average case is better carried out by careful catheter drainage and simultaneous general treatment. But if this cannot be efficiently carried out in the wards of a general hospital, the preliminary cystotomy of a two-stage operation is the best substitute, provided that adequate measures for the prevention of infection of the cystotomy wound and bladder be adopted.

Time might well be saved and the mortality lowered by the more detailed methods of prevention of sepsis after operation. It appears to be a fairly

Table of mortality of suprapubic prostatectomy at 12 general hospitals.

where surgical accidents such as hemorrhage occur. It cannot be expected that every newly qualified surgical officer will bring with him the knowledge and experience necessary for the successful conduct of these difficult cases. Some brilliant young men do come prepared, and it has been my pleasant experience to pass two years in the special department of King's College Hospital without a single death after prostatectomy. Further, Mr. Harold Edwards⁴ has published the statistics of the Urological Department at King's College Hospital during five years (1922-26), which showed a mortality of 8.7 per cent. in 126 cases. But this is exceptional, and it is during the early months of learning that the mortality figures of the operation creep up.

There are two other points on which I write with some diffidence, for they relate to matters of surgical opinion rather than to the discussion of general management. I am not quite certain that sufficient attention is paid to the complete examination and careful preoperative treatment of these cases, and I do not think that the measures taken to combat post-operative sepsis and hemorrhage are universally adequate. Complete preoperative examination and preparatory treatment require time, and mean that a surgical bed is occupied for a longer period. The shortage of hospital beds and the necessity for the rapid passage of patients to make way for emergency cases curtails very severely the time that can be given to this part of the treatment. But I cannot help

widespread belief that an indwelling catheter and continuous irrigation after the operation are difficult measures to apply, and will cause hemorrhage and epididymitis. This view is not in accord with my experience, and I believe that if this method, together with the other details of post-operative treatment that I have already described, were intelligently carried out, the post-operative period of healing and septic complications would be reduced. There should be no hesitation or delay in carrying out the measures for the control of hemorrhage that have already been described. Most of the danger of hemorrhage after operation is due to the treatment being applied too late. Hemorrhage is too often treated when the patient is moribund instead of at the beginning when he still has reserves of blood and strength.

A second question that arises in regard to the mortality is the influence that the type of operation has upon the death-rate. The most important division of operations is that into one-stage and two-stage prostatectomies. In the accompanying table of cases from general hospitals the total single-stage operations, so far as could be ascertained, was 2060; of these, 424 died, a mortality of 20.5 per cent. The total of two-stage operations was 1234, of these 215 died, a mortality of 17.4 per cent. There is a saving here of 3.1 per cent. In St. Peter's Hospital statistics, the number of two-stage operations was 461 with 59 deaths, a mortality of 10.3 per cent., which is higher by 0.5 per cent.

than the single-stage operation. These figures taken at their face value are, however, misleading if a true comparison of the two operations is to be made. Where the single-stage operation is the rule, the two-stage operation is reserved for the most serious cases, and is necessarily accompanied by a higher mortality. Thus in hospitals A, B, and C the larger number of operations were performed by a single-stage operation, and only a small number by the two-stage method, and the latter carried a much higher mortality. In hospitals E, F, G, and K the numbers done by each method were much more equal, and it was evident that not the worst cases alone were selected for the two-stage operations. Here the mortality of the two-stage operation was lower than that of the one-stage. In hospital D the figures of the one-stage operation are not quite certain, as some two-stage operations were probably included, but those given under the two-stage operations represented all the prostatectomies done during two years, so that no selection of cases adverse to the two-stage operation had taken place. Here the mortality of the two-stage operation is 2.0 per cent. below the total percentage and 3.6 per cent. below the probable one-stage operation mortality. It appears from these statistics that in general hospitals where all the cases are operated on in two stages there is a moderate improvement in the death-rate. It is probable that if the two-stage operation were

universally adopted in general hospital work, the difference in the figures would be greater. My own preference would be to try a more careful and prolonged preparation with a single-stage operation

and more careful instruction in post-operative treatment of these cases. If it were possible to close the bladder at once in all cases, the dangers that attend the post-operative treatment of an open cystotomy wound would be greatly reduced. This is not, however, possible at the present state of our knowledge, and it is not of great benefit to close the bladder in a few selected cases.

FAILURES OF PROSTATECTOMY.

The operation may be said to have failed or to be incompletely successful when free voluntary micturition is not re-established, so that there is difficulty in expelling the urine, in varying degrees up to complete inability; or when the frequent micturition and bladder irritation is not relieved; or again where there are recurrent attacks of cystitis, pyelitis, pyelonephritis or epididymitis, or the development or recurrence of stone; or where the wound does not close and a fistula persists. These failures can be traced in the great majority of cases to two causes, one or both of which may be at work—namely, sepsis and obstruction.

Post-prostatectomy Obstruction.—Obstruction after suprapubic prostatectomy varies from a slight difficulty in micturition to complete obstruction with suprapubic fistula. Other conditions than obstruction may delay the healing of the suprapubic wound after

FIG. 3.

prostatectomy—namely, general debility, glycosuria, prolonged retention of the drainage-tube, and adhesion of the lower lip of a too low-placed cystotomy wound to the pubic symphysis while the upper end of the wound moves freely. The chief causes, however, are sepsis and obstruction. In the open operation with a long abdominal incision the wound heals by first intention down to the tube aperture, the urine is usually passed along the urethra about the eleventh or twelfth day after the operation, and the wound is dry on the sixteenth day. The following are the average dates on which the urine was passed and the wound dry during six years. From these statistics seven cases have been removed. Four were two-stage operations where the first stage had been done for severe sepsis, and it was not possible to resect the indurated area of the abdominal wall so as to ensure rapid healing. In another there was a faecal fistula alongside the suprapubic wound, and another had a carbuncle that infected the wound. These cases were so unusual as to justify separation from the others in considering the common post-operation course.

Year.	Day average.	Day average.
1924	13.1	16.7
1925	12.1	16.4
1926	10.1	16.0
1927	10.0	16.3
1928	12.6	15.6
1929	11.8	16.3

Urine passed. Wound dry.

In 75 cases of severe obstruction following suprapubic prostatectomy submitted to me for consultation the following conditions were found.

1. Fibrous contraction at the site of the operation.
2. New growth in the wall of the prostatic bed due to (a) recurrence of simple enlargement of the prostate, (b) malignant growths.

Fibrous Contraction at the Seat of Enucleation of the Prostate.

There are two danger-points for the development of stricture after suprapubic prostatectomy—namely, at the membranous urethra and at the outlet of the bladder. At each of these points the mucous membrane

FIG. 5.

A B

of the urethra is torn across. It is rare to find contraction at the membranous urethra. This only occurs in 4.3 per cent. of the cases of post-prostatectomy obstruction that I have seen. The point of narrowing in 85.5 per cent. of cases is at the opening from the bladder into the prostatic cavity. In some cases there was also the development of thick masses of fibrous tissue in the wall of the prostatic bed. In addition to fibrous contraction at the vesico-prostatic opening, there was a variety of folds and

flaps of mucous membrane and nodules of prostatic tissue or of granulation tissue in the immediate neighbourhood of the outlet. In several there was a hard fibrous ridge passing backwards or laterally from the site of the internal meatus across the base

FIG. 6.

Malignant growth in pathological capsule of enlarged prostate. A, Anterior and posterior views of easily enucleated enlarged prostate. B, Anterior and posterior views of malignant growth in capsule dissected after enucleation of prostate.

of the bladder. The fibrous contraction formed a hard ring round the internal meatus, which was so narrowed as to admit a fine olivary bougie or a fine probe. In seven cases the internal meatus was completely obliterated and covered with mucous membrane, so that no trace of it could be discovered. In one of these cases a false passage had been tunnelled through the bladder base and opened into the bladder behind the trigone; in another a false urethra tunnelled through the right lateral wall of the bladder.

In all these cases the degree of obstruction was severe. In 43 per cent. there was a suprapubic fistula that had persisted since the operation. In the remaining cases there was great difficulty in micturition and recurrent attacks of retention of urine relieved with great difficulty by the passage of a catheter. In 39 cases where it was possible to ascertain the type of prostate removed at the original operation it was small, fibrous, and difficult to enucleate in 17, adherent and containing calculi in 3, and large and easily enucleated in 19. The number of the two main types of simple enlarged prostate—namely, the fibrous and the adenomatous—was practically equal. In all the cases the blind method of operation was performed, and in three it was done in two stages.

The causes of post-operation obstruction after suprapubic prostatectomy are: (1) imperfect removal of obstruction; (2) sepsis.

It is an essential part of the open method that these causes of future obstruction should be removed and that a free opening from the bladder into the prostatic cavity should be ensured, removing, if necessary, a wedge from the posterior segment of the ring of the vesico-prostatic outlet. At the end of this operation the prostatic cavity is open to the cavity of the bladder, so that there is no hour-glass formation by narrowing at the junction of these cavities (Figs. 1 and 2). The

sphincter of the bladder after suprapubic prostatectomy. As I pointed out many years ago, is the compressor urethræ, and there is no possibility, as there is no necessity, of restoring the internal sphincter. The freer the opening between the two cavities the better. I can see no object in narrowing this part of the bladder outlet, as has lately been described, and I am apprehensive that the late results of this attempt will show an increase in the number of cases of post-operative obstruction.

The second cause of the development of post-prostatectomy obstruction is sepsis. In many of the cases on which I have operated for this condition there is evidence of prolonged suppuration in the heavy scars that remain.

TREATMENT OF POST-PROSTATECTOMY CONTRACTION.

The treatment of post-prostatectomy obstruction may be by way of the urethra or by open operation. The urethral treatment may be carried out by the passage of metal sounds, by rupture, by a Kollman's dilator, by cutting with Young's punch or a urethrotome, or by burning with the high-frequency cautery. For the urethral method the stricture must be permeable and the tissue of which it is composed must not be too dense or massive. In such cases the passage of metal sounds is the easiest method, care being taken that the sound does actually enter the bladder and the point does not pass backward between the wall of the prostatic bed and the canopy that roofs it and push up the bladder base. For the Kollman dilator, Young's punch, and the high-frequency cautery a wide opening must already be present for the passage of the instrument, so that these methods are reserved for cases where there is a fibrous ring or a constricting fold with sufficient room to pass a No. 12/14 metal sound. In the more severe grades of obstruction these methods do not come into consideration, for the instruments cannot be introduced into the bladder.

I have now treated 40 cases of severe post-prostatectomy obstruction by open operation, and in all the cases the operation was successful in restoring free micturition without residual urine. I have elsewhere described the operation in detail.⁵ The essential points are the removal of all scar tissue from the abdominal wall, free mobilisation of the bladder, and removal of scar tissue at the opening of the fistula, and exposure of the bladder base with free dissection of all scar tissue or other obstruction at the vesico-prostatic outlet and, if necessary, in the prostatic bed (Figs. 3 and 4). The after-treatment is that of a suprapubic prostatectomy.

New Growth in the Prostatic Bed.

(a) *Recurrence of simple enlargement of the prostate.*—Incomplete removal of the enlarged prostate, when only the intravesical projection of the prostate is removed or when only one lobe has been enucleated, is occasionally met with and is easily recognised. A more important form of development of prostatic obstruction occurs when the enlarged prostate is reconstructed after what was apparently a complete enucleation.

From a patient aged 77 I removed a large bilobed adenomatous prostate in May, 1916, by the blind method. Ten years later he began to have difficulty, and on examination the prostatic area was occupied by what appeared to be an ordinary enlargement of the prostate gland. In 1926 I removed, partly by enucleation and partly by dissection, an adenomatous nodule with a complete ring of prostatic tissue (Fig. 5). From the posterior aspect the specimen resembled an ordinary enlargement of the prostate with an intravesical lobe. From the anterior aspect the ring was complete only at the upper part; below this was an open trumpet-like tube with a smooth lining on the surface of which small openings of gland ducts could be detected. Microscopical examination showed a fibromuscular stroma with prostatic gland acini of various sizes.

I have examined a number of similar cases in consultation where the prostate appears to have been reconstructed after prostatectomy. The recurrent simple prostate undoubtedly takes origin in layers of

the pathological capsule that have remained in the wall of the prostatic bed after an incomplete prostatectomy.

(b) *Malignant growth in the wall of the prostatic bed.*—In discussing the development of secondary malignant growth in simple enlargement of the prostate (Lecture II.), I referred to the position in which this might take origin. One of these positions is at the periphery of the enlarged gland.

The following case came under my care:—

A man, aged 64 years, had an enlarged, tough and somewhat fixed prostate which I considered as probably malignant although not hard or nodular. A round adenomatous nodule projected into the bladder and, to my surprise, a well-formed enlarged prostate with two lobes and an intravesical lobe shelled easily in one piece. On examining the prostatic bed I found a leathery capsule left behind. This I dissected out as a cuff and microscopical examination showed that it was composed of fibromuscular tissue with glandular alveoli and was infiltrated throughout with carcinoma (Fig. 6). Section of this prostate showed that the outer part only was infiltrated in places with cancer cells.

I have met with a number of cases where the prostate had been removed and it was stated that the gland had shelled out easily, yet after an interval of one or several years obstruction recurred. On examination there was a malignant infiltration of the wall of the prostatic bed. These cases belong to the group of secondary malignant growth of the prostate originating in the periphery of an adenomatous gland.

LEFT INFRAMAMMARY PAIN.

By DORIS M. BAKER, M.D., M.R.C.P.LOND.,

ASSISTANT PHYSICIAN TO THE SOUTH LONDON HOSPITAL
CLINICAL ASSISTANT TO THE NATIONAL HOSPITAL FOR
DISEASES OF THE HEART.

(With a Note by Dr. JOHN PARKINSON.)

Introduction.

LEFT inframammary pain has been the subject of discussion, controversy, and difference of opinion for many years. As far back as the middle of last century articles on this condition appeared in the medical journals, and in 1864 Martyn¹ described it as "one of the most frequent, intractable, and mysterious nervous affections we have to do with." Since then it has been mentioned by many writers, more especially under differential diagnosis from angina pectoris: yet in spite of this spasmodic interest in the subject it is a subject which has seldom been directly dealt with a view to its elucidation. In view of the significance of pain in this region to the layman, occasionally to the medical mind,^{2,3} I have attempted to describe a clinical picture which will readily lead to ready recognition, to arrive at some real meaning and importance, and to establish a prognosis and differential diagnosis.

Methods of Investigation.

The following investigations chiefly on patients attending the Hospital, with a few seen in private, are indebted to Dr. Parkinson, who suggested the investigation, and provided facilities for it.

(1) The following list of patients had pronounced left inframammary pain in their hospital records. The records were reviewed even 20 years later in an endeavour to establish the clinical course, prognosis, and treatment of the complaint.

(2) The examination of a certain number of patients who from week to week have presented themselves at the outpatient department giving this pain as their chief symptom, in order to obtain an accurate and complete clinical picture.

(3) The investigation by statistical methods of the incidence of the condition in a series of consecutive out-patients.

In deciding which patients to accept for this purpose attention has been directed to severity and persistence of the pain and its duration; in searching the old records of the hospital for suitable cases all of doubtful diagnosis have been excluded. Thirty-two cases have been collected whose records go back over a number of years, the longest 29 years. From the hundreds who have attended primarily with this complaint, 20 other illustrative cases have been selected for particular investigation and observed weekly or

FIG. 1.

(Case 14). The chief site of pain is indicated by a cross. The shaded area is hyperaesthetic.

monthly. In the statistical investigation consecutive out-patient cases during the year 1927 have been chosen.

From the reading of the literature on the subject it seemed of primary importance to decide as exactly as possible what was understood by the left inframammary or precordial region. The accompanying diagram (Fig. 1) shows the areas of hyperaesthesia found in Case 14, and it illustrates the parts under discussion; the areas involved primarily are DV and VI according to Head's segmental areas⁴; there is some extension above and below and to the subscapular region. The common association of left inframammary pain with left subscapular pain was described by Parkinson in 1910.⁵

The method of examination has been as follows:—

(a) Routine examination, including estimation of blood pressure and testing of urine.

(b) Wassermann reaction; X ray examination; electrocardiogram.

(c) Testing for hyperaesthesia by the simple method of lightly dragging the head of a pin over the skin. This was a method used by Sir James Mackenzie and Sir Henry Head.⁶ Tenderness was then elicited by palpating with the finger tips over the same regions. The parts examined were the left breast above and below the nipple and the region about the angle of the left scapula; and the results were entered on a chart.

A Typical Case.

To introduce the subject clinically, a typical example may be quoted.

CASE 14.—A woman, aged 51, complained of an almost continuous pain under the left breast, frequently also under the left shoulder blade, along with a dull ache in the left arm. The pain was always worse after the day's work in the evening, or in bed at night. It began about two years ago as a sensation of soreness and weight, occasionally as pricking in the left inframammary region. At first there were intervals of weeks or months of relief; latterly it was almost continuous. Other complaints were exhaustion,

dyspnoea on exertion, and difficulty in taking a deep breath at rest, palpitation, loss of appetite, and poor sleep. She volunteered that the skin below the left breast was often sore, and at times she could not bear her clothing against it.

On examination: a nervous, anxious woman. Pulse regular, 72 lying, 80 standing. Blood pressure, 160/90; later, 145/90. Urine normal. Routine examination of cardiovascular system, negative. Radioscopy, nothing abnormal. Electrocardiogram, physiological. Wassermann reaction negative. Hyperaesthesia, a large area in the left inframammary and mammary regions, also about the angle of the left scapula; some tenderness on palpation in both these areas (Fig. 1).

Ætiology.

Sex.—The condition is much more common in women than men; in this series were 43 women and 9 men.

Age-incidence.—Broadly there are two groups, younger patients in the late twenties and the thirties, and older patients in the late forties and fifties—that is, in women the years about the menopause. In children it is rare, and in the elderly uncommon.

Build and temperament.—This does not appear to be so clearly defined as has been suggested by some observers. Patients are either of the thin anxious type or stout and stolid; this latter build is seen more frequently in middle-aged women. The majority, it is true, present what have been described as nervous stigmata.⁷

Rheumatism.—Six only out of the series of 52 gave a history of acute rheumatism, and two of these had mitral stenosis; there appeared to be no relation between the conditions. On the other hand, so-called "rheumatic pains" in the middle-aged patient were very common.

Syphilis.—The Wassermann reaction, which was performed on most cases, was always negative.

Associated cardiovascular disease.—In this series 14 patients had signs of cardiovascular disease, 10 having high blood pressure and 4 mitral stenosis; the remaining 38 gave no evidence of structural disease. In the majority, therefore, the pain is the main feature, and no recognisable cardiovascular disease is present; statistics on this point are given later.

Immediate causes.—Though the onset is nearly always gradual and scarcely noticed, pain is occasionally described as follows: Case 26 had pain suddenly during the night following a cricket match in which he had bowled for three hours continuously. Case 16 after reaching up with the left arm for a book had sudden pain under the left breast which caused her to faint.

Symptoms.

Pain.—The patient becomes gradually aware of a discomfort in the region of the left breast, in some cases also at the angle of the left scapula. The pain is variously described; when continuous it is said to be a dull ache, a soreness, a weight, or a gnawing pain; when intermittent in character it is sharp, cutting, a prick, a stab, or a shooting pain. It is often said to radiate round the ribs or through to the left scapula. The relation to exertion is indefinite, perhaps it is felt most commonly when the patient is tired, after exertion; it is seldom induced by effort, though the constant pain may be accentuated by it; it is felt at rest and in bed at night. It is very rarely of great severity, though in five of the series it was momentarily sufficiently bad to cause loss of consciousness. Patients generally agree that rest improves the symptoms, whereas work, exertion, excitement, and fatigue aggravate them; some will even volunteer that they get relief from movement, especially those who get the pain at night and cannot rest in bed. There are seldom the secondary effects such as sweating, pallor, which are expected in severe forms of pain. Tenderness of the skin is often a complaint; a patient will say that during an exacerbation the pressure of the clothes gives discomfort. If the pain has been of long duration the patient will

have had considerable intervals of relief followed by relapses.

It is important at this point to realise that the associated phenomena are most helpful in arriving at a diagnosis. Gallavardin⁹ has said: "The general impression left the physician is the extreme diffuseness of the manifestations; there are so many things that there are too many."

Exhaustion.—A symptom on which Mackenzie¹⁰ laid stress is nearly always volunteered by the patient without questioning and it is often complained of quite as bitterly as the pain; this feeling is independent of work done and is claimed to be quite different from natural fatigue after exertion.

Dyspnoea on effort of a moderate degree is also a common complaint, as would be expected in the

FIG. 2.

Polygraphic record of the sighing breathing common to left inframammary pain.

lowered condition of health of which it can be an expression; with associated overweight it may be considerable. In contrast with exhaustion, for instance, dyspnoea is seldom mentioned until the routine inquiry is made.

Deep sighing respiration (see polygraphic record in Fig. 2).—Dyspnoea on exertion must not be confused with this symptom, named "suspirious" by the older writers—for example Walshe¹¹—and fully appreciated by them as a "neurosal" disturbance.¹² Modern writers refer to it in such terms as "deep sighing respiration," "inability to take a full breath," "an unsatisfying breath," "irregular sighing respiration." This is a very common symptom in patients with left inframammary pain, notably at rest, not on exercise. Gallavardin¹³ has commented on this association, and has noticed while screening patients during an attack that there appears to be a spasm of the diaphragm.

Palpitation.—This is a symptom in about 60 per cent. of patients, but not a very prominent one, except where there is associated high blood pressure or with much tachycardia.

Dyspepsia.—About 31 per cent. of patients complain of dyspepsia usually in the form of flatulence. This is of interest since it is common to hear this type of pain loosely ascribed to indigestion.

Pains elsewhere.—Complaint of pains and stiffness in other parts of the body is elicited from the majority, but on questioning only, since the pain under the left breast is, to the patient, by far the most important symptom.

Fainting and faintness.—Fainting, that is actual loss of consciousness, is unusual in this condition, although the pain was sufficiently severe to cause it in five of my patients. Feelings of faintness unassociated with pain, and particularly following exertion, often came with the long list of complaints.

Insomnia or disturbed sleep is a common association, there is generally no reason offered. In a few the pain may be the cause; they say "They don't know which way to lie"; and may get relief from walking about. In some we hear of a feeling of "sinking through the bed."

Nerves.—It is the rule for these patients to state that "My nerves are bad."

Giddiness.—Patients will often say they are giddy; this, on inquiry, is found to be a sensation of swimming or floating, not true rotation; the patient feels the ground is not firm beneath the feet.

Trembling and shaking.—This is a frequent complaint, often said to come in attacks.

In this condition where the diffuseness of the symptoms is the cardinal feature, the patient may not confine herself or himself to the complaints enumerated above, and such phrases as a "choking sensation in the throat," a "feeling of suffocation," "pins and needles in the limbs" will be familiar to everyone. Sir Clifford Allbutt¹⁴ has said, referring to left inframammary pain "these faintnesses, palpitations, gaspings, stiflings, bodily agitations, hyperæsthesias, and psychical commotions are so wholly unlike the ruthless grip of angina pectoris as these frantic alarms are unlike its silent passion."

Physical Signs.

Signs were necessarily few as symptoms constituted the essential feature in this condition. X ray and electrocardiographic examinations gave results within normal limits the Wassermann reaction, when tested, was without exception negative and nothing abnormal was found on investigation of the urine.

Blood pressure on first examination often showed a fairly high systolic reading; this seemed to be accounted for by the nervousness of the patient, as subsequent readings, except where the patient was admittedly suffering from high blood pressure, were within normal limits.

The pulse, taken with the patient both standing and lying, was found in the majority of cases to be of a moderate rate. In this series 25 per cent. only had tachycardia, which did not appear to be a feature of the condition. It is true that on first examination the pulse was often found to be rapid; this was attributable to the nervousness of the patient, as in the case of the initial blood pressure reading. The suggestion that these patients show an abnormal increase in rate on changing from the sitting to the standing position was not confirmed.

Hyperæsthesia proved a valuable sign and was positive in 68 per cent. of the series of both old and

FIG. 3.

(Case 24). Sites of pain are indicated by a cross. The shaded area is hyperæsthetic.

new. It was elicited by lightly dragging the head of a pin over the skin; the diagrams accompanying the illustrative cases show the usual distribution. The left inframammary region was found to be positive to the test more frequently than the left subscapular region. Tenderness on palpation with the fingertips was found in about 45 per cent.

The following are three illustrative cases of long-standing left thoracic pain:—

CASE 24.—A spinster aged 39. In November, 1920 attended the out-patient department of the Heart Hospital complaining of pain under the left breast when tired; it was dull and drawing in character. Two weeks previously, while kneeling in church, she had been suddenly seized by an exacerbation of the pain and fainted. On examination nothing abnormal was found; she was reassured and discharged. In September, 1927, attended again because of a faint in the street. Complained of pain under the left breast at the left scapula, and in the left arm; an ache felt during

exertion, after exertion, and sometimes at rest. Other complaints were undue exhaustion, shortness of breath. Examination: again negative. In April, 1920, attended by request. She felt better, but still had pain when tired or sitting at the end of the day; had also had great attacks of pain at night. Other complaints were great exhaustion, difficulty in taking a full breath. Examination: a thin, anxious woman. Nothing abnormal was found in the cardiovascular system. Pulse-rate 80 and regular. Blood pressure, 120/80. Hyperæsthesia to the head of a pin drawn lightly over the skin, and tenderness to palpation with the fingertip (Fig. 3).

CASE 1.—A married woman aged 53. In February, 1915, attended the out-patient department of the Heart Hospital complaining of pain below and above the left breast with a dead feeling down the left arm; it was almost continuous,

FIG. 4.

(Case 1). Sites of pain are indicated by a cross, shaded areas are hyperæsthetic. Feeling of "deadness" over the dotted area.

made worse by exertion and improved by rest in bed. Other complaints were palpitation, exhaustion, shortness of breath on exertion, loss of appetite, and poor sleep. On examination nothing abnormal was found. The patient continued to attend on and off till 1920, being treated with drugs, liniments, and plasters. In October, 1920, she was again completely re-examined; nothing abnormal being found she was reassured and discharged. In April, 1920, attended again by request. She still complained of pain, and now sometimes it was felt under the left shoulder-blade. Other complaints were undue exhaustion, bad palpitation, flatulence, and a difficulty in taking a deep breath. Examination: a stout woman of good physique. Nothing abnormal was found in the cardiovascular system. Pulse-rate 80 and regular. Blood pressure 160/95. Hyperæsthesia and tenderness to pressure (Fig. 4).

CASE 8.—A spinster aged 32. In March, 1920, attended the out-patient department of the Heart Hospital complaining of "pain at the heart"; it was continuous and spread to the left elbow, causing a feeling of loss of power in that arm. Other complaints were undue exhaustion, palpitation, shortness of breath on exertion, and indigestion. On examination nothing abnormal was found. Patient continued to attend, always with the same complaints. On one occasion note is made that the pain was felt at the left scapula, and she was unable to lift her arm to do her hair. In April, 1920, she was again completely re-examined, nothing abnormal was found, and she was reassured and discharged. In April, 1920, attended again by request. She still complained of the pain, but it was not so severe now as it used to be; it was generally sharp and shooting in character, shooting round the line of the ribs to the angle of the left scapula. Other complaints were great exhaustion, severe palpitation, nerves bad, and a difficulty in taking a satisfactory breath; "have to take deep sighs." Examination: a thin anxious woman, with a continuous coarse tremor of the hands. Cardiovascular system normal. Hyperæsthesia and tenderness to pressure (Fig. 5).

Statistics of a Series of Consecutive Cases.

Out of 332 consecutive cases attending the out-patient department of the National Heart Hospital, it was found that 42.3 per cent. presenting no evidence of cardiovascular disease complained of left inframammary pain, whereas only 22 per cent. of those with organic disease suffered in this way. The

statistical significance of these figures is that a patient suffering from this type of pain is more (not less) likely to be normal so far as the heart condition is concerned.

A further consecutive series of 266 was collected comprising normal patients and those suffering with high blood pressure or mitral stenosis; these latter conditions were chosen as representing the

TABLE I.—Total Cardiovascular Cases.

Blood pressure ..	32.3	0.8	0.8100

commonest cardiovascular diseases. It was found that of 43 per cent. normal patients, 63 per cent. gave this pain as their chief complaint and 37 per cent. as one of other symptoms; of 22 per cent. with mitral stenosis, 12.5 per cent. only gave it as their chief complaint, the rest mentioning it among other symptoms. Of 33 per cent. with high blood pressure, 57 per cent. gave it as their chief complaint, the others as one of other symptoms. The statistical significance of the percentages 43 per cent. normal,

FIG. 5.

(Case 8). Sites of pain are indicated by a cross, shaded areas are hyperæsthetic.

22 per cent. with mitral stenosis, and 33 per cent. with high blood pressure, is the same as for the first series—namely, that a patient suffering from this type of pain is more likely to be normal and less likely to be suffering from either high blood pressure or mitral stenosis.

Diagnosis and Differential Diagnosis.

The diagnosis is based chiefly on the site and type of the pain, with its indefinite onset as opposed to the paroxysmal character of the attacks in angina pectoris, and an absence of any direct relation to exertion. In addition there is a diffuse array of symptoms largely of a nervous order and dependent on a lowered condition of general health. Further there is an absence of physical signs unless there happens to be associated cardiovascular disease, and negative results from electrocardiographic and X ray examinations. The presence in the majority of

hyperæsthesia and tenderness in the inframammary and subscapular regions is confirmatory evidence. In differential diagnosis it is of first importance to distinguish this condition from true cardiac pain. This presents no real difficulty except where there is extension of the pain into the left arm. The following Table has been assembled to contrast the two conditions.

Differential Diagnosis from Angina Pectoris.

<i>Angina Pectoris.</i>	<i>Left Inframammary Pain.</i>
1. Commoner in men.	1. Far commoner in women.
2. Occurs during effort or excitement; effort is limited by pain.	2. Occurs any time, especially during fatigue; effort is limited by exhaustion rather than pain.
3. Pain in brief paroxysms, onset and offset abrupt; the paramount symptom.	3. Pain generally continuous, lasting weeks or months with intermissions, onset and offset gradual, duration indefinite: one of many symptoms.
4. Site of pain sternal, or across the chest, extension supramammary or brachial; spinal distribution C8, D1, 2, 3, also 4.	4. Site of pain left inframammary extension to left scapula, less often supramammary, rarely and slightly left brachial; spinal distribution DV, and VI.
5. Aspect expresses great pain.	5. No outward aspect of pain.
6. Hyperæsthesia none or only following a paroxysm.	6. Hyperæsthesia common and persistent, especially in long-standing cases.

Other Sources of Pain in the Left Inframammary Region.

It is, of course, recognised that pain under the left breast can be a manifestation of a pathological change in the structures of the chest wall and the organs and tissues, other than the heart, contained therein. When due to a local lesion the clinical picture and course is not that described in this paper, and the associated signs and symptoms are absent.

Herpes zoster (see Fig. 6), as mentioned by Balfour¹⁸ in 1898 can, before the appearance of the characteristic

FIG. 6.

Herpes zoster (D. VI. left) with area of hyperæsthesia to dragged pin-head.

eruption, give pain under the left breast and at the angle of the left scapula. Again, myalgia and myofibrositis of the muscles of the chest wall, sometimes called pleurodynia, gives pain in this area; G. R. Murray¹⁹ has recently shown how this condition may readily be diagnosed. To give yet one further example, Vaquez¹⁷ has described a cellulitis of the præcordial region due to continual fingering of the part by the patient; tender patches of induration can, he says, be found on examination.

Other conditions that should be mentioned are acute pleurisy, recognised by the "catch" in the breath and associated "rub," or if the result of chronic pleurisy and fibrosis of the lung, by X ray examination. Intercostal neuralgia gives pain along the main distribution of an intercostal nerve. Pain due to lesions involving the lower end of the œsophagus and cardia of the stomach is

described in detail by Bolton.¹⁸ According to Pottenger¹⁹ and others the innervation of the stomach, liver, and pancreas is from D.V to IX, an area including that under discussion—namely, D.V and VI. Among the rarer causes of left inframammary pain the following might be enumerated: mastitis of the left breast; osteo-arthritis of the spine; recently discussed by Gunter and Sampson;²⁰ disease affecting locally the posterior spinal nerve roots as aneurysm, neoplasm, or tuberculosis of the spine; fracture or periostitis of a rib; pneumothorax, mediastinitis, chronic and acute, and intrathoracic neoplasms involving structures of the mediastinum.

After-history and Prognosis.

The after-histories of the 32 cases whose records go back over a number of years show that these patients have had long remissions from their pain, but that they have had relapses coinciding in the majority with some illness, extra physical or mental strain, or reduced condition of health. For the most part they still have the pain at times, though in one case only has it got progressively worse. The prognosis as to life is good, the condition appears not to be dependent on any underlying cardiovascular disease, nor need the patient develop other signs or symptoms over a considerable period of years. The prognosis as to relief of pain is not so satisfactory, the trouble is very obstinate as regards treatment, and although long periods of relief can be confidently predicted, relapses are prone to occur.

Suggestions for Treatment.

It must be admitted that left inframammary pain often proves very resistant to treatment, particularly in long-standing cases, who seldom lose it entirely and in whom it tends to recur; the earlier after its onset the patient comes under treatment the greater the prospect of success. Probably the most satisfactory results are obtained with patients who are quick to accept the assurance that the pain has no relation to the heart. As the trouble is frequently associated with a lowered condition of health, mental strain, or overwork, much benefit results from rest, the pain improving and in some cases disappearing after a few days in bed. Where mental strain is the chief factor, inquiry should be made to see if any personal or domestic worry can be lightened. A holiday with a balanced amount of rest and exercise, fresh air, and tonics may be advised with good results. Any obvious focus of infection should naturally have attention. Excessive smoking seems to be a potent cause in some cases; and abstinence will often be necessary to obtain a cure. Of drugs, that which seems to have the most effect is bromide; little if any relief is got from the use of the usual analgesics, such as aspirin, phenacetin, phenazone, &c. Local measures are not advisable, as they tend to centre the patient's mind on the heart, a thing particularly to be avoided. Plasters have been freely used in the treatment of this complaint, with, however, no permanent relief of symptoms; one patient who had been plastered over a period of 11 years still had his pain. Similarly, massage has been recommended for the painful parts, but the results again do not support its use.

Summary.

Left inframammary pain is a very common symptom in patients without physical signs of disease, but with a group of symptoms expressive of physical or nervous exhaustion. It not infrequently leads to an erroneous diagnosis of heart disease, even of angina pectoris. Thirty-two cases have been studied whose records show that their condition has been one of long standing, together with 20 illustrative examples, with this pain as the main symptom. Further, the histories of 332 consecutive patients attending the out-patient department of the National Heart Hospital have been analysed, and it has been found that no less than 22 per cent. gave it as their chief complaint, and a further 20 per cent. included it amongst their symptoms. The condition is far

commoner in women than in men, affecting them in adult life, especially at the menopause. The pain is of gradual onset, and continues for weeks or months with intermissions, often over years. It may extend to the left scapula, less often to the supramammary region, or even to the left arm; this left brachial extension was found in 17 of the 32 cases showing long records; it may then simulate angina pectoris with which it has nothing else in common. A striking feature is its association with the symptoms indicative of nervous exhaustion and general ill-health, the most permanent symptoms being undue fatigue, nervous disturbances in breathing, and palpitation. The most significant physical sign, indeed almost the only one, is the presence of hyperæsthesia of the skin and tenderness of underlying tissues in the region of the left breast and the subscapular region. Signs of cardiovascular disease are not found, except when such common conditions as mitral stenosis and hyperpiesia happen to coexist. The distinction from angina pectoris rests upon the character of the pain and its site, the absence of a direct relation to exertion, and the lack of supporting physical signs after years of pain. A table of differential diagnosis is given. The prognosis as to life is good, as there appears to be no organic basis for this pain; but it is obstinate and very liable to recur, though it does not progress as does angina pectoris. Treatment is unsatisfactory, but the best results are obtained by reassurance, rest in bed for a time, improvement of the general and nervous health, a course of bromide, and if possible a holiday.

NOTE BY DR. JOHN PARKINSON.

A persistent aching pain below the left breast is so common a complaint and so liable to misinterpretation that Dr. Baker's study is sure to prove of wide interest. Now that coronary thrombosis is distinguished from angina of effort it is more necessary than ever to separate clearly from angina pectoris (in either form) these imitations of true cardiac pain. Left inframammary pain, especially if there is slight extension to the left arm, undoubtedly comes most often into such differential diagnosis. The original site, the absence of direct relation to effort, and the associated symptoms are here shown as a clinical complex in striking contrast with angina. Hyperæsthesia is found to be more common and more persistent than in coronary angina. The underlying nervous and general exhaustion, coming to the surface as a "heart-ache" instead of a headache, is treated best by moral support, reassurance, and rest; then by holiday and wholesome exercise.

POST-ENCEPHALITIC PARKINSONISM AND MILITARY PENSIONS.*

By RENÉ CRUCHET, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT THE UNIVERSITY OF BORDEAUX.

PENSIONS boards often find it very hard to decide whether post-encephalitic parkinsonism is or is not to be imputed to military service. This question is of the greatest importance, but I have found no information on it in English medical works. In France it is dealt with in the following way.

Determination of the Origin of Encephalitis.

Post-encephalitic parkinsonism generally occurs a year or two after the onset of encephalitis, or even three, four, five, or more years later. The expert endeavours to find out whether a bradykinetic syndrome¹ can be attributed to an encephalomyelitis contracted during the period of military service or not. The first difficulty is to determine the beginning and the signs of this primordial encephalomyelitis, for opinions are not always in agreement. It was for some time held that, encephalitis having only been described at the end of 1916 or the beginning of 1917, all Army patients who ascribed the beginning of their illness to an earlier date could not have encephalitis, since it did not then exist. This opinion is no longer accepted, as I have been able to demonstrate,² that cases were in existence on the French front as early as 1915 in the region of Commercy and Verdun, later in Bar-le-Duc from 1916 to 1917.

The case recorded by Arthur J. Hall³ in 1924 is particularly significant. It is the case of a soldier aged 37, sent home from the Anglo-French front in 1916, and considered to have an "atypical" paralysis agitans. It was not until 1918 that he made the correct diagnosis. It is probable that the beginning of the illness was earlier than 1916, the date of the first examination.

There is a growing tendency to think that encephalitis arose in the war zone from 1914, but was at first unperceived and developed, especially in the eastern region. From there it was diffused over the different fronts by the movement of troops and spread to the various parts of the world. Maximilian O. Pfister,⁴ in an article dated June 28th, 1929, supports this opinion as regards the appearance of encephalitis in China; he refutes Watson's hypothesis according to which the first case, a completely isolated one, was noted in Yunnan in 1915, and the disease was propagated from there in China from 1918 and 1919. According to Pfister, it was the Annamite troops, engaged in the district of Verdun in 1915, who brought the malady back to China at the time of their repatriation, beginning in the autumn of 1915. Encephalitis first broke out in the ports of Annam and was progressively disseminated through the whole country, following the most frequented commercial routes.

The Diagnosis of Encephalitis is not Necessary to Establish a Causative Connexion.

Diagnosis is only of use to the expert in so far as it allows him to appreciate the damage caused—that is to say, the degree of disablement. A diagnosis of encephalitis is not really indispensable. The Ministry of Pensions simply wants to know whether the infirmity may be attributed to service. They must then know if there is causative connexion between the present state of parkinsonism and a cause of whatever kind during the period of active service. There are a number of military men who returned home in perfect health and in whom the first symptoms of encephalitis did not manifest themselves until long

* Read on June 6th at the Naval, Military, and Air Section of the Congress of the Royal Institute of Public Health in Portsmouth.

after their demobilisation; in those cases causative connexion cannot exist and the imputation is inadmissible.

Therefore the demonstration of a causative connexion is the essential point and is sufficient to cause a pension to be awarded to a soldier suffering from parkinsonism, although it may be impossible to attribute the disorder to an encephalitic origin.

In certain cases the diagnosis of encephalitis is simple, for instance, in the lethargic type. When one finds in the history of a parkinsonian soldier during active service fatigue and somnolence, fever, even though moderate, disordered vision, and especially diplopia, the problem is solved; the pension is always awarded. But such characteristic symptoms are not always found. Should traumatism and concussions, febrile states, especially influenza, malaria, and other causes be rejected, or must they be called "encephalitis," which at the time escaped recognition? The only essential fact is that the causative connexion should be obvious; consequently each case must be carefully studied in order to find out, by close examination, if this connexion is evident to the expert.

Original Causes of Post-encephalitic Parkinsonism.

The most typical and usual cause is influenza; it is a well-established fact that the most serious outbreak of epidemic encephalomyelitis coincided in 1918 with influenza. According to certain authors, epidemic encephalomyelitis is only one of the nervous forms of influenza. Dr. F. G. Crookshank⁵ defended this view as early as 1919, bringing forward arguments based principally on the history of epidemiology for the last 450 years. For him epidemic encephalomyelitis represents the nervous form of influenza in adults, while epidemic poliomyelitis is the nervous form of influenza in children. As a result of the 1929 report of the American Matheson Commission⁶ on epidemic encephalitis, the majority of authors do not to-day share this opinion. The arguments against it may be summarised as follows.

Influenza is essentially contagious. Encephalitis is scarcely so. Nothing suggests a constant relationship between the two diseases. The ideas suggested by epidemiology permit us rather to oppose the one to the other. It is difficult to pronounce judgment on the identity or the difference between encephalomyelitis and Medin's disease. The cases of poliomyelitis observed at Bordeaux were exceptional, whereas in outbreaks of epidemic poliomyelitis or Medin's disease myelitic lesions are the rule and encephalitic lesions the exception.⁷

These divergences of opinion, which persist to-day, are interesting but unimportant. To an expert it is simply a question of nomenclature; whether we call the initial symptoms nervous influenza, epidemic encephalomyelitis, or poliomyelitis, the mere fact that they were in existence and that the causative connexion with the later parkinsonian syndrome can be established settles the question from the legal point of view, and the pension must be awarded. It is well known that many cases of influenza have thus been judged, such as that of Mayet and two other cases of my own.⁸

Another disease, often suspected, is typhoid fever. As early as 1917 I remarked, with Moutier and Calmettes,⁹ that a typhoid condition was legitimately ascribed to those tired and asthenic soldiers returning from the Army. The biological tests were always negative, it is true, but they might have been positive in a few cases, as Marc Etienne May and M. Kaplan have indicated. These authors record hyperthermia and forms of encephalitis in true typhoid fever. The characteristics which they mention are analogous to those which we observed in our first patients in the ple which was the beginning of their disease.

At the beginning we thought at first of atypical meningitis or of the polymorphic atypical meningitis, dementia præcox, which later on we considered as a parkinsonian syndrome. Why should we not consider the possibility of co-existence of spinal meningitis or of a parkinsonian kind.

syndrome? In fact, we must accept the causative connexion if we can follow the morbid phases from the beginning to the parkinsonian sequela.

Certain experts have refused to admit a connexion between malaria and the parkinsonian sequela. There is, however, no reason to deny it, if the causative sequence can be proved. I have noted several cases in which the malarial origin has been accepted, among them that of Bériel and Mayet, and another in my own experience.

In this case the characteristics of parkinsonism began to appear in December, 1921—that is, about 10 or 20 months after the attack of encephalitis, a normal length of time; they manifested themselves in difficulty of movement, stiffness and slowness at work. In February, 1922, they were very clear and Prof. Cestan (of Toulouse) diagnosed encephalitis with parkinsonism, which grew worse later on. But can this parkinsonism syndrome be connected with active service in the relation of cause and effect? One fact is clear, that the attack of encephalitis in February, 1920, began like one of those malarial crises which had already attacked the patient at Salonica, where he was in hospital from April 9th to May 18th, 1918: uneasiness, shivering, chattering of teeth, and high fever. These symptoms were followed after some hours by profuse perspiration with subsequent comfort, but on the following days the signs reappeared and this condition—at first intermittent—was succeeded by a permanent state of fever which persisted for forty days. Therefore the onset took the form of intermittent fever of a quotidian type—that is, a recurrence of serious malarial symptoms in a former malarial patient, the beginning of whose disease, contracted on active service, dates from 1918.

I saw a similar case in a soldier who clearly had had ten malarial attacks at Salonica before his return to France in January, 1919. He had no further attack until his demobilisation in November, 1919. In January, 1919, he had a bad attack with shivering, chattering of the teeth, and hyperthermia, which appeared to be cured by quinine. Two days after, diplopia and somnolence appeared, while the fever abated. This was the beginning of encephalitis, which had first manifested itself under the appearance of a malarial attack and later turned into regular parkinsonism, from 1921 to 1922. I consider that here, as in the preceding case, there is undeniably a connexion between the malaria contracted in the Army and encephalitis complicated later by a parkinsonian syndrome.

Diffuse meningo-encephalitis is admitted as a sequela of malaria by the ablest authors on tropical medicine. I will confine myself to quoting the opinion of Prof. A. Le Dantec¹⁰ who, in the latest edition of his remarkable précis, concludes that the right to the pension is undoubted in two cases.

The same may be said for trauma and concussion. It is well known that Parkinson's disease has sometimes been provoked by similar causes.

I had a case of that kind in December, 1926. It was the case of a quartermaster, badly concussed by a shell in July, 1917, who, in spite of violent shock, remained at the front until October, 1919. During all this time he complained unceasingly of headache, was continually depressed, and resigned his position as quartermaster. About six months before demobilisation he showed a tremor, at first slight, which grew steadily worse, his movements becoming more and more difficult and slow, especially on the right side; he took several holidays and when he was finally examined in August, 1924 a parkinsonian syndrome was recognised which predominated on the right side, with rigidity, a mask-like face and tremor of the left hand. In May, 1926, the expert first accepted the causative connexion between the original concussion of 1917 and the present parkinsonian syndrome. It seems difficult not to agree.

There is no reason why poisoning should not be incriminated. It is well known that at first, especially in England, botulism was held responsible. Indeed, one cannot refuse the pension if a causative connexion exists between the supposed poisoning or intoxication contracted while on active service and the later parkinsonian syndrome.

The Original Cause is Indefinite.

To discuss other and rare cases seems superfluous. The essential fact is that the initial cause may be impossible to define, and yet, because it has been observed, it should be sufficient, if there is a causative connexion, to determine the decision. Among cases

of this type, in which retrospective diagnosis was impossible, are the following.

A draughtsman, aged 40, came to me for the first time on August 5th, 1920. A diagnosis of post-encephalitic parkinsonism was obvious from the characteristic mask-like expression, inertia, wooden immobility, and monotonous speech. I saw him several times in September, 1920, and in November, 1928. His condition was always the same. In good health at the time of mobilisation on August 2nd, 1914, he had remained so until July, 1916. At that time, being in the neighbourhood of Beauvais, he had been removed from that town to a dressing-station, where he had remained for a month suffering from agitation, mental excitation, and trembling of the upper and lower limbs. His writing had become almost illegible and his speech jerky and explosive. Since then he has been unlike his former self—excitable, tactive, irritable, with a great need for activity, finding it impossible to stay in one place, walking about incessantly, even making magnificent and exaggerated plans for the future. In May, 1917, myoclonic spasms appeared in the limbs and were so violent as to wake him in the night and shake the bed. These spasms continued after demobilisation (March, 1919), and for the two following years. In November, 1919, somnolence and diplopia appeared; the latter disappeared in December but the somnolence persisted until February. He became less and less voluntarily active; he drew badly and was obliged to have an employee to take his place. The myoclonic spasms diminished, then disappeared at the end of 1921. Finally, in November, 1923, after financial difficulties, he sold his draughtsman's business.

Several doctors whom he consulted diagnosed encephalitis. My conclusion is that the origin of the encephalitis, which apparently dates from the period of somnolence and diplopia in November, 1919, is certainly earlier. It may be said that since July, 1916, the time of the patient's removal and treatment at Beauvais, he has been continually ill. Therefore it is only logical to refer the origin of the encephalitis back to the mental symptoms manifested since July, 1916. Consequently, I conclude that the origin of the present post-encephalitic parkinsonism dates from July, 1916—that is, from the time when the patient was in active service. As I requested in my report, the pension has been awarded.

These considerations, based on precise facts, show how many complex and delicate problems are raised by this question of the claim of parkinsonian patients to military pensions.

WOOLWICH MEMORIAL HOSPITAL.—Last year the number of in-patients rose from 1293 to 1850, who cost an average of £13s. per week, a slight increase upon the previous year.

HONORARIUM TO A HOSPITAL MEDICAL STAFF.—The governors of St. Albans Hospital have decided to grant this year the sum of £160 to the honorary medical staff. The amount was settled in consultation with the medical men concerned, and is subject to periodical revision. Last year there were 514 in-patients, an increase of 90; their average stay was 20-70 days. Road accidents were responsible for 123 in-patients—more than 20 per cent. of the total—and 188 casualty patients. The in-patients cost 43 1s. 10d. per week.

PARALYSIS OF THE LAST FOUR CRANIAL NERVES IN TABES DORSALIS.

By RONALD W. BROOKFIELD, M.D. LIVERP.,

M.R.C.P. LOND., D.P.H.,

ASSISTANT PHYSICIAN TO THE ROYAL SOUTHERN HOSPITAL, LIVERPOOL; FORMERLY MEDICAL REGISTRAR OF LIVERPOOL ROYAL INFIRMARY.

THERE are few cases of tabes dorsalis which do not show, sooner or later, evidence of involvement of the cranial nerves in addition to the usual spinal manifestations of the disease. Some degree of trigeminal anaesthesia is almost invariably found in the moderately advanced case, and strabismus, optic atrophy, and deafness are all quite common. But while some cranial nerves fall victims to the disease very readily, others appear to enjoy a high degree of immunity, and it is but rarely that the glossopharyngeal, spinal accessory, or hypoglossal nerves are affected. It is for this reason that the present case, in which the last four cranial nerves on the right side have been affected, is deemed worthy of record.

A chemical worker, aged 40, was first seen in the outpatient department at the Liverpool Royal Infirmary in July, 1928, and was later admitted to the hospital.

In 1903, he had had a urethral discharge, but no chancre had been noticed. His only other illnesses had been recurrent tonsillitis and quinsy in 1917, and an attack of abdominal pain and hæmatæmesis in 1922, following a prolonged period of dyspepsia. He had been married for 22 years and had had seven children, all of whom were alive and well. There had been no miscarriages. He had enjoyed very good health for several years before the onset of the present condition, except that for 18 months he had noticed occasionally a sensation as of "walking on air." Dysphonia had first been noticed in April, 1928, after a severe cold and sore throat and had been quickly followed by dysphagia. Food had appeared to stick at the level of the manubrium sterni and very soon he could only with difficulty swallow fluids. Regurgitation into the nose had occurred occasionally. There had been a constant tickling sensation in the throat, but no pain. In May he had first experienced lightning pains of some severity in the legs. In June pain had been felt under the right clavicle, and on looking at himself in a glass he had noticed what he described as a "different formation" of the right shoulder. His weight had fallen from 9 st. 2 lb. to 7 st. 8 lb.

When first seen he presented a worn and emaciated appearance. His voice was husky and there was a frequent and ineffective bovine cough. When stripped, the deformity and drooping of the right shoulder was obvious, and further examination showed this to be due to considerable atrophy of the sternomastoid and trapezius. There was marked hollowing above the clavicle, and the right scapula was displaced outwards and slightly downwards. Measurement showed the distances from the superior and inferior angles to the vertebral spines to be respectively 4 in. and 5 in., as compared with 3½ in. and 2½ in. in the normal side. The scapula and a whole vertebra less an inch lower than its fellow. The muscles, in spite of their atrophy, responded well to faradism and galvanism, though in the sternomastoid the anode closing contraction was equal to the kathode closing contraction.

Examination of the pharynx revealed weakness of the right half of the soft palate, the uvula being drawn over to the left on phonation. The pharyngeal wall and fauces were hyper-sensitive and the reflex response to stimulation excessive. This hyper-sensitivity was, however, less marked on the right side. The tongue deviated slightly to the right on protrusion but there was no atrophy or tremor. Common sensation was normal over its surface, except over the right posterior third where there was some impairment. Taste was examined with test solutions of sugar, salt, acetic acid, and quinine. This sensation was completely lost over the right posterior third. It was present over the rest of the tongue but there was often considerable delay before a given test solution was identified. Inquiry revealed no subjective alterations in taste or smell. The fifth, seventh, and eighth nerves were functioning normally. There was slight double ptosis. The eye movements were normal and there was no nystagmus. The pupils were small, the right more so than the left. Both showed some irregularity, and the reaction to light was

absent on the right side and only feebly present on the left. Accommodation was brisk. The cilio-spinal reflexes were absent. There was no impairment of visual acuity and the optic fundi and visual fields were normal.

Otherwise there were no signs of nervous disease. The gait was normal, there was no rombergism, no ataxia, and no alteration in muscle tone. The knee-, ankle- and arm-jerks were all brisk and the plantar reflexes flexor. The abdominal reflexes were present. There was no sphincter disturbance. The varieties of sensation examined were touch, tactile localisation, temperature, superficial and deep pain, vibration, joint, and testicular, and all were found to be normal. There were no trophic disturbances. No evidence was found of any lesion outside the nervous system apart from slight arterial thickening. The pulse-rate varied from 70 to 100 and the heart was normal.

Laryngoscopy showed complete paralysis of the right vocal cord with some abduction paralysis of the left. Oesophagoscopy revealed no structural disease of the pharynx or oesophagus. Radiographic examination of the oesophagus showed obstruction to the passage of the test

tempted to assume that it is practically immune to the encroachments of the disease. But if positive findings of glossopharyngeal damage are lacking from the case reports, negative ones are almost as conspicuously absent, and it seems not improbable that the apparent rarity of lesions of this nerve is at least partly due to the fact that such lesions are but seldom sought. Loss of appreciation of taste in the posterior third of the tongue is perhaps the most conclusive evidence of a glossopharyngeal lesion, but the majority of writers seem to have neglected the systematic investigation of the gustatory functions. Thus, though Grabower¹ found the glossopharyngeal nerves degenerated in his case of tabes with bulbar paralysis, he makes very little reference to the integrity or otherwise of the sense of taste during life. Pfeiffer² investigated a tabetic showing marked bulbar signs with special reference to the taste function, and found that there was delayed apprecia-

Photographs showing front and back views of the patient. The wasting of the right sternomastoid and trapezius muscles is well shown.

paste in the post-ericoid region, the appearances being indistinguishable from those usually produced by malignant disease. The contour and movements of the stomach, as seen under the screen, were normal, as also were the movements of the diaphragm. The electrocardiogram was normal in all leads. The serum Wassermann reaction was negative. In the cerebro-spinal fluid the protein was increased and the cells numbered 20 per cubic millimetre, all lymphocytes. The Wassermann reaction was strongly positive in 1 c.cm., 0.5 c.cm., 0.2 c.cm., and 0.1 c.cm. Lange's gold curve showed a luetic zone.

Progress.—The patient has been subjected to anti-syphilitic treatment and there has been considerable subjective improvement. He has gained weight and has now been free from lightning pains for over a year. The physical signs have, however, altered but little. The deviation of the tongue is now hardly noticeable, but the atrophy of the sternomastoid and trapezius is more pronounced than when he was first seen. His diet is still a fluid one, and the huskiness of his voice indicates the persistence of the laryngeal paralysis.

Discussion.

The diagnosis of tabes in this case has been based on the history of lightning pains, the pupil changes, and the serological findings, and is felt to be justified in spite of the absence of objective evidence of posterior root involvement. The marked affection of the cranial nerves stands out in contrast to the slightness of the other indications of the disease.

Judging from the scant reference to the glossopharyngeal nerve in the literature of tabes one is

tempted to assume that it is practically immune to the encroachments of the disease. But if positive findings of glossopharyngeal damage are lacking from the case reports, negative ones are almost as conspicuously absent, and it seems not improbable that the apparent rarity of lesions of this nerve is at least partly due to the fact that such lesions are but seldom sought. Loss of appreciation of taste in the posterior third of the tongue is perhaps the most conclusive evidence of a glossopharyngeal lesion, but the majority of writers seem to have neglected the systematic investigation of the gustatory functions. Thus, though Grabower¹ found the glossopharyngeal nerves degenerated in his case of tabes with bulbar paralysis, he makes very little reference to the integrity or otherwise of the sense of taste during life. Pfeiffer² investigated a tabetic showing marked bulbar signs with special reference to the taste function, and found that there was delayed apprecia-

tion of taste but that the sensation was nowhere completely lost. He reviewed all the previously reported cases of tabetic bulbar palsy and comments on the almost complete absence of adequate reference to taste. Whatever doubts may be felt as to the rarity of lesions of the glossopharyngeal nerve in tabes, the infrequency of paralysis of the spinal accessory can hardly be gainsaid. Graefinger³ has pointed out that some slight degree of atrophy of the sternomastoid and trapezius may not uncommonly be noted in tabetics, and he himself observed it in 25 out of 113 of his cases. Marked paralysis as seen in the present case is, however, an entirely distinct condition and I have only traced 14 examples in the literature. Of these, one only—namely, that of McBride,⁴ has been reported in English. The ten cases, occurring prior to 1904, were collected and reviewed by Avdakoff,⁵ who added an eleventh, while Davidson and Westheimer,⁶ Souques and Chéné,⁷ and Léri and Boudet,⁸ have reported three further cases. The degree of palsy varies greatly from case to case. In some it is unilateral, in others bilateral; sometimes the trapezius is affected alone, sometimes the sternomastoid. It is interesting to note that the vagus has always been simultaneously affected. In all the cases save one the spinal accessory palsy has only attracted attention after the disease has become well established. The exception is one of Seiffer's⁹ cases, where pain in the shoulder and difficulty in swallowing were almost the

earliest symptoms of the disease. In this patient, however, in addition to evidence of spinal accessory and vagus paralysis, the knee-jerks were found to be absent and ataxia rapidly supervened.

Paralysis of the vagus, though not common, is much less rare than that of either of the nerves just referred to, and case reports of tabetic bulbar paralysis in which the vagus has been predominantly affected are fairly numerous in the literature. Graefner³ found that minor lesions of the vagus were quite common; 54 cases out of 206 examined showed some degree of vocal cord weakness on laryngoscopic examination, indicating that the larynx is a *locus resistens minoris* in tabes. The severer degrees of vagus palsy are always characterised by difficulty in swallowing.

Pathogenesis.

Any attempt to interpret the findings in terms of pathology is necessarily somewhat hazardous. The pathological process would appear to be fairly circumscribed and the evidence all points to its being peripheral rather than central in its action; a lesion of nerves or nerve roots, rather than of the bulb. None of the long tracts traversing the medulla has been demonstrably affected, and the normal movements of the diaphragm and other respiratory muscles negative any involvement of the respiratory centre, to which the central connexions of the vagus are so intimately related. Moreover, the impairment of the functions subserved by the nerves concerned has been very complete and, to produce such a marked effect, a medullary lesion would have to be so extensive as almost inevitably to involve the long tracts or the respiratory centre. The morbid process would appear, therefore, to be operative outside the medulla and—remembering that the characteristic lesion of the posterior roots has its origin where the latter pierce the dura—it is not unnatural to conclude that in the present case the glossopharyngeal, vagus, and spinal accessory nerves, and to a less extent the hypoglossal, have been primarily affected at the same site. The early separation of the hypoglossal nerve from its neighbours to pass through the anterior condyloid foramen would militate against placing the lesion further peripherally.

No case of tabes where the spinal accessory nerve has been involved has, so far as I am aware, come to autopsy, but the post-mortem findings in Grabower's¹ case are of interest, inasmuch as the glossopharyngeal and vagus nerves were affected, though the spinal accessory escaped. In this case there was slight meningeal thickening and a small cyst beneath one of the cerebellar hemispheres. Microscopical examination showed that, with the exception of degenerative changes in the fasciculus solitarius, the nuclei and central connexions of the vagus and glossopharyngeal were intact. On the other hand, the trunks of these nerves were almost completely degenerated. In view of the clinical findings in the present case it seems not unjustifiable to presume that the underlying pathological condition is of the same nature as that detailed by Grabower, and that the symptoms have been produced by degenerative changes in the nerves themselves and not by any injury to their centres in the medulla.

I gratefully acknowledge Prof. John Hay's permission to publish this case, which was under his care, and am indebted to Mr. H. V. Forster and to Dr. R. E. Roberts for allowing me to quote the laryngological and radiological reports.

Summary.

Unilateral paralysis of the glossopharyngeal, vagus, and spinal accessory nerves is described in an early case of tabes dorsalis. Evidence is put forward for regarding the paralysis as due to degeneration of the nerve roots rather than to disease of the corresponding nuclei in the medulla.

Clinical and Laboratory Notes.

TREATMENT OF CHRONIC RHEUMATIC DISEASES WITH TRANSCUTAN BATHS.

By O. B. BODE, M.R.C.S. ENG.,
ASSISTANT PHYSICIAN TO THE GERMAN HOSPITAL;
AND

M. SCHOLTZ, M.D. BRESLAU,
HOUSE PHYSICIAN TO THE HOSPITAL.

In 1925 our attention was drawn to the transcutan treatment of chronic rheumatic diseases, and last year we decided on careful study of its action and results. The treatment aims at an optimal combination of several therapeutic agents often employed separately in the treatment of chronic rheumatic diseases. It is given in the form of baths, the preparation being added to the water.

Dose 1 contains 34 per cent. inorganic salts (calcium chloride, 80.5; magnesium chloride, 6.6; strontium chloride, 2.1; potassium chloride, 5.1; sodium chloride, 2.6; potassium bromide, 2.3; and lithium chloride, 1.1); 17 per cent. essential oils (turpentine, oil of wintergreen, bornylacetate); 1 per cent. camphor; and 48 per cent. water.

Dose 2 contains 28.4 per cent. inorganic salts (of the same composition as above); 31 per cent. essential oils; 2 per cent. camphor; 30.5 water.

The beneficial effect of brine baths upon chronic rheumatic conditions has long been established. The influence of these baths on the body is probably: (1) by a thermal action, and (2) by the absorption of chemical substances (ions) through the capillaries of the skin.

According to Ryszkiewicz¹ the constituents of the essential oils have some sensitising effect upon the cells of the body. This sensitisation has been compared with the effect of the shock produced by the parenteral administration of protein showing itself in rise of temperature, leucocytosis, and focal reactions.

Method and Results.

The patient is placed into a bath of 36° C. (96° F.), to which, within ten minutes, hot water is gradually added up to a temperature of 39°–41° C. (102°–106° F.). Then the contents of one bottle of transcutan are poured over the surface of the water and distribute themselves uniformly without being stirred. The patient should stay in the bath for another ten minutes. After the bath he is wrapped in a big bath towel and not dried. He is put into bed, where an intense perspiration sets in which lasts for about two hours. During this stage his face should occasionally be dried and a cold compress applied to the forehead. After this sweating he is well rubbed down and has to rest in bed for another six hours. Sensitive parts of the skin, such as the anus and scrotum, should be protected by the application of some vaseline before the patient enters the bath.

The number of baths given in individual cases must be judged by the condition of the patient, and mostly depends on the chronicity of the case. More than ten are rarely necessary. In patients bearing the treatment well a bath can be given every other day. There are two strengths of transcutan baths, and the first one or two baths should begin with strength I. Unpleasant symptoms which the patient may experience at the beginning of the treatment are palpitations, which can easily be relieved by bromide, and increase of pain in the affected parts.

Even elderly patients bear the treatment well, and in cases of hyperpiesia the blood pressure has been noted to fall. Indications for the treatment are: neuritis, especially sciatica, muscular rheumatism (fibrositis), subacute polyarthritis (septic foci should, of course, be dealt with), gout, osteo-arthritis without gross deformities, and joint destructions. Diseases of the skin and disturbances of the circulatory system are contra-indications.

We have treated about 40 cases in the last year. These cases came from our out-patient department and were taken into hospital for this treatment. About ten were private patients who took the baths at home under medical supervision. Most of these patients had been known to us for some considerable time, and all modern methods of routine treatment were tried before the transcutan baths. The number of baths given varied from 2 to 12. No other remedies were employed during the treatment.

Of nine cases of sciatica, seven were cured and two much improved. Of ten cases of fibrositis, eight were cured and one much improved; one, who showed a marked neurotic element, did not respond to treatment. Of 16 cases of subacute arthritis, ten were cured and six much improved. Of five cases of osteo-arthritis all were much improved as regards periarticular swelling, pain, and motility. One case of gout was much improved. We give a few examples.

A man, aged 43, who had had severe sciatica for several years and was walking on crutches, had had all methods of treatment before including intraneural injections. He left hospital after ten baths walking perfectly normally.

A woman, aged 50, known to us for two years, had severe bilateral sciatica, getting worse in spite of all treatment, and for the last few months was only able to walk stooping at almost a right angle. Transcutan treatment was given as a last resource and without much hope. The improvement after twelve baths can only be described as dramatic. The patient left the hospital walking straight with very little discomfort.

A man, aged 33, had recurrent attacks of lumbago after exposure to cold. A severe attack was absolutely checked by two baths.

A woman, aged 39, had severe pains in the muscles of her back and shoulders for a month, and was unable to lift her arms above the horizontal; she was cured and able to do her hair after three baths.

A woman, aged 31, with periarticular swelling of several joints, most marked in the left knee, and occasionally a subfebrile temperature, was discharged without pain and swelling after six baths.

A woman, aged 59, with marked osteo-arthritis with deformities, hardly able to walk, tried the treatment at her own request. Striking improvement as regards pain, periarticular swelling, and movements was obtained after eight baths.

A woman, aged 57, with typical gout, had no pain or swelling after nine baths.

Among our cases we have only had four relapses within several months; these could be attributed to exposure to damp. The symptoms were very slight and could readily be checked by a few baths. Like other authors, we have found that patients with a pronounced neurotic element did not respond to the treatment as well as the others, especially as regards pain. On consideration of our results we are convinced that the transcutan treatment is the most effective remedy in chronic rheumatic disorders we have come across.

We should like to express our thanks to Dr. F. Parkes Weber for permission to include his cases in our publication.

A DECEPTIVE X RAY SHADOW DUE TO A TUMOUR OF THE SKIN.

By ROBERT COOKE, M.B. BRIST., F.R.C.S. ENG.,
ASSISTANT, THE SURGICAL UNIT, WELSH NATIONAL SCHOOL OF
MEDICINE, ROYAL INFIRMARY, CARDIFF.

In January last a patient was referred to the out-patient department as a likely case of renal calculus. Examination indicated a traumatic mus-

cular lesion, but a radiogram of the urinary tract was taken. A dark shadow with very sharp margins showed in the renal region on the injured side. It was reported as probably being a renal calculus. Re-examination made me more than ever convinced of the muscular cause of the symptoms, and suspicion fell upon a very soft, pedunculated tumour (the size of a cherry) which had been noticed on the skin of the back in the right loin. The tumour was removed and further skiagrams (both antero-posterior and lateral) showed no shadow. Had there been a renal calculus the shadow would almost certainly have been superimposed on that of a vertebral body in the lateral view.

Unfortunately the little tumour was lost in transit to the pathological department, so that histological section (and subsequent X ray) was not made. It would seem to have been a simple pedunculated lipoma without any palpable trace of calcification.

Similar cases have been recorded before, but this case seemed worth reporting, for it may serve to remind us of the fact that simple skin tumours—with or without any calcification—may cast radiographic shadows which may lead to an error in diagnosis. The factors governing the density of the shadows caused by these tumours seem to be their relative nearness to the film, and the amount of air surrounding them. A short while after this experience, I read of a similar case reported by Delzell. In this instance a simple skin tumour was suspected only after a fruitless search for a stone had been made in a perfectly normal kidney.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY: PROVINCIAL MEETING.

At a meeting held by invitation in Birmingham on June 4th about 50 Fellows were present.

Afternoon Operating Sessions.

At the Queen's Hospital Prof. W. Billington performed nephropexy, removing the appendix through the same incision, and an interval appendectomy—both under percaïn spinal anaesthesia given by Dr. Kirby Thomas. Mr. Bernard J. Ward did a prostatectomy by the open method and a partial cystectomy for growth. He also showed cases in his wards of: (1) simultaneous transplantation of both ureters into the rectum for carcinoma of the bladder; (2) transvesical seminal vesiculectomy for melanotic sarcoma.

At the General Hospital Mr. Seymour Barling did a partial thyroidectomy, for second-stage exophthalmic goitre. Mr. H. H. Sampson performed nephrolithotomy. Mr. Percival Mills had intended to do an excision of the colon for carcinoma, but finding the growth too far advanced did ileo-sigmoidostomy. Mr. James Leather performed cholecystectomy in a case where, although no calculi were present, cholecystography showed no filling at the end of 12 and 18 hours. There were adhesions around the gall-bladder.

Clinical and Pathological Session at the Institute.

Cases and specimens were demonstrated at the Medical Institute by the Birmingham surgeons,

followed by a meeting at which Sir HOLBURN WARING, the President, took the chair.—Prof. BILLINGTON, after extending a cordial welcome to the visiting surgeons, showed four cases of Syme's amputation for senile gangrene, the operation having been preceded by *peri-arterial sympathectomy*. For 30 years he had taught the futility of Syme's amputation in such cases, but preliminary sympathectomy had altered his opinion; it cured the pain and the amputation stump was perfectly nourished. Even if a Syme was not indicated in such cases, a much lower amputation was now possible than was previously the case.—The PRESIDENT suggested that, apart from the good results obtained, it was better to amputate about seven inches below the head of the tibia, in view of the greater ease in fitting an artificial limb.

Mr. WARD showed a case in which he had performed a complete cystectomy for bladder growth five years ago; the patient was now in good health.

Mr. SAMPSON showed a case of *oesophagoplasty* in a girl with severe stricture of the oesophagus following caustic soda burns. For some time attempts had been made to dilate with bougies with the result that a perforation of the oesophagus into a bronchus was present when the case came under his care. The operation was performed in several stages; gastrostomy and then a length of jejunum was isolated. A tube of skin was infolded from the presternal area, and the side flaps freed and stitched across; the sex of the patient made this easier, owing to the loose submammary tissue. The oesophagus was then exposed in the neck and the lower end of the upper part transplanted to make junction with the skin tube over the left sternoclavicular joint. A fistula was expected from the free end of the oesophagus, but this had closed firmly. The loop of jejunum was then joined to the lower end of the skin tube, and the other end inserted into the stomach. Mr. Sampson stressed the importance of choosing a loop of jejunum with a good artery in the centre of its mesentery. All scars were now well healed, including the gastrostomy, and the patient was leading a normal working life. He acknowledged his indebtedness for some of his ideas to Professor Zaaij, of Holland, whose case of a porter with a similar condition had come under his notice.

Mr. BARLING, in presenting some cases of bronchiectasis after *phrenic avulsion*, spoke of the increased readiness of physicians to hand such difficult cases to the surgeon. While the benefit of the minor operation only was very marked, he thought that phrenic avulsion should be followed by cauterisation at a latter date.—Mr. BERTRAM LLOYD described and showed the results of cauterisation in similar cases. He laid stress on the low operative risk, and advocated the use of a large soldering iron. He uses the ordinary plumber's type, heated to dull black in an electric oven, which retained the heat for 15 minutes.—Mr. HUNTER agreed that phrenic avulsion in itself greatly improved the condition of the patient. He pointed out that after injection with lipiodol the radiogram in such cases showed two types: one in which the dilatation of the bronchioles was in grape-like formation, and the other which he described as the fingers of a glove, hanging downwards.

Mr. BARON T. ROSE exhibited several cases of *carcinoma of the mouth and tongue, treated with radium*. While the toilet of the mouth was of importance, it should not, he said, be carried too far, as the reaction following wholesale extraction militated against the efficient action of radium. Merely scaling, extraction of one or two really bad stumps with ordinary cleanliness, had proved to be better. Objection had often been expressed to mechanical applicators when interstitial insertion of radium needles was difficult, but he had found them of great assistance to him. He advocated the exhibition of radium around the primary focus before clearing the glands, as a good vascular and lymphatic supply was essential to good local results. It was unnecessary to remove the sternomastoid during the block dissection of the glands.—Mr. PERRIN agreed with

the latter statement, a thorough clearance of the anterior triangle being sufficient.

Mr. C. A. RAISON showed a case of extensive *lymphangioma* of the face which had been seen by him for the first time four years ago, when treatment by injections of alcohol, boiling water, iodine, &c., had already been tried, with almost no improvement, and the patient had returned with much extension of the lesion. He had recently treated the upper part of the face with radium, with marked improvement, and intended now to continue using radium with hope of an eventual cure.—The PRESIDENT spoke of the hopelessness of such cases under treatment by excision.

Mr. F. A. R. STAMMERS showed a good result of *lumbar sympathectomy* in a case of thrombophlebitis obliterans with intermittent claudication. He pointed out the advantages of this procedure over arterial sympathectomy, in that the whole of the sympathetic supply to the limb was cut. If a long series of cases was taken, it would be found that the good results of sympathectomy were transitory, frequently lasting only six weeks. The simpler operation, however, was of value in such conditions as ununited fractures, traumatic tuberculous joint, and varicose ulcers.—Mr. PERRIN spoke of several cases of thrombo-angitis obliterans in which the lesser operation had given much benefit.—Prof. BILLINGTON said that in his case of Syme's amputation after preliminary arterial sympathectomy the amputation was performed two years after the first operation. The stump was healthy and sound, indicating that benefit had lasted much longer than six weeks.

Mr. J. F. BRAILS福德 demonstrated several cases of *lumbosacral deformities*. A case of spondylolisthesis associated with spina bifida led him to suggest that all such cases were of congenital origin, and not traumatic. A condition which he ventured to call chondro-osteodystrophy, in a boy of three years and nine months, was of interest, in that the radiograms showed a condition similar to Perthes's disease in every joint. This was associated with dislocation of the lumbosacral vertebrae, large joint spaces, carious teeth, and double inguinal hernia. Daily administration of cod-liver oil, and the use of a posterior spinal support for three years had not improved the condition.

The architect's plans of the new Birmingham Hospital Centre were on view, and excited much interest.

ASTHMA RESEARCH COUNCIL.

SCIENTIFIC MEETING.

A SCIENTIFIC meeting of this council was held on June 6th, the chair being taken by Dr. A. F. HURST.

Prof. R. J. S. McDOWALL spoke on the

Physiological Aspects of Asthma.

He said that a large amount of what had been written by clinicians was true; they had actually cured asthma in the past. The physiologists had to inquire why the nasal element was important in asthma but was not the only element. General metabolism must be investigated. There was something wrong with protein metabolism in asthma: this might be due to disorders of digestion or of metabolism proper, and these disorders linked on to the psychological aspect of asthma through the phenomena of anapylaxis. When foreign protein entered the body the autonomic nervous system showed greatly enhanced irritability. The vagus could be set in operation by many mechanisms not yet understood. The eosinophilia of asthma had not yet been fitted into any scheme, but all the various aspects of the problem were being attacked by different workers, and their combined work made a coherent research.

Hereditry.

Dr. G. BRAY said that the hereditary factor was the most prominent feature in allergy in two-thirds

of the 200 children he had studied at Great Ormond-street, though the manifestation of the allergy was not always asthma. Sensitivity was found in both parents in 50 per cent. of the cases and on one side in 20 per cent. Of the latter, it was twice as often on the mother's side as the father's. The precipitating factor might depend on environment, mental or endocrine disturbances, alimentary dysfunction, or physical conditions. Males tended to improve and females to get worse towards puberty. The earlier the symptoms of sensitivity appeared the more likely were they to be multiple. Those with history of allergy on both sides had always developed their symptoms before the age of 10. A child born in a family with pure asthma lineage was much more likely to be affected with asthma than other forms of allergy, but even in the same family the symptoms varied.

The CHAIRMAN pointed out the prophylactic importance of the hereditary factor and the frequency with which the early symptoms of asthma were misinterpreted in children. It was curiously rare for any high proportion of children in a family to have hereditary asthma.—Dr. JOHN FREEMAN thought that the hereditary chart depended considerably on the number of intelligent relatives available. With a wider field the figures would be larger. He thought that heredity and determining tissue damage went together.—Dr. JAMES ADAM said that heredity was smothered by nurture. His heredity figure for 1120 patients was 25 per cent.—Dr. BRAY said that 50 per cent. of his patients were "only" children, and most of the others were the eldest of families in which the next child was still a baby. In adults the family history was usually lost.

Types of Asthma and Age of Onset.

Mr. F. COKE spoke of the importance of recognising different types of asthma, which was merely a symptom after all. The differences were fundamental, both for treatment and pathology. Four quite distinct types were: (1) when the asthma directly followed some chest trouble and was usually associated with a patch of congestion at one base; this was usually cleared up by a vaccine; (2) when the trouble started as a dry spasmodic asthma, and the patient was quite well between attacks; (3) a colloidal type, occurring almost always in plump middle-aged women with beautiful skins, paroxysmal rhinitis, and scanty, painful menstruation; (4) an aspirin-sensitive type, with clear-cut symptoms, and invariably associated with nasal polypi.

Dr. L. J. WITTS said that where the constitutional predisposition was very strong there was a tendency to early onset and associated allergic symptoms. In children asthma was a much more general disturbance than in adults, and dyspnoea might not be the most outstanding feature. In adults the paroxysms were shorter, sharper, and more easily provoked, and the patient was never quite well in between. The response to glucose was very good in children under 10, and diminished as years increased.

Dr. HUNST remarked that some of the worst cases had polypi; removal made the condition worse, but if the underlying ethmoiditis was dealt with cure usually took place. The belief that cure would follow vaccines or removal from the proximity of the specific protein was optimistic; some substitute condition would usually be developed. It was necessary to treat the central predisposing condition. This was the factor which was attacked by glucose.

Digestion and Asthma.

Dr. BRAY showed graphs illustrating the sub-normal secretion of gastric acid and chlorides and delayed emptying in a high proportion of 100 asthmatic children. There was often a good deal of mucus, and bile was completely absent. Twelve of the children had no acid at all, and 45 had less than 10 units; in normal children few or none had no free acid, and of 50 rheumatic convalescents only 20 per cent. had less than 20 units. The deficiency

seemed to be an innate quality; it appeared in hay-fever, eczema, and prurigo, but less in hay-fever. Treatment by acid was giving encouraging results, especially in rapid return of appetite and weight. Very young hereditary cases responded better than older ones.

Dr. F. T. HARRINGTON said that much of the mystery and difficulty in asthma were due to not beginning at the beginning; the treatment of dyspepsia in asthma often cured and never did any harm. The layman knew practically nothing of dietetics. The patients should always be allowed to give their own theories; they often provided the key. Very often they related discomfort after food or put the connexion more vividly still. Vomiting would cure an attack and the appetite often failed after an attack. The work of McDonagh on protein particles deserved attention. Allergy could often be reduced if digestion was improved. Inflammation of the nose was a result of digestive disturbance, but some asthmatics had no trace of ethmoiditis. Nasal and bronchial catarrh cleared up under digestive treatment. A distended stomach impeded movement of the diaphragm and thus mechanically produced bronchial spasm. Milk did more harm than any one other factor; no other animal took milk after weaning. It produced a sodden, catarrhal nasal mucosa. Constipation should be treated by rational diet rather than purges.

The CHAIRMAN said that in 24 of 40 adult cases the test-meal had shown normal acid. He hoped it would be possible to make patients secrete their own acid, without having to administer hydrochloric acid. Asthma was very often due to poisons swallowed from defective nose, teeth, or tonsils, and attention to these would cure the paroxysms. The stomach should be washed clear of mucus every morning to restore the mucous membrane.

Dr. E. P. POULTON mentioned another adult case of asthma with normal acid secretion, and one in a child where the acid had been very low at one test-meal and slightly above normal in a second, without any treatment.—Dr. ADAM said that in the majority of his cases there was hypochlorhydria, and ascribed it to defective diet combined with lack of exercise. It was one manifestation of defective ferment action throughout the body due to unsatisfactory hygiene.—Dr. BRAY said he had done repeated test-meals and found no differences.

Dr. JOHN FREEMAN described work associating urticarias and angioneurotic oedemas with infection of the gall-bladder. The cultures were difficult to grow, and the streptococci did not appear in the stools. Sensitive patients had been tested with house dust and with the solid residue resulting from evaporating tap water and dialysing off the concentrated salts. Work on mould spores had had to stop, as the mycologists themselves had not enough knowledge of moulds to help. A series of test-meals had shown that free acid was greatly diminished in sensitive patients. He concluded, from an experiment with the Prausnitz reaction, that the substance which entered the blood through the intestine and was specific for the offending protein was non-dialysable. One good meal discharged the sensitisation artificially induced in a normal subject.

Urinary Proteose.

Dr. G. H. ORIEL described experiments on urinary proteose, which was identical with the albumose long known in the urine of patients with acute infections. It was present in normal urine but increased enormously during an attack of any allergic condition. It was toxic to animals. In doses somewhat smaller than a skin-test dose it benefited some patients; an overdose caused an attack. It probably originated in the gut as a result of faulty digestion. The four methods of treatment were specific, dietary, and the administration of acid and glucose.

Dr. H. W. BARBER spoke on the clinical results of proteose treatment, which must be regarded as specific. It was the only effective treatment for urticaria and

angioneurotic œdema, which responded well; it was strikingly successful in dermatitis herpetiformis. Cases of light sensitisation, being extremely susceptible, were made worse, but some prurigos did very well, and children with Besnier's prurigo did better than adults. Uncomplicated psoriasis was little influenced, but when it was combined with rheumatoid arthritis both conditions were improved. The method was valuable when the offending substance was unknown.

Dr. POULTON said that he had produced a typical rheumatoid arthritis reaction with proteose from a case of that disease in a patient with fibrositis.—Dr. FREEMAN likened proteose to the "histamine-like" substance discovered by Thomas Lewis in cases of dermatographia.—Dr. BARBER answered that the active principle of proteose was an antigen more like Mainwaring's anaphylatoxin, produced by a primary action on the sensitised liver-cell; it was not histamine, though it acted like histamine on plain musculature.—Dr. BRAY mentioned American work, showing the presence of proteose in the gastric mucus; the action was intensified by achlorhydria and delayed by normal or excessive acid.—In answer to a question, Dr. BARBER said that the proteose was probably not identical with the soluble substance produced in infectious conditions.

Sinusitis.

Mr. C. GILL-CAREY distinguished two types of sinusitis in asthma: suppurative limited to one or two sinuses, which responded well to rhinological treatment, and a generalised thickening of the lining membrane, which perhaps should not be called sinusitis at all, as it was probably not due to bacteria originally. The second group were difficult to treat; radical surgery was not justified by the results, but local silver preparations were sometimes helpful.

Dr. BRAY asked whether the condition was the cause or an effect of allergy. The pus was sometimes not neutrophil but eosinophil.—Mr. GILL-CAREY said he regarded it as an effect.

Eosinophilia.

Miss MARJORIE GILLESPIE described research into the variations in the eosinophil count. In asthma patients it hardly ever dropped below 4 per cent., and the highest recorded was 57 per cent. in a man who was having no attacks. The average was between 7 and 10 per cent. During the attack the percentage fell to one-half. It rose considerably during the menstrual period and in pyrexia. Detoxication caused no variation. Adrenalin reduced the count; uræa raised it and caused acute symptoms; large doses of sodium bicarbonate did not alter it. It bore no relationship to the alkali reserve; it rose with the blood amino-acid content, but not relatively.

Dr. BRAY criticised the percentage count as being misleading; the total number was lower than normal in attacks but the percentage might rise because of the general shortage of lymphocytes in the attacks. In normal children the percentage was 2 of 10,000; in asthmatics it was 3, but of 15,000 or 18,000.

Dr. F. A. KNOTT described the examination of sputum plugs for eosinophil cells. A large number contained no bacteria, and when organisms were present they were generally Gram-negative. Eosinophilia in the sputum pointed definitely to eosinophilia in the blood. His figures agreed with Dr. Gillespie's. About a half of the cultures produced a wheal in a non-sensitive person and contained histamine, the production of which locally by a specific small-tube infection might be one slight cause of the asthmatic state. Over half the specimens of faeces showed undigested residues of some kind. They mostly came from small children of the achylæ type described by Dr. Bray, and tended to contain lactose-fermenting bacilli, supposed to be proteolytic but giving no skin reaction.—Dr. HURST remarked that the treatment in these cases should be dietetic; desensitisation was useless.

Dr. HARRINGTON outlined treatment by diastolisation, and described and showed the inflatable rubber bougies in use and the apparatus by which ease in breathing was tested.

Dr. HURST asked his opinion on lavage with carbon dioxide, which could be bought in small cylinders and had given good results in his own nasal catarrh; Dr. Harrington agreed that it was a useful palliative.

At the meeting of the Medical Advisory Committee it was decided to form an asthma research club for free private discussion of problems and results. Dr. Freeman consented to act as secretary.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

THE quarterly meeting was held at the house of the British Medical Association on May 22nd. Dr. NATHAN RAW, the President, being in the chair.

PSYCHIATRY IN AMERICA.

A discussion on American psychiatry and any practical bearing it might have in the application of recent local government and mental treatment legislation was opened by Dr. A. A. W. PETRIE (Banstead), who gave an account of a recent visit to American general and mental hospitals, psychiatric clinics, reception units, observation wards, and mental deficiency institutions, as well as mental hygiene centres and various forms of child guidance organisations and the associated nursery schools. Observations were also made of psychiatric work in connexion with juvenile courts. Dr. Petrie had visited Montreal, Toronto, Chicago and vicinity, Boston, Worcester, Wrentham, Washington, Baltimore, Philadelphia, Yale University, and New York City and State. Each State had its own method of dealing with the problems involved.

In the progressive Eastern States it was usual, he said, for the mental hospital service to be a subsection of the State welfare services under a medical commissioner. Concentration of executive authority in the State rendered progressive development easier, and it was more possible to obtain legislative and other changes. In New York and New England well organised State social services were being developed. The larger unit provided by the State allowed in America a co-ordination of activities not possible in smaller units. New York State, for instance, dealt with over 63,000 patients who are drawn from a population of 44,000,000. The recent Local Government Amendment Act, however, did make one authority in an administrative area responsible for the treatment of the earliest stages of mental disorder, and therefore it was hoped that well co-ordinated and efficient reception hospitals would take the place of the present wasteful division into observation wards of doubtful efficiency. He expressed the further hope that the Mental Treatment Bill, when it became law, would allow of the development of voluntary clinics on the same lines as in the Maudsley Hospital and the famous Phipps Clinic in Baltimore. The latter was greatly under the dominating personality of Dr. Adolph Meyer. It consisted of 60 beds and an out-patient department, and education and research were prominent features. Notable also was the clinic at Philadelphia, a hospital somewhat resembling Bethlem in London. It had decided to take a place in the country for certified cases of longer duration, and leave in the city a clinic for out-patients. The psychiatric institute which had been established in New York in connexion with the medical unit of the Columbia University would be one of the most notable in the world. Reception hospitals were increasing in number, which was one of the most hopeful signs in the United States.

Dr. Petrie doubted whether such clinics and reception hospitals should be an actual part of the

hospital to which they were attached. The out-patient department at the Boston Psychopathic Hospital, which was the clearing-house for Boston area, attracted as many patients as the corresponding out-patient department at Boston General Hospital. In the event of noisy patients having to be taken, double windows were provided. The work of these reception units was largely determined by the source of the admissions. In the Chicago Clinic, with its 175 beds, about 100 beds had to be cleared weekly in order to deal with the probable new admissions. Dr. Petrie usually found that these units had not sufficient staffs to deal with the great amount of material passed through them. A unit with 600 beds was being projected in New York. The chronic patients in the large State hospital in America were not any better dealt with, in Dr. Petrie's opinion, than this class were in England, and in the former country overcrowding prevailed at many places. Much difference of opinion existed in America as to what was the best size of mental hospital. In Massachusetts, a very progressive State, 2000 patients was the usual limit. He found in the States a similar tendency to that in England to modernise old hospitals by building new and up-to-date units for the newer mental patients, and infirmary blocks or hospitals for those suffering from physical diseases. He also saw in America good examples of the villa or colony hospitals.

The consultant medical staff of American State Hospitals were, said Dr. Petrie, usually appointed on a liberal scale. In the progressive States the house medical staff was in larger proportion to the patients than in England; in Massachusetts there was one assistant physician to each 150 patients. And a most useful appointment which was common in the States was that of clinical director or clinical psychiatrist, who was placed equal in rank with the deputy medical superintendent and the pathologist. He directed and co-ordinated treatment, and was usually a teacher in a medical school. The laboratory facilities were similar to those in England, but one frequently saw a more elaborate equipment. A further aspect was that lectures to psychological and theological students and social workers in general were encouraged in the States. Much could be done in this way to break down the prejudice and mystery which were generally associated with mental hospital work. A sharp division existed between nurses and attendants, based upon the preliminary education required. Attendants had no special training. The line of cleavage would become more marked in the future when a complete secondary education for the nurses was demanded.

Occupational therapy, Dr. Petrie considered, was more broadly developed in the States than in this country. At St. Elizabeth's, Washington, for 4000 patients, 16 occupational therapy officers were engaged. The hospital farms tended to be larger than here. Canning of meat was commonly seen. Hydrotherapeutics was well organised, and hot baths and packs were usually employed, sometimes under conditions which in this country would be termed "restraint." Electrical treatment plant installations were generally of a high standard. Diathermy and other high-frequency apparatus was frequently seen and often used to induce high temperature in the treatment of general paralysis. Ultra-violet and infra-red light rays were in general use, and it was common to see automatic recording apparatus in connexion with bath treatment and blood pressure.

Out-patient departments for mental cases were usually run in connexion with the State hospitals. This certainly kept the medical staff in touch with the early phases of the disease. It was considered an advantage that the granting of trial or discharge should be vested in the medical superintendent, such decision being assisted by staff conferences at which the patients were examined. The terms of commitment, he said, varied in the different States, but, on the whole, were not very different from those obtaining

in England. Temporary observation was permitted for from 10 to 30 days. Several States permitted voluntary admissions, but owing to the overcrowded condition of the mental hospitals few were received on this basis in the State hospitals. The cafeteria (self-service) system (which he described in some detail) was worth consideration, as there was a minimum of waste from it. Still, he did not think that even the advantages of the system would justify the cost of initiating it in this country. An interesting development was the wide establishment of beauty parlours and hairdressers' shops in State hospitals. They did not cost a great deal and did much to improve the appearance and increase the self-respect of the patients. Another pleasing feature was the combined canteen and club rooms which were provided for the patients on parole. The cost per patient per week in the States averaged about 35s. In Canada it was rather less, in New York a little higher.

Dr. Petrie was favourably impressed with the mental defective "schools" which he inspected at Wrentham and Letchworth. To a great extent the institutions trained their own people as there were not many trained teachers available for the work. Child guidance, nursery schools, and parent guidance were comparatively new features, and all these agencies had a psychiatrist who acted as director. Sometimes a children's physician, a social worker, and one who specialised in recreation were added.

This work had been started in association with juvenile delinquency. The mental hygiene movement had done much to stir and educate public opinion in the States, and one reason progress was being made was that the professions and laity in the States were being educated to take a more reasonable attitude towards mental illness.

Dr. J. R. LORD (Horton) said his visit to the States to attend the World's Mental Hygiene Congress was a short but intensive one. He had been enlightened on many subjects and disillusioned on a number of others. The medical profession in America was not, he said, anything like as unanimous on the value of sterilisation as was thought. The layman, however, had taken up the subject keenly. An important discussion took place at the Congress on the organisation of the mental hospital in the mental hygiene service. Dr. Lord expressed his own view that if care were not taken there was a danger that psychiatry might again become a closed system, and revert to a position of isolation. There should rather be a psychiatrisation of all medical and social services, leaving to psychiatry the care and treatment of actual mental disorders from their earliest stages. The magnitude of the problem of the mentally afflicted in the United States was much greater than in England. The rate per 100,000 of the general population in America for first admissions to mental institutions of all kinds was 76.0; in England and Wales it was 45.4. In America 277.7 per 100,000 of the population were in mental institutions; in this country 290.6. To the American figure for comparative purposes must be added 24.0 for parole cases, giving a total figure for that country of 301.4. But this was not the whole story. American State institutions were for the most part shockingly overcrowded, even up to 50 per cent. of their accommodation.

State control of mental institutions had been commented upon favourably, but Dr. Lord could not help thinking that such a state of affairs would not have been tolerated if the responsibility for providing the accommodation had lain with local authorities. He had always laid it down that the more closely local people were identified with the care and treatment of their mentally afflicted and defective, the sooner ignorance and prejudice regarding them would be dispersed and the need for judicial intervention reduced to minimum requirements. It was for the State to lay down great principles and advise how they should be carried out, reserving to itself a veto when such principles were disregarded. One

thing appeared to him to be certain, and it was that America had no intention of solving its psychiatric problems by bricks and mortar alone. Child guidance and welfare work of all kinds organised for the prevention and early treatment of mental disorders; eugenic measures and parental education were to have the drive of the State dollars for the future—hence the reluctance to increase the State hospital accommodation. America had also lessons for us in the importance it attached to the psychiatric education of medical men, social workers, occupational therapists, and others in the field of public welfare. Research work, too, was more widely developed and received greater support and encouragement both from the State and private citizens than in this country.

Touching on legal matters, Dr. Lord said that as regards the mental services (and certainly not if the Mental Treatment Bill became law) America had little or nothing to teach us except perhaps in respect of recent enactments in one or two of the more progressive States, and also in the way in which patients are allowed out on leave or discharged. Although many State hospitals and municipal clinics could admit voluntary patients (the state of mind qualifying for such seemed to him almost to exclude any aberration) this departure did not receive much encouragement from the hospital authorities judging by conversations he had had with many superintendents from all over the States. The modern practice was admission on two medical certificates sworn before a judge or magistrate. This is thought to be the wisest course in non-litigious cases, to avoid future complications. In some of the States patients, litigious or not, could be detained for from 5 to 30 days on two medical certificates, unsworn or, if a court order was required and did not accompany the patient, on notification, the judge or magistrate issued a temporary commitment order and fixed a date for the "hearing." If the patient or his friends demanded it they could be present at a "hearing"; if no such demand were made the judge confirmed the order. The "hearing" might be within 5 to 30 days if, in the meantime, the patient had not been discharged or been classified as a voluntary patient. Such court orders were always necessary in litigious cases after 5–30 days, but not always before this time. Objectionable forms of judicial intervention still existed, but America did not seem to mind. A period of temporary treatment for 12 months without any judicial intervention as proposed under our Mental Treatment Bill was, generally speaking, unthinkable in America. Only in Maryland had the law on commitments been much relaxed. As in England it was the hospital in America comparable with our registered hospital which received a majority of voluntary admissions. He hoped that our experience under the Mental Treatment Bill would not, as regards voluntary admissions to public hospitals, be the same as in America. He felt sure it would not if Clauses I–IV were properly administered by the local authorities.

Other speakers followed, mainly seeking explanations or further information.

A RADIOLOGICAL INSTALLATION.—At the quarterly court of governors of the London Hospital last week, Lord Knutsford reported that about £5000 is being spent upon the installation of new apparatus for radiography and for treatment by rays of very short wavelength.

HULL ROYAL INFIRMARY.—The work of this institution last year constituted a record. There were 4227 in-patients, 15,801 out-patients, and 23,938 casualties—a total of 16,000 more than were treated as recently as 1919. The average in-patient stay was 20.60 days, compared with 22.01 in 1928. The annex at Sutton is expected to be completed before the end of the year.

Rebiews and Notices of Books.

DISEASES OF THE SKIN.

Treatment in Detail. By NOXON TOOMEY, M.D., late Instructor in Dermatology, University of St. Louis, St. Louis, U.S.A.: Lister Medical Press, 1930. Pp. 512. £7.50.

THIS is the third volume of a series of which Pathology and Diagnosis form the other sections. It will doubtless make a wide appeal, for in the treatment of diseases of the skin there is more divergence of method and less tendency towards standardisation than in any other branch of medicine. The experienced dermatologist will approve the classification and general plan of the book, the casual reader its simple, almost colloquial style. There are no tiresome introductory sections on the theoretical principles concerned either with internal medication or local applications. These are adequately discussed under the various diseases where necessary, and the author proceeds directly to his purpose from his first section which is on eczema. The briefest study of this section makes it apparent that the author is a master of technique in therapy, and has personally supervised every detail of the measures advocated under the various headings. As he himself remarks, "there is no cutaneous disease in which therapeutic skill is better brought out than in eczema." All the formulæ given are easily memorised and have the support of years of universal experience behind them. The author wisely abstains from offering too many alternatives. He names no sources of information, and in this respect, too, he is wise, for it is obviously gathered directly or indirectly from the records of all nations. A word of caution seems necessary. The book is not an elementary treatise on the therapeutics of skin diseases, and can only be used with advantage when a wide experience in diagnosis and pathology has been gained. With so much that is modern and universally accepted, it is disturbing to find that the author still advocates the use of X rays in certain stages of the treatment of lupus vulgaris; the appalling sequelæ which many dermatologists in this country and abroad are frequently called upon to treat have led to an almost complete abandonment of radiotherapy for lupus in expert European circles, where reliance is placed upon actinic and certain caustic applications. The treatment of dermatitis repens, which has been known in this country since the days of Radcliffe Crocker, is considered in a new and interesting light, and the method advocated seems applicable to other dermatoses of a chronic and resistant character. There is a good index, and the paper and printing are of excellent quality.

The book is likely to find its way into all dermatological libraries both public and private. It makes good reading, and is compact with stimulating information.

MODERN SUNLIGHT.

By LEONARD V. DODDS. London: John Murray, 1930. Pp. 322. 7s. 6d.

AS Sir Oliver Lodge states in his preface, this book deals fully with medical opinions on the subject, and is put together in simple and readable form. Technicalities are avoided since the book is written for the general reader, but, on the whole, the information offered is remarkably accurate. There are a few statements which the medical reader will criticise. For example, we doubt whether the earlier detection of a scarlet fever rash by the use of daylight lamps in fever hospitals would be a valuable asset in saving life, but it might certainly play a part in limiting spread of infection. It is unfortunate that in a book meant for the lay reader the impression should be given that helio- and actino-therapy have rendered any form of surgical interference unnecessary in surgical tuberculosis. The book is of interest in the support

it gives to the value of actinotherapy, which has been seriously questioned or alternatively attributed to psychological effects. Abstracts of recent veterinary work show that breeders and trainers give light treatment regularly to both horses and greyhounds, and the opinion is expressed that such treatment has introduced a new factor in the calculation of racing-odds. The experience is quoted of workers at the Rowett Research Institute, who found that irradiation of cows increases the period of maximum yield and safeguards the health of the animals. The director of the institute of cattle-breeding of Königsberg reports that farmers are recommended to procure quartz lamps to prevent the occurrence of rickets in cows and valuable breeding bulls. Bees are the latest recruits to ultra-violet light treatment. We are informed that the hive hums contentedly, comes out as if the sun were shining, and manifests its well-being by building more cells and hatching the larvæ in shorter time. Among the less reputable uses to which ultra-violet light has been put is, we are told, the "making of antiques" by darkening and bleaching modern furniture and the making of "vintage" wines. This small manual will attract both medical and lay readers, for it contains interesting information and is written in a pleasant unassuming style.

L'ANESTHÉSIE LOCALE EN OTO-RHINO-LARYNGOLOGIE.

Par G. CANUYT, Professeur de clinique d'oto-rhino-laryngologie; et J. JOUBLOT, Chef de clinique, à la Faculté de Médecine de Strasbourg. Paris: Masson et Cie. 1930. Pp. 231. Fr.40.

Prof. Canuyt, who is well known for his work on local anaesthesia, has given us here, in collaboration with Dr. Joublot, a straightforward account of his methods in the department of oto-rhino-laryngology. Their technique is simple; the only solutions employed are 5 per cent. cocaine for surface application to mucous membranes, and 1 per cent. novocain with 0.2 per cent. of potassium sulphate as a synergist both for infiltration and nerve-blocking by injection; one drop of 1 in 1000 adrenalin is added to each c.cm. of either solution just before use. The authors deny that the use of adrenalin is followed by vasodilatation; on the contrary, they maintain that it favours coagulation and hæmostasis. Synthetic preparations of adrenalin are not mentioned, and the experimental proof of the advantages of ephedrine is not held to be complete enough to warrant its substitution over adrenalin. Of cocaine substitutes, butyn, or buteline as it is called in France, was found satisfactory for surface application, but is not recommended for injection; for this purpose novocain is exclusively employed. The authors state that the anaesthetic power of novocain is insufficient for the method of imbibition, or surface application; but in a later chapter, on the subject of removal of adenoids in children, they say that they are accustomed simply to paint the nasopharynx with a weak solution of novocain because "this local anaesthesia is safer than a general anaesthetic and satisfies the parents who thus know that their child will be operated on without pain." The confidence of parents in this respect does not seem justified by the facts. General anaesthesia is condemned for the removal of adenoids because of the danger of death from a general anaesthetic of any kind; similarly for tonsillectomy, general anaesthesia is said to be contra-indicated in all circumstances as being dangerous and predisposing to hæmorrhage and, especially, to broncho-pulmonary complications.

In this country, where general anaesthetics are largely given by men who have specialised in the subject, and where our students are instructed in administration by such specialists, few laryngologists will support so sweeping a statement, which takes no account of the injury inflicted on the nervous system of a sensitive child. In aural surgery the authors are less opposed to general anaesthesia, which they recommend for the mastoid operation unless contraindi-

cated by the condition of the patient. For the radical mastoid operation, it has hitherto been difficult to secure adequate local anaesthesia of the tympanic cavity; this the authors secure by direct application of Bonain's liquid, which, however, is not likely to be successful unless there is a large perforation of the membrane. Local anaesthesia is advised for laryngectomy, but Prof. Canuyt, rather surprisingly, prefers laryngostomy to this operation for the treatment of cancer. The greater part of the book is taken up by careful and minute directions for the production of anaesthesia for every kind of intervention in the nose, throat, and ear, including the lower jaw but excluding dentistry. These directions are practical and simple, well illustrated by diagrams, and as here drawn together, constitute a useful book of reference for all workers in these regions.

TEXT-BOOK OF PATHOLOGY.

Second edition. By D. N. BANERJEE, M.D., Demonstrator of Pathology, Carmichael Medical College, Calcutta: Medical Bureau. 1929. With 305 illustrations and 9 coloured plates. Pp. 646. Rs.12.

JUDGING by the prevailing standard of European pathology, one would be bound to say that this is a bad book. It teaches practically nothing of general principles and is by no means free from inaccuracies of commission and omission. It includes bacteriology, animal parasitology, laboratory methods and laboratory diagnosis, and starts from cases in the wards rather than from bodies in the post-mortem room. It would be plainly absurd to concentrate the teaching of pathology in India round the same topics as are used in England; to give it any reality to medical students pathology must deal as far as is possible with the diseases which happen to be common. And looking at Dr. Banerjee's book from this point of view and considering the conditions under which it is intended to be used, we can imagine that it will continue to serve a very useful purpose. It is remarkably cheap.

THE PROGRESS OF LIFE.

By A. MEEK, D.Sc., Professor of Zoology in the University of Durham. London: Edward Arnold and Co. 1930. Pp.193. 10s. 6d.

LIKE many biologists who spend a good deal of their time in actual contact with live animals in their natural haunts, Prof. Meek is altogether unsatisfied with natural selection and Mendelian heredity as adequate explanations of the world about him. He cannot get away from the conviction that the environment impresses itself on the organism which reacts to it and that such changes are or may be inherited. It is indeed a little difficult to see why anyone should want to get away from such a point of view except out of respect for convention. Prof. Meek's interpretation is Lamarckism with the addition of the "memory" conception urged by Cope, Samuel Butler, and Semon; hence he calls it "psychogenetic evolution." Equally he condemns all theories of particulate inheritance, especially the modern doctrine in which the gene is all-important. Here he is perhaps rather too sweeping. It may be that there are many mechanisms of inheritance, and that the same end is achieved by a variety of routes, the organism being relatively indifferent which it takes. Reproduction among the higher animals is usually sexual but parthenogenesis and budding and splitting of eggs also occur; the fact of reproduction is evidently controlled by the end which is attained, not by the mechanism which happens to be used. And so, too, perhaps it is by various means that the product of reproduction resembles its parents.

SLOUGH MATERNITY HOME.—Viscountess Astor, M.P., recently laid the foundation-stone of a maternity home which is being erected at Slough by public subscription. It is the first institution of the kind in Buckinghamshire.

THE LANCET.

ON: SATURDAY, JUNE 14, 1930.

THE SIMON COMMISSION AND MEDICAL SERVICE.¹

The first volume of the Report of the Indian Commission, the Simon Report, which this week, deals lucidly with many, if not problems with which Great Britain is faced in attempting to reach the goal of British India in the future, which was laid down by the Chelmsford Report in 1917. That policy justly associates Indians with every branch of administration, and is designed to develop training institutions, with a view to the realisation of responsible government in the country remains an integral part of the Commonwealth. It is at once clear that the Simon Report must deal with vast and that controversy will be inevitable, studiously fair the recommendations may be; this reason the document is being issued in instalments at an interval of a fortnight, the Commission hoping that the general survey, which makes the first part, will be mastered before the foundations in the second part are criticised. The difficulty of approaching the public seems entirely soluble, for although all political parties are represented in the personnel of the Commission, far deeper than those usually labelled political are the questions in the question of the British sphere

The survey of the administrative departments, the function in the Indian Empire, the Indian Service receives just and sympathetic notice. It is noted that, while the Service was primarily for one, so that all the officers are required to serve some years as officers in the Indian Army, the process of transference to civil administration for many years in operation whereby their appointments could become those of the civil of a district; so that the Indian Medical Service has a double rôle to play. As is well known, the Lee Commission the number of officers has been limited to those required, first, for the medical reserve for the Army, and secondly, for the treatment of Europeans by European men. The new policy in relation to recruitment must, moreover, limit the powers of the civil surgeon, European or otherwise, in the administration. Here we find some of the reasons for the difficulty which the Indian Medical Service has had in the recent past in obtaining a full cadre of officers; but so, we may discern a prospect that this will not be permanent—even if it is not to disappear. In the last available report of the Health Commissioner with the Government of India there is a passage, written three years which bears directly upon this situation, and the optimistic view. "From the early days

of British rule in India," says the Commissioner, "the importance of public health was realised, but the policy of Government was based on the view that it was necessary, first of all, to educate the people and to secure their goodwill towards public health measures. For this reason attention was first concentrated chiefly on medical relief." In other words, it was evident that, while the benefits of treatment are obvious, those of preventive medicine may go unappreciated, because their influence is not immediate or because, when manifest, it is misunderstood. Now preventive medicine must be based upon central administration, and this is the position which is now being reached in India. Under central administration real co-operation between the British and the Indian man of science will appear, and the immense field for scientific work which the problems of epidemic disease present in India will attract the right people for their elucidation.

NERVOUS SEMIOLOGY IN EPILEPSY.

THE progress of medicine has admittedly been achieved by a process of step by step evolution. Hence the necessity for an occasional broad survey of the existing state of knowledge. Recent observations require to be evaluated and correlated with known facts and current conceptions. And it is eminently desirable that those who have given special attention to particular problems should indicate from time to time the admitted direction of the stream of contemporary thought. Dr. KINNIER WILSON, in the Morison Lectures delivered before the Royal College of Physicians of Edinburgh early this month, chose as his theme Nervous Semiology with Special Reference to Epilepsy. His philosophic treatment of certain general considerations, to the importance of which he has become increasingly attached, was of great interest. A differentiation of nervous diseases according to a purely clinical arrangement obviously has limitations, for the same symptom or group of symptoms can arise in conjunction with lesions at different physiological levels and as a result of different pathogenic actions. Again, the clinico-anatomical method, while it has led to discoveries and advances of the first importance, has too its limitations. Hence aetiology must be regarded as the sole basis for the scientific arrangement of nervous disease. But investigation may often lag behind surmise. We shall find insuperable difficulties in establishing disease entities unless we can prove that a given causative agent produces invariably and solely the same reaction in the body exhibiting the same syndromes and amenable to the same treatment. A pathogenic agent can be regarded physiologically as a stimulus, and physiology recognises only three classes of stimuli—pure excitants, pure depressants, and those which first excite and then depress. Clinical symptoms are to be considered as representing either excitation or cessation of function, or a series in which the latter follows the former. Again, all symptoms are functional in the sense of being related to function; only when a sign is residual and static can it be regarded as organic. According to the nomenclature of HUGHLINGS JACKSON all symptoms are either positive or negative. Again a positive symptom, as exemplified by various forms of involuntary movement and pain, is an indication of the action of a functioning mechanism. Further, the localisation of a symptom, a functional system and a lesion is, in each instance, a different and separate thing. No specificity attaches in a general way to nervous symptoms, and the same may be said of

¹ of the Indian Statutory Commission. Vol. I.

² The Medical Officer, June 7th, p. 251.

pathological changes; NISSL soon gave up the view that specific poisons produce specific cell alterations. The general conception of the essential non-specificity of neural tissue reactions, whether mesenchymatous or parenchymatous, is, in Dr. WILSON'S opinion, unassailable. A "disease process" calls forth vital efforts to cope with noxae, and while many symptoms are proof of health, many lesions are evidence of attempts at repair. Along such lines of thought Dr. WILSON believes we shall gain a truer insight into the activities of the nervous system.

A large part of neural semiology is indicative of increase of neural function, but some varieties of epileptic seizure are considerably more inhibitory or akinetic than kinetic or excitatory. FOERSTER has suggested the possibility of sensory inhibition through hypothetical efferent fibres in relation to the symptom of pain. Impressions from the periphery in numerous instances never penetrate to the cortical level, since they are damped down or shut off at lower levels, and it may be justifiably assumed that there is some form of protection in respect of cortical action. Dr. WILSON utilises in modified form HUGHLINGS JACKSON'S conception of three levels of the nervous system. The highest level corresponds to the whole cortex outside and above the anatomical projection centres; this projection constitutes the middle level; while the lowest is taken to include what may probably be regarded as the older system—viz., basal ganglia, brain stem, cerebellum, and spinal cord. A theoretical division of fits into those of the highest, middle, and lowest level is conceivable. While every fit preceded by a definite aura must be a highest level fit in so far as that symptom is concerned, the aura is merely the prelude of the fit and not its cause. Thus fits of lowest level type, if an aura is present at all, must somehow be able at the outset to influence the cortex, assuming that to be the seat of commencement. Dr. WILSON is of opinion that there is no differentiation between the aura of hysterical fits and of organic epileptic seizures. "It is surely proper to consider hysterical seizures as highest level fits par excellence." Thus, among the symptoms referable to excitation or transcortical release on the highest physiological level are (1) an aura in consciousness; (2) types of movement coördinated and quasi-purposive, occurring either in association with convulsive movements or by themselves; and (3) post-convulsion movements and actions of the same high level class. Acute and post-epileptic phenomena form indeed an integral part of the whole. The term epileptiform convulsion should be confined rigorously to Jacksonian epilepsy—i.e., fits of the middle physiological level. When we speak of the involuntary movements of Jacksonian epilepsy we can mean little else than that they cannot be transcortically prevented. The defective inhibition may conceivably be represented by change at some wide region or in some cellular layer remote from the spot where the arcs are in action. Reflex epilepsy is an expression which has never been defined with any precision. Two cases were referred to in some detail by Dr. WILSON as demonstrating the occurrence of pure reflex response to extrinsic stimuli through areas whose nodal point is certainly situated in the cortical grey matter. The motor area of the neuro-physiologist is nothing more nor less than a motor or sensorimotor ganglion pushed up into the neopallium. Prominent authorities take the view that consciousness exists on different physiological planes. Can the motor phenomena of an epileptic seizure be produced at other (lower) levels than the cortical? In the decerebrate animal the will produce

attacks. The distinction, sometimes still advanced by the clinico-anatomist, that the clonic element in fits is of cortical origin, the tonic of infracortical origin, cannot be upheld in its entirety, for both tonic and clonic convulsions have been produced by PIKE and ELSBERG in animals deprived bilaterally of the cortical motor areas, although it is true that DANLY claims to have proved that in the dog the cortex is required for the clonic component. A fit is difficult to define. "The clinician may claim any temporary, disorderly, paroxysmal, recurrent, uncontrolled manifestations of either motor or sensory processes as in essence a fit," and this on any physiological plane.

The term striatal epilepsy was first employed by AUGUST WIMMER, in 1925, for attacks of tonic spasm which he believed might have a striatal basis. SPILLER, in 1927, described two similar cases of brief tonic spasm under the designation "subcortical epilepsy." These spasms were brought on by voluntary movement of the limbs concerned, and the contractions were painful. Again, STERLING has suggested the term "extrapyramidal epilepsy" for cases of spastic contractions in the course of post-encephalitis, or during a more acute period, distinguished by painful spasms of fingers, toes, limbs or segments of limbs, and inclusive of facial or torticollis movement. Dr. WILSON holds, however, that the association of tonic spasm or painful spasmodic contractions with destructive lesions of the corpus striatum must be examined under very considerable reserve. Tonic spasms, being release or excitatory symptoms, cannot result from outfall of striatal cells, and the actual mechanism involved must have occupied an extra-striatal position. General tonic seizures were described by HUGHLINGS JACKSON as cerebellar fits, and Dr. WILSON has described a number of cases of the kind in his paper upon Decerebrate Rigidity in Man and the Occurrence of Tonic Fits. These attacks are found in association with a variety of conditions. The assumption of tonic attitudes and the appearance of tonic contractions are most likely to develop when the lesion dissociates physiologically the cerebral hemispheres from cerebello-mesencephalo-pontine levels, and where, therefore, striatal function also is in complete abeyance. Referring to tonic fits, Dr. WILSON remarks, with graphic humour, that "hysterical fits in the grand manner are out of fashion." One type of fit, however, occurs which has intimate affinities from the standpoint of form with what obtains in fully developed tonic fits attended by physiological decerebration. The physiology of hysteria is one of many matters in neurology which call for serious research. Certain lowest level fits are characterised by symptoms in which affective or visceromotor phenomena predominate. It is permissible to speak in general terms of "periventricular epilepsy," by which may be designated cases remarkable for localisation of the disorder in neurosympathetic centres, at least in major degree to the exclusion (absolute or relative) of sensorimotor phenomena of somatic type. It is difficult to ascertain whether peripheral or cortical cells form the starting-point. We must postulate an open way between the focus and the percipient cortex, since in few of the seizures is consciousness ever lost. The victim is aware, only too acutely, of some violent disorder referred to his viscera, but is incapable of inhibiting it. Prominent among these lowest level fits are the "vaso-vagal attacks" of GOWERS, "pseudo-angina" and "nerve storms." The patient complains of attacks of palpitation of the heart, difficulty in breathing, a suffocating

sensation in the throat, hot flushes, coldness, sweating, shivering and trembling, nausea and other epigastric sensations, and often also an indescribably distressing feeling of impending trouble, of fear, even of imminent dissolution. Another type of case is characterised by continual yawning with constant voiding of urine, followed by violent giddiness, headache, and occasional vomiting. Dr. WILSON concluded his learned disquisition thus: "If we could but discover the secret of inhibition and of de-inhibition, if we had some scientific means of reinforcing the former at the moment when escape from control is imminent, could we but determine that switching off of the current which in some patients can be effected by potent stimuli aroused through other channels at the crucial moment, our treatment of epileptic episodes would not be so nugatory as it often proves to be."

By this running summary of Dr. WILSON's Morison Lectures our readers should be stimulated to read the full text when it appears in the *Edinburgh Medical Journal*.

CARDIAC PAIN.

PAIN is the commonest symptom which leads patients to seek medical advice; it is the greatest safeguard we possess against the risks of undetected mischief with the inevitable consequences. When the pain is located in the chest, it is often suspected, rightly or wrongly, of being of cardiac origin. In the most serious type of cardiac pain—namely, angina pectoris—there is often little objective evidence of heart disease. The diagnosis then rests solely on the subjective symptoms, in fact on the patient's description of the paroxysms, for it is rarely that the doctor himself has the opportunity of witnessing an attack. The importance, therefore, of being able to differentiate this from other types of precordial pain is obvious.

The outstanding feature on which the diagnosis of angina is based is its association with exertion or emotion. It is typically brought on by physical exertion or relieved by rest. The pain itself limits exertion and brings the patient to a standstill, just as dyspnoea limits exertion in the congestive type of heart failure. It has, however, long been recognised by clinicians that in some cases the pain is not relieved by rest, and may arise in the absence of any apparent exciting cause. Most of these cases are examples of coronary occlusion with myocardial infarction, and can be recognised by the associated symptoms of that syndrome. There still remains, however, a third group of cases in which precordial pain is the patient's chief complaint, but in which that pain is not attributable to any organic heart lesion, and is not of serious significance. This type of pain used to be spoken of as false angina—a term which has rightly fallen into disrepute—for the name angina, however qualified, is associated in the lay mind with sudden death, and the patient who is branded with it lives in continual dread of a most painful and fatal malady. The benign type of precordial pain is much commoner in women than in men, and often appears at the time of menopause. It generally differs from true angina in affecting the chest wall in the vicinity of the cardiac impulse, though not uncommonly it may radiate through to the back and involve the left arm. Its nature and diagnosis are fully discussed by Dr. DORIS BAKER in our present issue.

Dr. BAKER followed up the after-histories of a series of patients who have come to the National Heart Hospital complaining of left inframammary pain. As she points out, the pain is generally

only one—though the principal one—of a large and varied group of symptoms. Its most common associates are undue fatigue, nervousness, faintness, palpitation, and certain peculiar disorders of respiration. The very multiplicity of these symptoms serves to clinch the diagnosis. They are all attributable to a common cause—namely, nervous exhaustion—and though they may prove very intractable to treatment, their prognostic significance is relatively trivial. In all types of pain, wherever situated, there are two factors to be considered—the lesion causing the pain and the sensitivity of the perceptive nervous mechanism of the patient. LIBMAN has called attention to the importance of hyper- and hyposensitivity in patients suffering from angina pectoris, the prognosis being much more favourable in the former group. This can readily be understood by the analogy of the pain of gastric ulcer. The hypersensitive subject seeks medical advice at an early stage when the ulcer is amenable to medical treatment. The hyposensitive patient, on the other hand, may suffer little inconvenience until the ulcer either erodes a large blood-vessel, causing profuse hæmatemesis, or else eats its way right through the coats of the stomach and the case comes to the surgeon as a perforation. In the type of precordial pain to which Dr. BAKER refers it is the hypersensitive nervous mechanism which is the important factor, and treatment with sedative drugs is the line which should be adopted. As the after-history of these cases shows, though the pain may persist with remissions from time to time, the ultimate prognosis is extremely good.

THE STAPHYLOCOCCAL INFECTIONS.

THE study of staphylococcal infections from many points of view takes up more than half of the Guy's Hospital Reports for April, 1930. Invasion by staphylococci can take such varied forms, from the simple pustule to severe septicæmia, that it is difficult to regard it as a single entity; but the symposium, which opens with a survey of staphylococcal fever by Dr. J. A. RYLE, shows that its manifestations must not be dismissed as isolated phenomena, but always considered as potential general infections. Diffuse infections with *Staphylococcus aureus* have nearly all a primary skin focus, a pustule, sty, boil, carbuncle, or diffuse furunculosis; fever is present more commonly than is generally supposed, and in a considerable proportion of all cases with fever there is either a true bacteraemia or a septicæmia usually with metastases. The sites of metastatic abscesses vary with different age-periods; in children osteomyelitis of the long bones is common, while in adults the kidney is often the site of election with resulting perinephric abscess. In severe septicæmia multiple lung abscesses are frequent. Skin abscesses are not uncommon, and a solitary focus in the tibia may give rise to a Brodie's abscess. In a series of ten patients, all of whom were males between the ages of 13 and 42 years, Dr. RYLE found that three had histories suggesting previous ill-health, three were overworked medical men, and one was a neglected boy in poor circumstances. In seven out of the ten there was an account of a primary focus, either a boil or other cutaneous sepsis. All had fever, and all, with one exception, developed localised abscesses; only one death occurred in the series, in a man who developed a cerebral abscess. Dr. RYLE found that these results supported his previous experience of staphylococcal fever during the war and in hospital. In estimating the prognosis he says: "Given a

sound physique, a reasonably early diagnosis, a good leucocytosis and watchful care, the great majority of cases should recover, although the course of the disease is often very prolonged."

The differential diagnosis is notoriously complex. Dr. RYLE makes the distinction from typhoid fever on the presence of an active or recent primary focus, the absence of marked splenic enlargement, rose spots or intestinal symptoms, and the presence from the beginning of a leucocytosis. He adds that the pulse in staphylococcal fever is frequently slow in proportion to the temperature. Hæmoptysis, night-sweating, and pleuritic effusion may well suggest a diagnosis of acute pulmonary tuberculosis; but again the leucocyte count, the history and sputum examinations should help to decide the issue. Dr. RYLE emphasises the frequency and diagnostic significance of sweats in staphylococcal fever, whether due to a focal or general infection; after tuberculosis and infective endocarditis it should be regarded as one of the most important of the "sweating" fevers. In discussing treatment he refers to the methods of Sir WILLIAM GULL. At a time when various remedies for rheumatic fever were being vaunted, GULL decided that without a knowledge of the natural course of the untreated disease it was impossible to judge the efficacy of therapeutic measures. He therefore reported, with close care and the collaboration of Dr. H. G. SUTTON, a series of cases treated, apart from nursing and symptomatic measures, by mint water alone. Using this series of controls, he found no evidence that the course of the disease was influenced by the remedies supposed to be specific; the work was a model of reasoned clinical research. Dr. RYLE holds that the present vogue for the use of vaccines and chemotherapy in septic states has as slender a basis as had the old rheumatic remedies which were discredited by GULL's efforts. In his view, "when the body is competing with a vast invasion of living organisms it can scarcely be regarded as a sound principle to inoculate it with a few more millions of dead organisms; in practice I have never yet been assured of resultant benefits. Nor have I seen good done by injections of eusol or mercurochrome in cases of septicæmia, or been persuaded by the literature of the subject that the happy results which sometimes follow the treatment are due to it." The principles of treatment which he recommends are three: first, good nursing; secondly, a copious fluid intake of at least six pints of fluid in the 24 hours for an adult; and, thirdly, watchful clinical care for metastatic abscesses, and considered judgment which to open and when to open them. Osteomyelitis calls for early operation. An established perinephric abscess should be dealt with without delay, and the loin may be incised with advantage in perinephritis even though no pus be found. Abscesses in skin and muscle should, of course, be opened when "ripe." Pulmonary abscesses are better left to themselves. Pleuritic fluid may be aspirated. Should a stage of weakness and low fever without organisms in the blood stream follow upon an acute septicæmic phase, sunshine and fresh air are invaluable adjuncts to treatment. Even a slight persistent pyrexia should, however, suggest the possibility of a hidden abscess, and the body should be searched systematically with a finger-tip in likely regions for any tender point or points. If there is any suspicion of a focus in bone, a careful radiographical examination is also necessary.

Mr. J. L. JORCE's communication to the symposium will give guidance on the therapeutic procedure in renal cases. He advocates conservative treatment at

operation where possible, since removal of an affected kidney may be deeply regretted should its fellow become involved subsequently. But some cases which subside spontaneously without healing progress finally to complete destruction of the renal tissues; in these nephrectomy is the rational treatment. Resection of the affected portion of the kidney in acute cases does not seem to Mr. JORCE a useful procedure, and he advises rather the relief of tension and drainage in the early stages, with subsequent nephrectomy if this conservative policy proves insufficient. Staphylococcal lesions of the skin are dealt with by Dr. H. W. BARBER. He indicates the principles of treatment in which fresh air and exercise coupled with plenty of vegetables and fresh fruit in the diet play an important part. He also finds little value in chemotherapy and considers that vaccines require great skill and experience for their proper use. As far as local treatment goes, he advises applications of iodine for boils, and emphatically disapproves of the use of poultices or boric fomentations. Typical and atypical cases where staphylococcal lesions are present are described by Dr. HUGH BARBER, Dr. W. J. COTTON, Dr. J. F. VENABLES, and Dr. LESLIE J. WITTS, while Dr. F. A. KNOTT outlines a method of differentiation between active and inactive leucocytosis which he devised, primarily for another purpose. It is based on the principle that if washed bacteria are added to fresh blood, the active leucocytes will act as phagocytes, while inactive devitalised white cells will not function. This procedure has not been tried out by Dr. KNOTT in inflammatory conditions, but he suggests its possible application to prognosis. If from any hæmatological evidence a healthy leucocytosis could be distinguished from one produced by a flagging hæmopoietic system the prognosis not only of staphylococcal but of streptococcal infections might be less difficult.

Annotations.

"No quid nimis."

PENAL SERVITUDE FOR THE INSANE.

MEDICINE and law notoriously disagree in their views of the relation between crime and insanity. The strange tangles which result from the legal position were illustrated afresh lately in the Court of Criminal Appeal. A man named Daniel Kenneally had been sentenced at the Central Criminal Court to ten years penal servitude for wounding Arthur Broomfield with intent to murder him. Kenneally and his victim, it appeared, were fellow-workmen at a brewery. Kenneally, at the time of the wounding, said "I have had news this morning of my father's death; that man killed my father, and I have killed him. Am I right in doing so?" This was obviously a delusion; his father was not dead, and Broomfield had had no quarrel with the father. The judge at the trial thought the accused was insane; Kenneally had had a good character for ten years, but there was evidence of his having suffered from insane delusions for some time. After conviction, Kenneally was actually certified insane, and was transferred or recommended for transfer to an asylum. Three questions will occur to any medical practitioner who reads these facts. First, how came Kenneally to be convicted at all? The answer to this question appears to be that the defending counsel, seemingly thinking that the circumstances were not strong enough to justify a plea of insanity within the rule in *McNaghten's case*, withdrew the plea of "Not Guilty." Counsel are generally disinclined to plead insanity in

borderline cases, because insanity means an indefinite incarceration in a criminal lunatic asylum as against a definite and possibly shorter period in prison. Here, however, counsel did not plead "Not Guilty," doubtless hoping to offer reasons for mitigating the sentence. This brings us to our second question: why was Kenneally, whom (according to the Court of Criminal Appeal) the judge at trial thought insane, sentenced to ten years penal servitude? The answer must be that the judge thought this best in the man's own interest, knowing that Kenneally would receive curative treatment during his sentence. The tribunal, indeed, could hardly allow Kenneally to remain at large; there was thus no alternative to a sentence of imprisonment. Lastly, what did the Court of Criminal Appeal do about it? The answer to this third question is that the learned judges reduced the sentence to three years penal servitude, evidently shrinking from the prospect that, if Kenneally should be discharged from the asylum as cured, he would be liable to serve the balance of a long period of imprisonment. The Court of Criminal Appeal, it seems, gives the man three years in which to obtain his cure. It is all very perplexing, but what can we expect of the law which, while declaring that guilt involves a consciously criminal intention, still retains the ridiculous phrase "guilty but insane." That phrase did not form the verdict in this particular case, but Kenneally's trial is a remarkable infringement of the rules of common sense. The man should not have been found "guilty"; he should not have been sentenced to ten years penal servitude, nor yet to three. Who can doubt that the insanity from which he is now certified to be suffering was already upon him when he wounded Broomfield? How long will it be before we have some simple machinery whereby a man like Kenneally can be placed directly in some curative institution without the farce of trial, sentence, penal servitude, and appeal?

EXPLOSION OF ANÆSTHETICS.

THE American Medical Association's committee on anesthesia accidents has come to the conclusion that the hazard of explosion is negligible compared with other risks, such as post-operative pulmonary complications. Since, in their opinion, the machines and methods which are inherently liable to the accident of explosion are the very ones which greatly reduce liability to these complications, they hold that the risk of explosion should not deter anesthetists from employing such machines and methods. But the underlying assumption is surely open to criticism, for the current view of post-anesthetic infections of the lung is that they are determined more by the site of operation than by any other consideration. Whatever the anesthetics employed, lung troubles follow operations on the upper abdomen more often than elsewhere. As might be expected, the report deals largely with ethylene. Explosions from ether are entirely avoidable, since for their occasion a naked flame or cautery must be used in the vicinity of the ether. But in the case of ethylene the unavoidable danger arises through electric discharge originating within the apparatus that has to be employed for administration of the gas. With present existing apparatus there appears to be no certain means of avoiding explosion, although the accident is fortunately rare. It is so rare, in fact, that the committee considers the risk should be run, in preference to employing other methods which more often cause pulmonary sequelæ, although free from explosive risk. "For full anesthesia the concentration of ethylene is above the explosive limit. The chief risk of explosion comes when the ethylene is shut off, and the patient's lungs and the apparatus itself are washed out with oxygen or oxygen and carbon dioxide. During this process the mixture of gases passes through the entire explosive range. The mixtures of ethylene and

oxygen used for analgesia during labour are highly explosive." The most explosive combination is the 25 per cent. ethylene and 75 per cent. oxygen mixture. The committee records a dramatic and fatal explosion with this mixture. Their recommendation is that non-conducting rubber should be eliminated, and so far as possible the entire apparatus should be constructed of metal. In particular they suggest that a small spirometer or a simple rebreathing chamber should be used in place of the rubber rebreathing bag.

WORK OF THE ROTUNDA HOSPITAL.

THE report of the Rotunda Hospital for the year 1928-29 has been presented by Dr. Bethel Solomons, Dr. W. A. Taylor, and Dr. O'Donel Browne. During the year under review 2034 women were delivered in the hospital, and 1805 in their own homes. There were 12 deaths—10 in the hospital and 2 in the extern department, which are accounted for in the following ways: tuberculosis, 2; broncho-pneumonia (shortly after delivery), 1; sepsis, 4; accidental hæmorrhage, 2; hyperemesis gravidarum, 1; chorea, 1; and eclampsia, 1. The outstanding feature of the report is the phenomenally low morbidity-rate which obtained in the hospital during the year. Of the 2034 women delivered only 57 were morbid, as judged by the British Medical Association standard, and when it is realised that this figure includes the deaths, and that but few of the women attended any antenatal clinic, it is doubtful whether any other maternity hospital has ever produced such astonishingly good results. There were 13 cases of placenta prævia without a death, and Dr. Solomons claims that he has not lost a case from this complication during his Mastership. There were 9 cases of eclampsia with one death, 43 cases of accidental hæmorrhage, 27 cases of prolapse of the cord, 521 cases of albuminuria, and 1 case of rupture of the uterus, successfully treated by hysterectomy. In the list of presentations 67 are described as "face," and 16 as "face to pubes." Both figures are obviously wrong. In the list of operations we find that 903 operations were performed on the 2034 patients, so that nearly every second woman had to submit to some operation. Cæsarean section was performed on 34 occasions, and twice for uterine inertia. Cæsarean hysterectomy was performed twice, once for uterine inertia. The perineum was lacerated in 602 cases—a very high figure. The fact that the morbidity-rate was kept so low in spite of the large number of operations performed is a tribute to the skill of Dr. Solomons and his staff, but will in no way satisfy those who believe that conservative methods offer the only hope of lowering the present high mortality-rate associated with childbirth and had always regarded the Rotunda Hospital as a bulwark against easy but dangerous midwifery. The gynaecological department was very active, and operations were performed on 664 women. There were seven deaths, of which four might justifiably be excluded. The hospital has its own radiological department, and Dr. C. L. McDonogh, the radiologist, treats cases both with X rays and radium. The report contains a short account of the paediatric department by Dr. B. Crichton, and concludes with a short pathological report drawn up by Dr. F. S. Bourke.

ADHESIVE SPECTACLES.

SOME of the medical and scientific papers in Germany have recently been discussing the possibility of doing away with spectacles, at least for the higher grades of refractive error, by the use of glass scales applied directly to the cornea. The principle has already been tried in the extreme case of conical cornea, and Prof. Leopold Heine has been extending it at the eye clinic of the University of Kiel. Adhesive glasses (Haftgläser) as he calls them are thin glass

scales adapted to the curvature of the cornea and worn beneath the eyelids. The curvature, which varies accordingly to the refractive error to be corrected, is calculated mathematically by a special instrument. It is claimed, for instance, that a myope of 20 dioptries, condemned to wear clumsy heavy concave glasses, can by placing a pair of suitable scales under his eyelids be converted practically into a person with normal sight, with very little alteration in the appearance of his eyes. Indeed, in the *Umschau* for March 22nd photographs are given of a high myope in whom the contrast in appearance of the two types of correction is very striking. In the photograph without spectacles there is a correcting scale beneath the left eyelid, and the difference between this and the right eye is not discernible. Astigmatism, if present, automatically disappears. In hypermetropia the scales should be especially valuable where the crystalline lens has been removed for cataract and a thick convex glass has to be worn. Prof. Heine, who has made the subject his hobby for years, states that, while adhesive glasses occasion the wearer some inconvenience at first custom is soon established just as is the case with artificial dentures. The scales become a part of the eye, accommodating themselves to all its movements, and are lubricated by the lacrimal secretion. At first they can only be worn for an hour or two, but after a time more or less all day. The range of vision afforded to the wearer is much greater than with ordinary spectacles. The scales are made by Zeiss, of Jena, of special glass which is not attacked by the fluid of the eye. Prof. Heine believes they are less dangerous to the wearer than spectacles when playing tennis or cricket, since the eye is naturally protected by the socket, and the scale shares this protection. Their potential value for the short-sighted swimmer is obvious. Whether they are likely to come into common use time only will tell. At present there is little practical experience to go on; the cost is high, the initial discomfort is great, and the outlook is doubtful. But undoubtedly the same could have been said of the first dental plates, and now everyone wears them.

AMYTAL

AMYTAL is the trade-name of iso-amyl-ethyl barbituric acid, and it has now been employed as an anæsthetic in a fair number of cases. As it is given intravenously it has the same disadvantage as the other drugs given by injection—namely, that it is only possible roughly to estimate the required dose, and this cannot be regulated by symptoms, and varied accordingly in the way that makes inhalation anæsthesia so comparatively safe. It appears that amytal, if used without risk, is rather a hypnotic than a true anæsthetic. For dogs in the laboratory it has been of great service as an anæsthetic, but for the human subject it is best used in the same way as avertin is—that is to say, as an excellent means of pleasantly inducing unconsciousness while the patient is in bed, so avoiding mental disturbance and rendering the patient easily susceptible to true anæsthesia induced by some other means. J. T. Mason and J. W. Baker¹ regard very favourably the combination of amytal and spinal anæsthesia. They say that “unless thoroughly familiar with both amytal and spinal anæsthetics the anæsthetist may find it easier first to establish the level of anæsthesia with the spinal anæsthetic, and thereafter administer the amytal. However, with studied judgment the most satisfactory of all results may be obtained by administering in the room beforehand sufficient sodium amytal to put the patient barely in a twilight stupor, such that he is free of anxiety yet can still be aroused to coöperate for the lumbar puncture.” It seems that this cannot be an easy state to hit off exactly, for they remark that when the amytal is first given the patient often proves hypersensitive,

and makes lumbar puncture difficult. The amount required to produce sleep is generally from grs. 3 to 9 and excitement before sleep comes is very rare. The sleep after operation is from 24 to 48 hours, and during this time the patient needs careful watching to avoid mechanical respiratory obstruction. There appears to be considerable risk of insufficient pulmonary ventilation during this period, and also a large percentage of patients require catheterisation.

ENLARGEMENT OF THE ROYAL FREE HOSPITAL.

THE Royal Free Hospital celebrated its centenary in 1928, and to mark the occasion an appeal was launched to provide funds for development. The desired improvements, placed in the order in which they could best be carried out, were as follows: (1) provision of new quarters for the female venereal diseases department; (2) a “central extension” comprising a boiler-house and engineering department, central kitchens, enlargement of the pathological department, and new quarters for the obstetric and gynaecological unit; (3) completion of the Alfred Langton Home for Nurses; and (4) provision of private rooms for paying patients. At about the time when these ambitious proposals were made public it was announced that Mr. George Eastman, of Rochester, New York, had offered to give £200,000 for a dental clinic at the hospital on condition that an endowment fund of £100,000 was raised. Lord Riddell and Sir Albert Levy at once agreed to provide this endowment, and the result is that the clinic is nearly finished and will be opened in the autumn. The rebuilding of the venereal disease quarters is also nearly complete; the contractors have begun to put up the central extension, and it is hoped that work on the nurses' home will begin shortly. The financial position in regard to these developments may be summarised as follows:—

	Cost.	Raised to date.
	£	£
V.D. new quarters	10,000	10,000
Central extension	225,000	95,000
Nurses' home extension	65,000	20,000
Dental clinic building and equipment	200,000	200,000
Endowment	100,000	100,000
	600,000	425,000

Of the £95,000 raised for the central extension, £50,000 is a further gift by Sir Albert Levy. The provision of pay-beds will have to be left over till the present commitments have been met. Meanwhile the hospital is to be congratulated both on its aims and on the extent of their realisation. The public should not be slow to find money for a charity which has found so much for itself. That the Royal Free Hospital deserves their support is obvious to anyone who considers its record or its opportunity.

STUDIES IN SCARLET FEVER.

THE May issue of the *Jahrbuch für Kinderheilkunde* is devoted to infectious diseases, with papers by the various workers in the children's fever section of the Wilhelmina Hospital in Vienna. Most of them describe clinical studies of scarlet fever, and their approach to the subject makes the reader regret that pædiatricians in this country get little or no opportunity for the scientific observation of children with infectious fevers. E. Gabriel and H. Zinchinsky write on second attacks of scarlet fever, and analyse their own cases. The gross material is represented by 20,000 cases of scarlet fever admitted between 1902 and 1929. This total has to be reduced slightly because of incomplete observations, but among the large number of cases remaining there are 387 examples of second attacks—a percentage of 1.9. From the distribution of these cases in the various years and from general epidemiological considerations it appears

¹ Surg., Gyn., and Obst., May, 1930, p. 828.

that fresh infection must be assumed to cover the facts. The cases were further divided into four groups: (1) those in which both attacks were unmistakable; (2) those in which there was doubt about the first attack but the second was unmistakable; (3) those in which the first attack was certain, but the second left room for doubt; and (4) a group in which during the same period of hospitalisation three unmistakable attacks of scarlet fever occurred. The first and last groups present many points of interest; in the first there are 179 cases where both attacks were observed by the authors of the paper. A typical case illustrating the material used is that of a two-year-old girl who was admitted with unmistakable scarlet fever on July 13th, 1908. Whooping-cough developed on the 26th after the onset of nophritis. By August 6th the child was afebrile, the lungs clear, and the urine free from albumin. On Sept. 11th, however, a second unmistakable attack of scarlet fever occurred with fever, rash, and sore-throat, with peeling beginning on the 25th. Particulars are given of many other cases illustrating the various groups and subsections described and the whole study of over 80 pages is full of interesting facts and deductions.

A second paper by Zinchinsky deals with endocarditis as a complication of scarlet fever. Out of the 20,000 total cases already mentioned he is only able to find ten with evidence enough to justify the diagnosis of endocarditis. Seven of them came to autopsy, and in these the scarlet fever was of the "septic" type, with endocarditis of the infective or malignant variety. The three remaining patients survived, and two of them had typical polyarticular acute rheumatic symptoms late in the scarlet fever, so that the etiology of the resulting mitral disease was in doubt. Only one case out of all the 20,000 appeared to be a genuine example of mitral insufficiency following scarlet fever, and it is therefore concluded that this form of streptococcal infection plays no practical part in the production of permanent damage to the mitral valve. Zinchinsky also contributes a paper on two cases of primary suppurative meningitis with scarlet fever. In one of them a child of 8 years with severe scarlet fever developed otitis media in the second week, and signs of meningitis at the end of the third week. A hæmolytic streptococcus was cultured from the cerebro-spinal fluid and the child died. No direct connexion between the aural disease and the meningitis was established at autopsy. The second example began with mild scarlet fever, but developed otitis media by the thirteenth day of the illness and meningitis by the twenty-seventh day. The cerebro-spinal fluid confirmed the diagnosis of suppurative meningitis, being turbid with excess of cells, mostly polymorphonuclear leucocytes. Bacteriological cultures were sterile in this patient, and greatly to the surprise of the observers he began to make a recovery after only three days of meningeal symptoms, eventually becoming quite well.

MEDICAL BENEFIT IN NORTHERN IRELAND.

THE Medical Benefit Bill,¹ writes our Belfast correspondent, did not pass its second reading in the Senate without weighty opposition, which was voiced by senators who are strong supporters of the present Government and who represent large country districts. The opposition was based on the grounds that there was no demand for such a measure in rural areas, and that it was the most unpopular piece of legislation yet introduced. Neither the farmers, whose agricultural prospects were gloomy, nor the farm-workers, whose wages sometimes only amounted to 2s. per week, wanted to pay the extra penny per week for the doubtful advantages conferred by medical benefits. Great regret was again expressed that the report of the Local Government Committee had not been adopted. Protests against the rushing

of the Medical Benefit Bill were made at a meeting of the Ulster Senate on June 5th, when a Government motion was put forward to suspend standing orders so that the third reading of the measure might be taken. Ultimately, however, the Bill was read a third time and passed.

NATURAL HISTORY OF DENGUE.

DENGUE appeared in Athens in the autumn of 1927, and in the following year it reappeared and spread so quickly that there was a pandemic in the city and numerous other foci throughout the country, especially in the ports.¹ Among those who studied the outbreak were G. Blanc and J. Caminopetros,² and they have been able to record a number of important facts about the disease. They show, for instance, that dengue serum, when kept in properly sealed tubes and at laboratory temperature (15-18° C.), can preserve its virulence for at least 54 days. Man may be attacked by symptomless dengue though his blood at the same time is virulent for others. Likewise the guinea-pig shows no evidence of febrile illness after inoculation with active dengue serum, but its blood becomes virulent five days afterwards. As regards the insect vector, these workers have ascertained that *Stegomyia fasciata* has been abundant in old Greece for a long time, and it is extremely common in Athens, where it is a domestic species and breeds in the customary situations. Experimental reproduction of dengue by means of infected *stegomyia* was successful—in the first instance with mosquitoes actually fed upon patients, and secondly, with those caught in dengue-infected houses. By triturating the bodies of infected mosquitoes in normal saline solution and conveying the material to the island of Spinalonga, which is 350 kilometres from Athens and remained free from dengue, they were able to reproduce the disease in two volunteers from that island. Their experiences upon the rearing and breeding of *stegomyia* in captivity correspond on the whole with what is already known. Some individual insects captured in Athens in October survived the winter and lived over 200 days. During the whole period they were fed upon human blood and remained active even at a temperature of one degree below zero, and the cages were taken daily in a motor-car to the hospital for feeding experiments. The net result of this work was to confirm that of Siler, Hall, and Hitchens on the ability of *stegomyia* to transmit the virus of dengue, and the inability of *Culex fatigans* to do so. An incubation of eight days in the body of the mosquito is necessary for the virus to develop, but at a temperature of 22° C., although the virus is conserved in the body of the insect, it is not transmitted by its bite. From the experiments of Siler and his co-workers³ it is known that the virus can be conserved in the body of the insect for very considerable periods—in these experiments for 92 days. When the temperature is depressed below 20° C. they lose their transmissibility, but regain it directly it rises to 20-22° C. The results noted by Blanc and Caminopetros differ from those of the American workers in that they find that the virus of dengue persists in the blood of patients beyond the first three days of the illness, and remains infective for 15 days and can be passed with ease through Chamberland filter L at atmospheric pressure. Many attempts were made to transmit dengue to the lower animals. The dog and the rabbit seem to be resistant to infection, while the white rat succumbs quite exceptionally. Monkeys, on the other hand, appear to be slightly susceptible and have what Nicolle and Lebailly term an inapparent infection; although they do not show any ill-effects their blood remains virulent for man for 18 days. These facts

¹ See THE LANCET, 1928, II., 431.

² Ann. de l'Inst. Pasteur, April, 1929, p. 367.

³ Siler, J. F., Hall, M. W., and Hitchens, A. P., Jour. Amer. Med. Assoc., 1921, lxxxiv., 1163.

¹ See THE LANCET, May 31st, p. 1204.

were ascertained by experiments on nine monkeys of four different genera.

All the facts and epidemiological investigations so far accumulated go to show that a definite and persistent immunity is evoked by dengue, but convalescent serum taken after the crisis and for six months afterwards has no protective qualities. It has been found that neither the virus of yellow fever nor convalescent serum in that disease have any modifying action on the virus of dengue. This virus, it is found, cannot withstand desiccation and is probably contained in the serum globulin. It is destroyed by the action of bile in dilutions of 1:5 to 1:15 within five minutes. Pituitary and thyroid extracts have no action, and it is resistant to alcohol, formal, and Lugol's solution. In continuation of the inoculation experiments, Blanc and Caminopetros claim to have demonstrated that by repeated inoculation at short intervals with bile-treated virus, it is possible to protect to a certain extent against the fresh active virus.

ALEXANDER WOLLASTON.

THE medical profession mourns a distinguished colleague in Alexander Wollaston, the gallant and learned explorer, who was murdered in Cambridge last week. From Clifton, where he received his early education, he went to King's College, Cambridge, where he became a Fellow. He entered the London Hospital as a medical student, and shortly after qualification commenced the series of exploratory missions of which his adventurous life was largely made up. In 1905-07 he was a member of a British expedition to Ruwenzori, Central Africa; he joined an expedition which was engaged in 1909-11 in Dutch New Guinea; and of the second expedition to the same district which was in operation for the two years before the war he was leader. During the war he served as a surgeon in the Navy, was mentioned in despatches and received the D.S.C. Lastly he was medical officer and naturalist to the Everest Expedition in 1921. With this wonderful record of adventure behind him he seemed at one time content to live an English country life, and he settled in Gloucestershire with a young wife and children. But his own College sought his help as tutor, and his brief tenure of the post showed how right had been the choice. The scene at his funeral testified to the widespread grief at his tragic end.

Dr. Christopher Addison has been appointed to succeed Mr. Noel-Buxton as Minister of Agriculture and Fisheries.

AFTER a lengthy hearing, the suit brought by the Scarlet Fever Committee in the United States of America against the Lederle Laboratory, for infringement of the patent dealing with scarlet fever antitoxin and the toxin used in the Dick test, has been decided in favour of the Scarlet Fever Committee. The American patent was held to be valid.

We regret that the name of Colonel William Coates, of Manchester, was omitted from the list of Birthday Honours given in our last issue. He has been promoted to the rank of Knight Commander in the civil division of the Order of the Bath.

BIRMINGHAM HOSPITALS CENTRE.—It was recently announced that Mr. Harry Vincent, a Birmingham business man, had promised £100,000 to the Birmingham Hospitals Centre scheme on condition that £350,000, including the sum already collected, was subscribed by June 6th. When the period of grace expired the fund stood at £378,000, and the redemption of the promise brings up the total to £478,000. Messrs. Cadbury Bros. Ltd., have given £100,000, which includes the value of the site, and the individual contributions of members of the Cadbury family amount, in addition, to £40,000.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. R. Russell is transferred to the Permanent List.

The following appointments are notified: Surg. Lt.-Comdr. J. F. H. Gausson to *Victory*, for R.N. Hospital, Haslar; Surg.-Lts. J. M. McNamara to *Ladybird*, and D. R. F. Bertram to *Codrington*.

ROYAL NAVAL VOLUNTEER RESERVE.

The following appointments are notified: Surg. Lt.-Comdrs. F. L. Cassidi to *Constance* and H. O. Martin to *Rodney*. Surg. Lts. R. L. Stubbs to *Victory*, for R.N. Hospital, Haslar, and F. W. Chippindale to *Champion*. Proby. Surg. Lt. W. B. Wilson to *Marlborough*. Surg. Sub.-Lt. A. F. Davy to *Champion*. Proby. Surg. Sub.-Lts. W. H. O. Watson to *Renown*; J. O. Livingston to *Rodney*; R. W. Riddle to *Concord*; H. A. Lockhart to *Courageous*; and J. F. M. Milner to *Warspite*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. & Bt. Col. (temp. Col.) A. C. H. Gray, R.A.M.C., to be Dir. of Pathology, War Office.

The undermentioned Lt.-Cols. from R.A.M.C., to be Cols.: Bt. Col. R. B. Ainsworth and Temp. Col. D. S. Skelton.

The undermentioned Lt.-Cols. retire on retd. pay: A. W. Gibson, E. V. Aylen, and W. Davis.

Majs. to be Lt.-Cols.: Temp. Lt.-Col. A. Dawson, vice Lt.-Col. & Bt. Col. R. B. Ainsworth; Temp. Lt.-Col. O. E. M. Morris, vice Lt.-Col. A. W. Gibson; Bt. Lt.-Col. (temp. Lt.-Col.) R. E. U. Newman, vice Lt.-Col. E. V. Aylen, to retd. pay; E. W. M. Paine, vice Lt.-Col. W. Davis, to retd. pay; and Temp. Lt.-Col. J. B. Grogan, vice Lt.-Col. (temp. Col.) D. S. Skelton.

Majs. to be temp. Lt.-Cols.: J. B. Grogan, E. M. O'Neill, G. B. Edwards, and J. W. L. Scott.

Capt. H. A. Hill to be Maj.

Col. E. P. Sewell, late R.A.M.C., retires on retd. pay.

Lt.-Col. J. Mackenzie, from R.A.M.C., to be Col.

Maj. & temp. Lt.-Col. E. M. O'Neill to be Lt.-Col., vice Lt.-Col. J. Mackenzie.

Maj. & Bt. Lt.-Col. W. C. Smales to be temp. Lt.-Col.

ARMY DENTAL CORPS.

Capts. J. Morrey and J. Baillie to be Majs.

TERRITORIAL ARMY.

Capt. J. W. Wayte to be Maj.

Lt. R. Lodge (late R.G.A., Spec. Res.) to be Lt.

ROYAL AIR FORCE.

Flight Lt. E. P. Carroll is transferred to the Reserve Class D (11).

INDIAN MEDICAL SERVICE.

Lt.-Cols. J. O. Clements and C. L. Dunn retire.

COLONIAL MEDICAL SERVICES.

Dr. J. A. Henderson, Senior Medical Officer, Palestine, to be Senior Sanitary Medical Officer, Jamaica.

The following appointments have been made: Dr. S. M. Bernard, Lady Medical Officer, Federated Malay States; Dr. G. F. West, Medical Officer, Malayan Medical Service; Dr. P. J. Gonsalves, Assistant Medical Officer, Seychelles; and Dr. E. B. Murray, Medical Officer (Anæsthetist), Straits Settlements.

DEATHS IN THE SERVICES.

Lt.-Col. Frederick William Gee, C.I.E., who died after an operation on June 2nd at the Royal Northern Hospital at the age of 67, was the eldest son of the Rev. William Gee, of East Coker, Somerset. He received his early education at Sherborne; afterwards he entered University College Hospital, obtained the M.R.C.S. Eng. and L.S.A. in 1886, and graduated M.B., B.S. at the University of London in the following year. A year later he entered the Indian Medical Service and was at the relief of Chitral in 1895 (medal and clasp). In 1897 he served on the North-West Frontier (Tochi clasp), and three years later, when he was promoted to the rank of Major, he was with the anti-Boxer campaign in China (medal). He also saw service in East Africa, where he was at one time base medical officer, and in the operations in Somaliland (mentioned in despatches, medal and clasp). He became Lt.-Col. in 1908. For work in Mesopotamia during the late war (mentioned in despatches) he received the C.I.E., and he retired in 1920.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles Contributed by Invitation.

LXXXVI.—CHEMICAL TESTS OF PANCREATIC EFFICIENCY.

PART II.*—SIGNIFICANCE OF THE TESTS IN VARIOUS CLINICAL CONDITIONS.

IN acute lesions of the pancreas the function tests are often valuable, but in chronic lesions they are often disappointing.

Acute Diseases of the Pancreas.

A patient suspected of having acute hæmorrhagic pancreatitis is generally regarded as a surgical case and in urgent need of exploratory laparotomy. None the less, in the limited time available, whilst the patient and the theatre are being prepared, Loewi's reaction, an examination of the urine (for sugar in particular), and an estimation of urinary diastase can readily be performed. The results would almost certainly be of real value to the surgeon, either in confirming his diagnosis and thus supporting a direct attack on the pancreas, or in lending no support to his diagnosis and thus possibly justifying post-

indicated in Part I. of this article. The usual findings in chronic pancreatitis, and in neoplasm of the pancreas, and when the pancreatic duct is obstructed—e.g., by a calculus—will be found tabulated below.

Diabetes Mellitus.

In most diabetics the islets of Langerhans alone are seriously affected. In some, judging from post-mortem histological examination, there is no evidence of damage to the islets, in which case either a functional inefficiency of the islets or a disturbance of the balance between the different ductless glands, or a disorder of other mechanisms controlling the output or availability of the internal secretion of the pancreas must be assumed. In most cases of diabetes efficiency tests reveal no abnormality of the external secretion of the pancreas, and it is assumed that the lesion or functional inefficiency is mostly limited to the islets. In a few cases there is extensive disease of the whole gland (in dogs about nine-tenths must be removed to cause diabetes), so that there is both diabetes and an inefficient external secretion. This comparatively small group has been classified separately by some writers as "true pancreatic diabetes." With the exception of this group, therefore, the external secretion tests given above are of no value in diabetes mellitus, but are useful only in the examination of diseases of the whole gland or its ducts.

Hyperinsulinism, or Idiopathic Hypoglycæmia.

Of recent years a few cases of hyperactivity of the pancreatic islets have been reported. At operation or

† Figures refer to adults.

ponement of the operation to allow of further investigation, or suggesting that an alternative surgical approach would be more useful. It is still necessary to approach the subject with great caution since none of the series of suspected cases of acute pancreatitis (published together with control cases), has been large enough to permit dogmatic statements. The results in normal and diseased persons of the three tests which can be performed at short notice are included in the Table.

Chronic Diseases of the Pancreas.

In chronic diseases of the pancreas if two or three tests give positive results the existence of pancreatic disease is likely; but if all give negative results, pancreatic disease is not excluded. An examination of the urine, including an estimation of diastase, should be made as a routine. The naked-eye appearance and microscopical examination of the feces likewise should always be undertaken, but other tests should be reserved as an extension of particular clinical observations and for the special investigations

post mortem either an adenoma or a carcinoma of the islet tissue has been found. The neoplasm may be localised, in which case it can be removed surgically, but it is more often diffused throughout the gland. The symptoms are those of a persistent overdose of insulin, and the blood-sugar is low except when suitably relieved by carbohydrates.

Summary of Results of Tests.

The Table, which gives the results of those tests of pancreatic efficiency which are generally considered the most helpful, illustrates the fact that all the pancreatic function tests so far devised are frequently equivocal.

Other Tests in Pancreatic Disease.

Certain other tests have been tried with even less conclusive results. Of these Sahli's glutoid capsule test, Schmidt's beef-cube test, Wintermiz's sajodin test, and Cammidge's test have now almost completely fallen into disuse.

Calcium oxalate crystals have been observed in the urines of patients with pancreatic disease, as in many other conditions, and there is nothing to indicate that

they have any special connexion with pancreatic lesions. Indicanuria has likewise been selected for notice in pancreatic disease, but whilst it is reasonable to assume that when there is a deficiency of protein-splitting ferment, there will be greater opportunities for the putrefaction of proteins by bacteria in the large intestine, there is no evidence that tests for indican are of any special value in suspected disease of the pancreas.

A similar attitude is justified in regard to tests for occult blood in faeces. A positive reaction indicates hæmorrhage somewhere in the alimentary tract. If clinically there is a carcinoma of the head of the pancreas, and blood is found in the faeces, there is a presumption, but no proof, that the growth is ulcerating into the bowel. E. C. Dodds and his colleagues have shown that the alveolar CO_2 rises during the secretion of gastric HCl and falls during the secretion of pancreatic juice, but the possibility of utilising this observation as an index of the output of pancreatic juice has not been explored. In any case the technique is too complicated to be used in routine clinical work.

AN OUTBREAK OF SUPPOSED PSITTACOSIS

AT ASHTON-UNDER-LYNE, DURING FEBRUARY AND
MARCH, 1930.

By D. SAGE SUTHERLAND, M.D. GLASG.,

Bacteriological Reports

By H. B. MAITLAND, M.R.C.S. ENG.,

PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY AND
DIRECTOR OF THE PUBLIC HEALTH LABORATORY.

THE occurrence of four closely related cases of acute illness in the same household, one of which proved fatal, following the death of a parrot in the same house, is so suspicious as to merit report in detail.

The parrot, described as a "festive Amazon," had been purchased during April, 1929. It was kept in the dining-room or the kitchen, and was stated to have suffered from catarrh and snuffles when purchased, but it appeared to be in fairly good health during the following summer. Its only abnormality was some shortness of breath when attempting to fly.

During January, 1930, it showed ill-health by ceasing to talk, and was very ill for a fortnight before its death on Feb. 23rd. There was said to be a mucopurulent blood-stained discharge from the nostrils, and the cook, who had cleared the nose with a match-stick "scores of times," placed the cage on the kitchen range for warmth. On the night of its death the owner, a medical man, had taken the cage to his bedroom and had got up to attend to the parrot. Its symptoms, in addition to the discharge from the nostrils, were hicough and diarrhoea. The stools were loose and offensive, and contained blood. The feathers were ruffled and the wings drooped. It was morose, and became weak and very breathless before death. It was destroyed by cremation. There

was no direct contact between the sick parrot and some other birds in an aviary in the house, and no illness among the small birds, although occasionally one was found dead. There is some evidence of indirect contact of these birds with other parrots. On March 17th, after the death of the parrot, the birds were certified by a veterinary surgeon to be in good health, but three were found dead a day or two later, and as a precautionary measure all the birds in the aviary were destroyed. There is evidence that the aviary was not kept with strict cleanliness, nor were rigid precautions taken against food and water being fouled by the birds. Before the arrival of the birds there were no mice; after their importation the house became overrun.

The cook states that during the winter months the parrot was frequently kept in the kitchen, and that she cleaned the cage and fed the bird. She took precautions in washing her hands before handling the household food, and was careful to see that the parrot did not contaminate food which was being cooked or consumed in the kitchen. The housemaid is said to have been afraid of approaching the bird closely.

The individuals who came most intimately in contact with the parrot were the cook and the owner. Case 1, who fondled and petted it a great deal. On Feb. 25th, two days after its death, he became ill. He had suffered from influenza some years before, and his symptoms in this illness were much more acute and sudden than he would have expected from an attack of influenza. He had been in a very debilitated state of health, due to the heavy demands of his practice, which to some extent may account for his infection. The second patient, who fell ill seven days later, was 63 years of age, and suffered from asthma. On account of his acceptance of the mayoralty of the town in the previous November, he found his public duties, added to his professional work, a severe strain, and this was further increased at the time by the medical care of his son. He had suffered from what was considered to be an attack of influenza on Feb. 6th, and attended a banquet while unwell. His indisposition lasted several days. It has been suggested that the parrot may have been infected from this illness, but it is known that the parrot was definitely ill before. It is noteworthy that, with the exception of Case 1, the infection selected the older members of the household, and the incidence does not suggest that infection was conveyed by food.

Clinical Reports.

CASE 1.—A medical man, aged 32, fell ill on Feb. 25th, 1930, two days after the death of a parrot. He suffered from chills, severe frontal headache and vertigo, and on the following day remained in bed, his temperature being 101°F . He can recall his own symptoms at the onset only of his illness, and states that he felt dazed and irritable. He was medically attended by his father and nursed by his mother, his wife, and the nurse-dispenser, with all of whom he came in close contact. After his father was taken ill on March 4th he was looked after by his uncle, also a medical man, who reports that the headache was very severe and that the patient suffered from photophobia and intolerance of noise. There was great irritability. The tongue was coated and the face pale. On March 4th the temperature was 103°F ., the pulse-rate 96, and the respiration-rate 24. There was impaired resonance with fine crepitations at the right pulmonary base behind. Cough and expectoration were absent at this time. The patient complained of flatulence, and the abdomen was distended and tympanitic. There was no abdominal tenderness or enlargement of the liver or spleen. No rash was noted. The bowels were constipated and the urine contained a faint trace of albumin. Two days later the temperature was 102°F ., the pulse-rate 90, and the respiration-rate 24. The patient was seen in consultation with Dr. Crighton Bramwell, who found impaired resonance and crepitations at the right base, and some loss of resonance in the axilla, but no bronchial breathing. On March 7th the temperature was 101.8°F . The tongue was still furred, and there was slight epistaxis. The general condition remained the same. He was seen by me on the afternoon of this day, and I noted loss of resonance in the right lung. Cough was very infrequent and there was no expectoration. The face was pale and sallow. The tongue was thickly coated.

The general appearance was of marked toxæmia. The patient was listless, feeble, restless, and suffered from nausea. Stools were loose and offensive. There was marked decubitus. The mental condition was then quite rational, but he was reported to have been rambling and incoherent. On March 8th he felt slightly better, but the temperature was 104° F. He felt relief after coughing up some jelly-like material. The headache, which up to now had been prominent, was less, and appetite was returning. On March 9th he had slept well, and felt much better. He was admitted to Monsall Hospital in the afternoon. His temperature was 102° F. on admission, and on the following afternoon it subsided to normal. The acute period of his illness extended to 14 days.

Bacteriological Report (H. B. M.).—Serum (collected March 7th, 1930) did not agglutinate "H" suspensions of *Bacillus paratyphosus* A, *B. paratyphosus* B, *B. paratyphosus* C, *B. aertrycke* (Mutton), *B. enteritidis*, or *B. abortus*. *B. typhosus* was agglutinated to a titre of 1 in 320. "O" suspensions of *B. typhosus* and *B. paratyphosus* B were not agglutinated. Blood (collected March 11th) was inoculated into two budgegins and two mice, which remained well. Cultures of faces and urine did not reveal any pathogenic intestinal bacteria.

There was no evidence for or against psittacosis. The illness was apparently not caused by any of the pathogenic intestinal bacteria. The agglutination of *B. typhosus* is not considered significant.

CASE 2.—A medical man, father of Case 1, aged 63 fell ill on March 4th nine days after the death of the parrot and seven days after the commencement of his son's illness. He had previously suffered from bronchial asthma and attacks of dyspnoea. The invasive symptoms were chilliness, pains in the limbs, severe headache, and slight epistaxis. On March 6th his temperature was 103.4° F. On the following day he had a very severe paroxysmal cough. He complained of severe pain in his temples, especially on coughing, and had some diarrhoea. The stools were offensive and slimy, but did not contain blood. The tongue was thickly coated.

When seen by me on March 7th he was propped up in bed and was very restless, muttering, and delirious. He was only able for brief intervals to collect his ideas sufficiently to give rational answers. Very fine crepitant râles were noted in both bases. The respiration-rate was not accelerated and there was no expectoration. He had slight cough, which was not unduly troublesome. The pulse-rate was 100. There was no abdominal distension. Two days later, on March 9th, when admitted to Monsall Hospital, the temperature was 101° F., pulse-rate 122, and respiration-rate 36. The urine contained a faint trace of albumin. The tongue was coated and the skin flushed. The heart sounds were regular, but the first sound somewhat muffled. There was a moderate degree of arterio-sclerosis. Expiration was prolonged over both lungs, but vocal resonance was normal. There was no abdominal distension. The patient was talkative and rambling, but slept for short intervals during the night. On March 10th the temperature was 102.8° F., the pulse-rate 120, and the respiration-rate 34. He was still restless and delirious, and spent a very disturbed night. The tongue was furred, dry, and covered with sordes. On March 11th his condition was distinctly worse. There was definite pallor and cyanosis. The temperature showed little change and restlessness was more marked. There was scattered bronchitis, but no definite consolidation. During the following night he was so collapsed that his friends were summoned and he died of evidence of failing circulation and commencing terminal hypostatic pneumonia. Before death he relapsed into a state of low muttering delirium, with irregularity of pulse and with occasional consciousness. His temperature at midnight was about 101° F. He died on the morning of March 13th.

At the commencement of his illness it was his opinion that he became infected from his son, whom he attended, and that the disease in both instances was contracted from the parrot.

Bacteriological Report (H. B. M.).—Serum (collected March 7th, 1930) did not agglutinate "H" suspensions of *B. typhosus*, *B. paratyphosus* A, *B. paratyphosus* B, *B. paratyphosus* C, *B. enteritidis*, or *B. abortus*. *B. aertrycke* (Mutton) was agglutinated to a titre of 1 in 40. "O" suspensions of the above first three organisms were not agglutinated. No pathogenic intestinal bacteria were found by culture from the feces or the urine (obtained post mortem).

The disease was apparently not caused by any of the pathogenic intestinal bacteria.

Autopsy Report (J. S. D.).—There is a fairly thick layer of fat. The muscles are well developed and of good colour. The pericardium is normal and contains no fluid. There is a large soft ante-mortem clot in the right ventricle and pulmonary arteries. In addition there is much soft red post-mortem clot filling the right auricle and ventricle;

the left side is almost empty. The valves are normal and the myocardium is of healthy aspect. The heart is of about normal size and weight. The aorta shows moderate atheroma throughout. The right pleura shows a small adhesion at the apex and a broad fibrous adhesion to the diaphragm, but no recent pleurisy. The right lung is well aerated and free from consolidation; there is some general congestion and very slight oedema posteriorly. The left pleura has a small fibrous adhesion at the apex but no recent pleurisy. A sector of the upper lobe of the left lung anteriorly is somewhat collapsed. On section there is consolidation of the anterior and upper two-thirds of this lobe, while the posterior part shows only slight oedema. The consolidation is red-grey in colour and nowhere as firm as in lobar pneumonia. Its margins are ill-defined and it lacks uniformity, reaching maximal intensity in the front of the lobe and in an area 5 by 7 cm. at the apex; at the latter site there is also much oedema. The lower lobe is

FIG. 1.

FIG. 2.

Temperature charts in Case 1 (March 9th to April 1st) and Case 2 (March 9th to 13th).

well aerated and shows only slight hypostatic oedema. The trachea is normal, apart from some patchy congestion. The larger bronchi contain some mucus, but there is no apparent lesion. In the small intestine there is no special congestion of the mucosa and no ulceration. The Peyer patches are atrophic and invisible. In the submucosa of the upper two metres of the jejunum there are about a dozen small circumscribed bodies of pale yellow colour. They measure 2 to 5 mm. in diameter and are of soft consistence suggesting small abscesses (? chyle cysts). The omentum contains much fat. The liver is of about normal size; on section it is generally pale with slight nutmeg appearance; probably fatty infiltration. The spleen is about twice the normal size, tumid, and fairly firm. The pulp is dark red and full, scraping out on the knife. The mesenteric lymphatic glands are small and inconspicuous, of normal aspect. The pancreas is normal, apart from some adiposity. The kidneys are of normal size and the capsules slightly adherent. The surface is finely granular from arterial atrophy, but there are no hemorrhages or other apparent lesion. The urinary bladder shows only very slight congestion of the mucosa. The prostate is fairly large and fleshy. The pia arachnoid is thin and transparent, and there is a slight excess of clear fluid but no special congestion of pia or grey matter. The puncta cruenta are fairly prominent on section, but there are no hemorrhages.

The other structures appear normal.

Histological Report (J. S. D.).—In the more solid parts of the pneumonia the lung alveoli are filled, though not distended, by fibrino-cellular exudate. The cells are mainly neutrophil polymorphonuclear leucocytes and are usually not in large numbers. Red blood corpuscles occur in the exudate in places. Towards the margins of the solid patches, where consolidation is less dense, there is less fibrin and more residue of serous fluid. In these parts the congested capillaries of the alveolar walls frequently show small hyaline thrombi. Sections stained by Gram's method and by Leishman's stain have been examined but no cocci resembling pneumococci or other organisms have been found in any part. While this does not exclude the presence of such organisms, it would suggest that they must, if present, be in small numbers. The medium and larger blood-vessels in the consolidated areas are free from thrombi. The bronchioles in the pneumatic areas show some desquamation of epithelium and occasional accumulations of polymorphonuclear leucocytes. There is also some

congestion of the vessels in their mucosa, but no cellular infiltration. The appearances are not such as to suggest a primary bronchial lesion, as the inflammatory changes are not more advanced in the bronchioles than in the lung, nor is the pneumonia more advanced immediately around the terminal bronchioles than at the peripheries of the lobules. The bronchi in the non-consolidated areas and one of the main bronchi, separately examined, show desquamation of epithelium, which is no doubt due to post-mortem autolysis.

The liver lobules show moderate congestion of the central sinusoids and slight fatty infiltration at the periphery. In almost every lobule there is a focus of necrosis of liver cells varying in size from about 1/10 to about 1/2 of the lobule area. These foci are always near the centre of the lobule and are usually confined to one quadrant; larger ones appear to surround the central vein. In these areas the dead cells have slightly shrunken protoplasm which stains strongly with eosin; the nuclei have disappeared. The sinusoids between the dead cells contain fairly numerous polymorphonuclear leucocytes and occasionally small adherent eosinophil thrombi. No organisms are recognised in relation to the necrosed areas.

The only notable feature of the spleen is a loading-up of the pulp with red blood corpuscles, giving an appearance of diffuse hæmorrhage in places. Leucocytes are present in small numbers, but there is no appearance of large mononuclear cells such as accumulate in the spleen in typhoid affections. No definite coecal or bacillary organisms are found in films stained by Leishman's stain in sections stained by Gram or Leishman's stain. The films of bone marrow show abundant myelocytes and leucocytes, but no definite departure from normal. The glomeruli of the kidney are slightly congested. The tubules show some early post-mortem autolysis but no necrosis or other definitely pathological change. In the parietal cerebral cortex and mid-brain there is more congestion of the vessels than was assumed from naked-eye examination. No certain pathological changes can be made out in any part.

Summary.—The main features are the pneumonia in the upper lobe of the left lung and changes in spleen and liver which point to an infection with toxæmia. There is nothing definite to suggest an intestinal infection. The pneumonia is not quite of the usual type. It has the main histological features but not the characteristic gross distribution of a lobar pneumonia. On the other hand, it does not suggest a lesion disseminated by the bronchi, being confined to segments of one lobe and showing no histological evidence of a primary bronchiolar lesion.

CASE 3, the wife of Case 2 and mother of Case 1, was aged 62. She had as premonitory symptoms, malaise and languor for a few days, and took to her bed on March 8th. She complained of severe headache and slight epistaxis and of feeling tired and shivery. The temperature was 103° F. There were no physical signs in the chest or abdomen and her sleep was undisturbed. She was admitted to Monsall Hospital on March 9th. There was a previous history of fairly good health. On admission the temperature was 102° F., pulse-rate 120, and respiration-rate 24. At 2 o'clock on the same morning the temperature was 101.4° F., pulse-rate 84, and respiration-rate 28. The tongue was heavily furred and dry. There was some stomatitis. The heart sounds were regular. Examination of the chest showed no obvious abnormality. She was somewhat constipated, but had no distension, tenderness, or rigidity of the abdomen. On March 10th the temperature was 103° F., pulse-rate 126, and respiration-rate 24. She had a fairly good night, but complained of slight headache and malaise. The bowels were opened after an aperient. The stools were greenish in colour and offensive, without mucus or blood. The tongue was heavily furred. An occasional moist râle was heard in the left lower lobe of the lung. The heart was noted to be slightly irregular in rhythm, with a reduplication of the second sound. On March 11th the temperature was 102° F., pulse-rate 112, respiration-rate 20. The urine contained a trace of albumin. There was shortness of breath and slight headache. The face was flushed, and of a dusky toxic appearance. On the 12th she had slept little. The tongue was dry and in the left lower lobe numerous moist râles were heard. An occasional moist sound was audible at the right base. The heart was still irregular and the urine contained a dense cloud of albumin. There was a very marked loss of appetite. On the 13th the temperature was 103.2° to 102° F., the pulse-rate 88, and the respiration-rate 32. She slept for only one hour. The stools were loose and pea-soupy in character and there was severe diarrhoea, the bowels being opened 14 times in 24 hours, with some incontinence both of bowels and urine. After digitalis the heart sounds became more regular and of better quality. On March 14th, after restriction of diet and the administration of pulv. cret. aromat. c. apio, the diarrhoea became less; the patient slept better. On the 15th the temperature had

fallen to 101° F. and she felt more comfortable, but continued to be somewhat dazed and apathetic and answered questions with hesitation. Cough was very slight. The urine contained a heavy deposit of albumin. From the 16th to the 23rd the temperature subsided gradually to normal. The stools were normal and the urine contained a faint trace of albumin. The pulse-rate dropped to 72 per minute. Vocal resonance was normal on the 18th, but a few scattered crepitations were still audible. Slight oedema of the right ankle and foot was observed. On the 19th her temperature did not exceed 100° F., but her general condition was still poor and occasional irregularity of the pulse was noted. She was feeble, and answered questions slowly. The tongue was still heavily furred. On the 20th there was oedema of both ankles. The skin was dry and appetite poor. A blood count made on this date showed: red blood corpuscles, 5,003,000; white blood corpuscles, 8000; polymorphonuclear leucocytes in excess; hæmoglobin, 70 per cent. On the 21st the temperature was 99° F., pulse-rate 61—volume and tension poor—and respiration-rate 32. She was still very drowsy and indifferent. On the 22nd the temperature subsided to normal and the general condition was slightly improved. The pulse was more regular and the tension better. Mentally she was rather brighter. On the 23rd she was reported to be distinctly improving. There continued to be a faint trace of albumin in the urine.

Bacteriological Report (H. B. M.).—Blood (collected March 11th) was inoculated into two budgerigars and two

FIG. 3.

Temperature chart in Case 3 from March 9th to April 3rd.

mice, which remained well. Cultures of faeces and urine did not reveal the presence of any pathogenic intestinal bacteria. The sputum was inoculated into two mice on March 13th. Both died after five days, but no pathogenic bacteria were isolated from them. No pneumococci or hæmolytic streptococci were detected in cultures of the sputum.

There was no evidence for or against psittacosis. The disease appeared not to be caused by any of the pathogenic intestinal bacteria.

CASE 4.—A nurse dispenser, aged 60, states that she had felt tired for some days, although she continued to carry on her duties. On March 8th she was troubled with headache, backache, pains in the limbs and occasional shivering, and remained in bed. On March 9th she suffered from diarrhoea, and from the 10th there was some bleeding from the nose. On admission to Monsall Hospital on March 10th her face was flushed, her temperature was 103° F., and she had severe headache, but no abdominal distension. The spleen was not enlarged. Some moist râles over the anterior surface of the right lung were noted, and also some fine crepitations over the left base, but there was no loss of resonance. The heart was normal. On the following day the tongue was coated, the temperature 102° F., the pulse-rate 98, and the respiration-rate 24. The face was still flushed and there was severe frontal headache. She was very depressed. Diarrhoea had ceased and cough was absent. There was an herpetic eruption on the upper and lower lips, and twitching of the facial muscles, but the reflexes were normal. On March 12th the temperature was 102.5° F., pulse-rate 108, and respiration-rate 24. Headache had disappeared. The face was still flushed. On March 13th the temperature was 103.4° F., and the pulse-rate 108. There was some slight headache and cough and the tongue was still thickly coated and flabby. There was some loss of resonance and harsh crepitations at the right base behind, also some fine crepitations below the left scapula. On the 14th there was a morning remission of temperature to 99° F., and in the afternoon it was 101.8° F. On the 15th

the temperature was 102° F., pulse-rate 98, and respiration-rate 32. The stools were relaxed. There was a short dry cough, but no expectoration. The face was still flushed. The mental condition remained clear. There was some impairment of resonance at the right base and the tongue was furred. The slight facial twitching was now absent. The skin was moist and the headache was very much less. The stools were loose and the motions offensive. On the 17th

FIG. 4.

Temperature chart in Case 4 from March 10th to April 7th.

slight blood and mucus were reported in the stools and the tongue was still coated. The temperature had fallen to 99° F.; the pulse-rate was 104, and the respiration-rate 26. The face was less flushed. On the 18th the stools were frequent and relaxed, normal in colour, with no blood or mucus or abdominal distension. Cough had ceased. The tongue continued to be furred on the dorsum, but clear at the edges and tip. The heart sounds were regular. No albumin was noted in the urine. She made some complaint of weakness, and on the 19th lassitude was very marked, but the appearance of the stools approached normal and the bowels were open 4 times in the 24 hours. On the 20th the temperature fell to normal. The tongue was less furred and the patient felt better generally. A blood count showed: red blood corpuscles, 4,080,000; white blood corpuscles, 8000; hemoglobin, 70 per cent. A differential count showed: polymorphonuclear leucocytes, 65 per cent.; large lymphocytes, 10 per cent.; small lymphocytes, 25 per cent.

Bacteriological Report (H. B. M.).—Blood (collected March 11th) was inoculated into two budgerigars and two mice, which remained well. Cultures of urine and faeces did not reveal the presence of any pathogenic intestinal bacteria.

There was no evidence for or against psittacosis. The disease was apparently not caused by any of the pathogenic intestinal bacteria.

Commentary.

All the cases show a somewhat remarkable parallel in their symptomatology, which corresponds with that of cases recently described in the medical journals as parrot disease. All suffered from an acute infection of a toxic nature and of sudden onset, associated with pyrexia, severe headache, chills, coated tongue, slight cough, epistaxis, and anorexia, and in all cases there was some pulmonary involvement of an indefinite nature. Defervescence showed a very gradual and regular decline, with absence of morning remissions. The pulse-rate was at no time greatly accelerated in relation to the temperature. At some period diarrhoea was a feature to a greater or lesser extent, and was sometimes associated with abdominal discomfort or distension. There was no splenic enlargement or rash. A dazed appearance, mental torpor, and a tendency to cyanosis was present in all. Muttering delirium and insomnia were features of the most acute period of the illness. Marked prostration resulted and convalescence was slow.

While the features of the four cases described are indistinguishable from influenzal pneumonia, catarrhal symptoms at the onset were not a prominent feature and pulmonary involvement was late. Moreover, these cases occurred when influenza was not prevalent, no other member of the household or relation suffered from an influenzal illness of a more benign type, and the weight of the clinical evidence tends to the opinion

that these illnesses were in some way definitely associated in aetiological relationship or had some common source of infection. On the other hand, there is evidence which cannot be overlooked, that the acute illnesses were fortuitous and due to an independent source of infection unconnected with the parrot. The occurrence of exceptional cases of illness of an influenzal nature in four of the less resistant individuals of the household, predisposed by age or other cause, at the coldest period of the year, may be considered not improbable. The absence of a definite organism, or the presence of a specific virus common to the four cases, lends weight to this view. The post-mortem appearances in the fatal case bear some resemblance to fatal cases observed elsewhere associated with parrot disease. Presuming that the parrot had suffered for a considerable period from infective disease communicable to man, it is difficult to explain why these cases should have occurred in such close relationship to one another, unless it be presumed that the disease is capable of being communicated from human sources, and that the first victim infected the other members of the family. Fatal disease in parrots may exhibit similar symptoms, although due to varying causes, and there may be more than one disease in parrots which is infective to man. There is the further possibility that a parrot may be susceptible to human influenza, and that the virulence may be increased by animal passage. Increased virulence may account for the frequent occurrence of severe influenzal attacks in association with sick parrots. The destruction of the parrot rendered it impossible to obtain any definite scientific evidence of the nature of the disease in the parrot, and consequently, in the absence of further proof, it would be unwise to dogmatise regarding the definite nature and source of infection of these illnesses.

MEDICINE AND THE LAW.

A PARTNERSHIP DISPUTE.

THE almost invariable lesson of litigation over a medical partnership dispute is that dragging the matter into the law-courts has done nobody any good. Excessive publicity is usually given to domestic and personal details which are not really of public interest; accusations are made which, even if rebutted, leave unpleasant recollections; money is spent which could have been turned to better use; finally, the medical profession as a whole receives an advertisement of a kind which it does not greatly desire. Such a dispute has lately been occupying several days of the time of a judge of the Chancery Division. Two practitioners, nearly 60 years of age, evidently found further cooperation impossible after two and a half years of partnership. One of them served the other with a notice purporting to dissolve the partnership and removed the other's name from the surgery during his absence. The other doctor thereupon applied to the High Court for an injunction restraining his partner from excluding him from the partnership premises; he asked also for a declaration that the notice for termination of the partnership was void and he finally requested the Court to dissolve the partnership. The defendant doctor alleged gross neglect and breaches of the partnership articles. He too asked that the judge should order a dissolution. As this was what both parties desired, some simpler and less expensive remedy than litigation might well have been found. But the allegations of neglect naturally were an obstacle to peaceful settlement; moreover, the partnership agreement attached pecuniary consequences to a dissolution; in effect (it was stated), if the defendant were entitled to a dissolution, he would have to pay the plaintiff £150; if the plaintiff were in the right, the defendant would have to pay £1500. Mr. Justice Bennett had to decide whether the plaintiff (1) had grossly neglected the

business of the partnership, or (2) had committed a breach of the articles so as to entitle the defendant to expel him from the partnership. This involved examining evidence about two classes of acts on the part of the plaintiff—namely, acts of alleged negligence in connexion with patients and conduct calculated to lead patients to think lightly of the defendant by criticising in hostile or contemptuous words the defendant's diagnosis or treatment. In any event, it will be observed, it was the plaintiff's conduct which was in question although it was the plaintiff who initiated the proceedings. The judge came to the conclusion that the defendant doctor failed to prove that the plaintiff had deliberately and intentionally made such criticism as was alleged; "I do not think," he said, "that the plaintiff at any time intended to be disloyal to his partner." The other part of the case was more difficult. There had been an allegation about a little girl on whom it was afterwards found necessary to perform an urgent operation for appendicitis. Here the judge considered that the plaintiff's conduct had fallen short of the standard which the parents and the partner had a right to expect. Another allegation related to a refusal to go out at 1.45 A.M. to attend to a patient; this, in the circumstances, the judge held not to be necessarily gross neglect of the business of the partnership. A third incident concerned a refusal to attend a patient at 9 P.M. some six miles away; the plaintiff's explanation was that it was one of the defendant's patients, that the defendant was known to be returning in half an hour and that it was proper to leave the case to be dealt with on his return. The judge held that the plaintiff refused to go and see the case because at that stage of the partnership he was not disposed to turn out late at night to see one of his partner's patients; "no doubt the plaintiff's temper got the better of his judgment." These incidents, in the judge's opinion, amounted to this: there was one case of neglect by the plaintiff and one case in which his loss of temper led him into an error of judgment. Mr. Justice Bennett did not think that one act of negligence or one error of judgment could be interpreted as gross neglect of the partnership business. Taking the case as a whole, he was not prepared to say that the plaintiff had been guilty of gross neglect. The clause in the articles required proof of some regular course of careless conduct or something of the nature of wilful neglect. This proof was wanting. The plaintiff consequently succeeded in his action; the defendant was not entitled to expel him. At the same time it was clearly a case in which it was quite impossible for the partnership to continue; the court would, therefore, decree a dissolution. The defendant was ordered to pay the costs of the action except those of the two items on which the plaintiff had been found at fault.

The inevitable question arises—why was this unfortunate litigation not avoided? Ample opportunity exists for settling such disputes by arbitration. Partnership articles can provide for such settlement and, what is more important, partners must realise that it is their duty to their profession to avoid washing their dirty linen in public. The Chancery Division has perhaps never had better judges than at this moment. Mr. Justice Bennett, in particular, with his early training at the common law, is the ideal judge for an issue of disputed fact. But the recent case remains on record as an instance of litigation which is better avoided. The first method of preventing such incidents is to take more care in entering upon a partnership between persons whose temperaments may be incompatible. No medical partnership can be carried on satisfactorily unless there is mutual goodwill between the partners. The second is to settle the affair quietly before some arbitrator in whom all parties can repose trust and thus to avoid taking the whole world into one's confidence. It is well for any partnership agreement to contain a clause that any question, dispute, or difference shall be settled by arbitration.

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, MAY 27TH-31ST, 1930.

(Concluded from p. 1263.)

COMMITTEE BUSINESS.

Public Health Committee.

Sir John Moore moved the adoption of the report of the Public Health Committee. The number of exemptions from parts of the D.P.H. course had given rise to some anxiety and a table of the exemptions for the year was therefore once more printed in the report, individual cases being described at some length. The committee urged licensing bodies to scrutinise with great care certificates presented to them and to make stringent inquiries to ascertain whether the student had carried out the prescribed rules.

Mr. K. W. Monsarrat asked if there might not be some elasticity for service candidates who desired to take the diplomas of tropical medicine and of public health while on leave from colonial appointments.

Sir George Newman replied that the point had been under consideration and had been referred to a sub-committee. Meanwhile every case was most carefully considered on its personal merits with regard to the actual experience and position of the applicant. It must, however, be clearly realised that the diploma of public health had been instituted for persons seeking posts in this country and that experience of public health duties abroad, however valuable, was no substitute for the special knowledge required here.

Pharmacopœia Committee.

Dr. H. H. Dale introduced the report of the Pharmacopœia Committee, which recorded that 1955 copies of the British Pharmacopœia, 1914, had been sold in the year ending May 24th, 1930. The committee had completed the task of considering additions to the Pharmacopœia. They had been guided by the following general principles:—

(a) They have accepted the opinion expressed by the Committee on Civil Research, Subcommittee on the British Pharmacopœia, that "the British Pharmacopœia should contain only those standard articles which are in general use throughout the Empire. Where it is desired that official recognition should be given in any part of the Empire to any local drugs or local substitutes, we suggest that this should be left to the Governments concerned, which, by means of supplements or addenda to which they may accord the necessary sanction, can meet any local requirements or introduce any modifications or alternatives desired."

(b) In the case of groups of substances containing the same or similar active principles—e.g., vegetable substances containing tannic acid—it has been thought advisable to reduce the number of drugs described.

(c) Certain substances which are little used or are believed to be of doubtful therapeutic value have been omitted.

(d) Preparations such as the hypodermic injections and certain of the "liquors" have been omitted on the ground that standard formulae are not necessary, and that it is preferable that potent drugs should be prescribed by the physician in quantities by weight as required.

Special formulae for suppositories have been omitted and a general method will be described, leaving to the discretion of the physician the dosage of the medicament to be incorporated. Formulae for several mixtures and for some of the compound pills and powders have been omitted.

It had thus been possible to reduce the number of substances described and to make room for more precise tests of purity and for biological tests and other new information. The Pharmacy Subcommittee had nearly finished a systematic review of those galenical preparations which will be described in the new volume and had made good progress with the definition of new preparations. The subcommittees dealing with special drugs had presented a number of monographs to the Commission. Progress had been made with the question of vitamin tests and an investigation into a standard colour test

for cod-liver oil had been initiated. A survey of the nomenclature had been made with a view to bringing it into line as far as possible with the International Agreement and the United States Pharmacopoeia. The text of the International Agreement appeared as an appendix to the report.

Executive Committee.

At the meeting of this committee immediately preceding the meeting of the Council the Registrar reported that the following names had been restored to the Register from which they had been erased under Section 14 of the Medical Act.

John M. Bickerton, Arthur F. R. Dove, Percy L. Hope, Thomas J. McCarthy (I.), Grace O. C. Mackinnon (S.), William A. Malone (I.), Sylvia Marsh (I.), David Morrison, Daniel J. Mulholland, Thomas S. Reeves (I.), Annie E. G. Rowlands, Laurence A. Waddell (S.), John F. W. Waters.

It was resolved to raise the price of the office copy of the Medical Register to 10s. and that this price be charged to the Stationery Office.

THE NEW VOTING PAPER.

Sir Holburt Waring presented the report of the Finance Committee on the question of the voting paper.¹ The proposed new form is shown below.

ELECTION OF DIRECT REPRESENTATIVES FOR ENGLAND, 19 .

MEDICAL ACT, 1886.

(49 and 50 Vict. c. 48.)

ELECTION TO THE GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION OF THE UNITED KINGDOM BY REGISTERED MEDICAL PRACTITIONERS RESIDENT IN ENGLAND.

BALLOT PAPER.

..... Vacancies.

The Registered Medical Practitioner voting must put a mark thus X against the name or names of the candidate or candidates for whom he votes.

Column for the Voter's Mark X.	Names of Persons Nominated.	Registered Address.	Registered Qualifications.
	A. B.		
	C. D.		

1. Each Voter shall mark the Voting Paper delivered to him with an X against the name or names of the person or persons (not exceeding the number of persons to be elected) for whom he intends to vote. Any mark placed on the Voting Paper by which the Voter may be afterwards identified renders the vote invalid.

2. The Voting Paper must be folded face inwards.

3. The Voting Paper must be placed inside the Identification Envelope.

4. The Identification Envelope must be securely fastened.

5. The Voter must sign the declaration printed on the Identification Envelope.

6. The Voter must place the Identification Envelope inside the covering envelope.

7. The Voter must dispatch the covering envelope to the Registrar, and it must be received there on or before the

8. If the Identification Envelope is transmitted by post postage must be prepaid.

No matter other than the Voting Paper should be placed inside the Identification Envelope.

Please examine the extract from the Register placed on the Identification Envelope and mark thereon any corrections you desire to be made. A form for the registration of additional qualifications will be sent on application.

Dr. Bone agreed that this was a great improvement, but thought the same formula should be used on the ballot paper as in No. 1 of the instructions. The

President pointed out that the instructions 1-8 were laid down by the Privy Council and therefore obligatory. Dr. Bone therefore withdrew this criticism but still objected to the notes at the bottom of the page as irrelevant and unjustifiable, and suggested that there should be an indication that the instructions were to be torn from the ballot paper at the dotted line. It was agreed to add at the top a notice that the practitioner, before voting, should read the following instructions. The President pointed out that the first note at the bottom was a warning to the voter, in his own interest, as the ballot papers were not opened by the Registrar but kept until a fixed date.

ROYAL INSTITUTE OF PUBLIC HEALTH.

THIRTY-FOURTH ANNUAL CONGRESS.

The Annual Congress of the Royal Institute of Public Health was held at Portsmouth from June 4th-9th, with Major-General J. E. B. SEELY as President, and the Lord Mayor of Portsmouth (Councillor J. E. SMITH) as Honorary President. The importance of the Navy and the Dockyard to the town was reflected in the scientific communications, for discussions on marine medicine and hygiene, including the industrial hygiene of dockyards, were prominent. Members of the Congress had the advantage of visiting the Royal Naval Hospital and H.M. Dockyard, and of going over a great ship.

Health of Men at Sea.

Presiding over the Services section, Surg. Rear-Admiral H. C. WHITESIDE, officer-in-charge Haslar Hospital, set out some of the problems of the seafaring doctor. Nowadays the difficulties of fresh water supply have been overcome in the Navy; every ship carries a distilling plant. The recruiting naval medical officer must be an efficient oculist, able to detect any visual defect, whether of refraction or of colour-vision. In tropical waters the doctor must pay great attention to the condition of the food, especially vegetables and fish. He must also be prepared to determine the potability of shore water used for any reason on board. In our great ships many of the ratings are, of necessity, troglodytes, living and working in enclosed spaces, perhaps unduly crowded, in spite of the special arrangements made to provide ventilation. When a wave of influenza occurs, we have the very best conditions for a manifestation of latent tuberculosis. In spite of all that is being done the Navy invaliding rate from tuberculosis is still too high. Surg.-Captain L. M. MORRIS pointed out the present need of the Navy for the more intelligent type of man. The smaller the Service the greater the care required in the selection of personnel. During recruiting much attention is paid to the candidates' temperament; the parent is asked to fill up a form in some detail, so that the recruiting medical officer can form an idea as to the mental health of the candidate, and the presence or absence of the temperamental qualities required for the Navy.

Dr. W. HANNA (Liverpool) considered that cadets and others who intend joining the mercantile marine should receive a training in hygiene on training ships, and qualify in ambulance and first-aid work; all should receive some instruction in the dangers of venereal disease. Any pamphlets on venereal disease intended for sailors should contain the necessary information, not isolated but incorporated with directions for the maintenance of general good health.

At the Royal Naval Dockyard, Surg.-Commander H. D. DRENNAN is responsible for the medical care of the workers. In addition to the medical examination on entry, a periodical examination is made of certain classes of workers. All lead workers appear before the medical officer fortnightly; during the two years Surg.-Commander Drennan has been in the Yard he has not come in contact with a single case of lead poisoning.

The vision of welders is tested monthly and of motor transport drivers yearly. Divers are medically examined every week, and before each dive of over five fathoms. The fresh water tank party are examined monthly and on each occasion before they enter tanks, the diseases especially looked for being enteric fevers, diarrhoea and dysentery, venereal and skin diseases, otorrhoea and pyorrhoea; the party wear canvas suits and gymnasium shoes. The excreta of workers who have suffered from enteric fever are examined in the Royal Naval Hospital on three occasions to prove their freedom from infection. When workers who have contracted tuberculosis are certified free from infection, employment is found for them in the open air or in large airy workshops. Dr. M. ASTON KEY (Portsmouth) praised the Dock-yard arrangement whereby half the men employed were taken on permanently, thus taking away the awful shadow of the "sack." Excellent canteens are provided. It was a serious mistake for men living far away to scurry home to their meals midday; the extra time spent in rest was of distinct value.

Tropical Medicine.

Presiding over the Tropical section, Dr. J. B. CHRISTOPHERSON (London) discussed in his address motives in dress. Men's dress, owing to outdoor pursuits, and the necessity of defence against enemies, had developed principally along the lines of protection and utility; with women adornment had always been almost the entire motive. But the average woman would not be able to stand the tropics unless she clothed herself for health, convenience, and utility. Dr. G. CARMICHAEL LOW (London) hoped that the biochemical tests recently devised for the diagnosis of climatic bubo would be more widely used in order that their value might be determined.

State Medicine.

Presiding over the Section on State Medicine, Prof. H. R. KENWOOD emphasised the importance of the maintenance of adequate nutrition to keep up the resistance of children to infectious disease. Dr. C. KILLICK MILLARD (Leicester) proposed an improved and extended application of Mr. E. D. Simon's suggestion of rent allowances for children. To pay for these, Dr. Millard proposed that the rents of municipal houses should be increased all round by, say, 1s. 6d. a week. Additional sources of money would be a lodger tax and a tax on all children who were earning and living at home. He contends that such a scheme could be made self-supporting. The new Housing Bill (No. 2) by providing for differential rating would enable some such scheme to be adopted with local modifications. Dr. C. O. STALLYBRASS (Liverpool), in his paper on variation in virulence in the course of epidemics, said that modern tendencies had been to discount the importance of variations in the pathogenicity of the organism. He took diphtheria as a crucial example in which death was due to the potency of the diphtheria bacillus and not of the secondary invaders. Dr. Stallybrass adduced statistical, clinical, and bacteriological evidence that the diphtheria bacillus had varied in potency in the course of recent epidemics both in Liverpool and Czechoslovakia. In Prague Drs. Feierabend and Schubert had found that in strains of bacilli from fatal diphtheria in which antitoxin therapy had failed, the potency of the bacillus was increased. Investigation was required not only of each disease, but also of individual epidemics. Dr. R. J. BLACKHAM (London) called attention to the therapeutic value of lactic acid milk powders in the feeding of infants. Sir BRUCE BRUCE-PORTER (London) pleaded for the institution of honorary librarians in hospitals.

Tuberculosis.

In the Section on Tuberculosis Sir HENRY GAUVAIN (Alton) expressed his belief that healing resulted from constantly changing conditions of intensity of sunlight; abundance of sunshine was often not desirable

in debilitated patients at the beginning of treatment. Dr. O. BERNHARD (St. Moritz) confessed to an uneasy feeling about placing patients with surgical tuberculosis among patients with the open pulmonary or laryngeal form of the disease; they were, he thought, more susceptible to droplet infection than the healthy. Dr. JAMES WATT (Godalming) suggested that slight cases of pulmonary tuberculosis whose career might be damaged by having been to a sanatorium, should be treated in a special ward at a convalescent home. Dr. JANE WALKER (London) who, she said, makes a point of employing delicate servants, finds that after they visit the local tuberculosis officer it is very difficult to get them to do any work; tuberculosis officers should not perpetuate the evils of the sanatorium. Councillor S. W. BEALES (Grimsby), finding it difficult to carry on the work of a tuberculosis care committee without a fund, had tried various ways of acquiring money, and had discovered that dances at dance halls, arranged on the 50-50 basis, were a fruitful source of income.

Industrial Hygiene.

Sir THOMAS OLIVER (Newcastle-upon-Tyne) presided over the Section on Industrial Hygiene. Dr. W. J. O'DONOVAN (London), after emphasising the multiple nature of cheiropompholyx, complained of the strenuous desire of patients and approved societies that panel and works' doctors should certify any dermatitis of the hands as due to occupation; county court juries are apt to look upon contrary medical evidence as hired perjury. Dr. PROSSER WHITE (Wigan) gave an interesting communication on sensitisation in the diagnosis of the traumatic dermatoses which should be studied in the unabbreviated form. Dr. H. M. VERNON (Industrial Health Research Board) dealt with warming by the panel system of low temperature radiation. Concealed hot-water pipes and electrical heating by means of insulated wires embedded in plaster in the ceiling had been used for some time; a more recent method was to pass a current through a zig-zag ribbon layer of graphite material embedded in the lower side of fire-clay plates suspended 10 feet above the floor.

Mosquito Control.

A visit was paid to the British Mosquito Control Institute on Hayling Island. Here for ten years Mr. J. F. Marshall has been carrying on scientific work to help local authorities and private individuals to exterminate biting mosquitoes in this country. British mosquitoes comprise 26 species—three anophelines and 23 culicines; about three-quarters of these species bite, especially at night in hot, stuffy weather. Five species breeding in fresh water are common, the others are rare. In most inland places six species of mosquito are found; at the seaside the number is brought up by the addition of two other species which breed in salt water. The seaside is worse than inland for two other reasons—mosquitoes breed better in salt water; these salt-water mosquitoes can fly further than fresh-water species. In view of the forthcoming visit of the British Medical Association to Winnipeg, it is of interest to know that a strenuous anti-mosquito campaign is being carried out there.

The amenities of Southsea with its open common and pleasant gardens, the view of a sea crowded with its liners, yachts, and battleships, the harbour, and the forts, contributed largely to the success of the Congress.

ST. BARTHOLOMEW'S HOSPITAL, ROCHESTER.—This hospital last year admitted 2038 in-patients who cost £8 0s. 8d. each. The 9521 out-patients cost 7s. 1d. each. The reconstruction of the out-patients' department, including a separate casualty department with theatre, and an enlarged X ray department, will be completed during the present year. There was a deficit in 1929 of £2338, which brings the total debt on the general maintenance fund to over £14,000.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Ideal and the Real in Public Health.

THE Governor of New York, Mr. Franklin D. Roosevelt, has announced the appointment of a special health commission to study the public health law and to make an appraisal to determine the possibility of a more effective application of the latest results of scientific research in preventing disease and conserving health. In making the announcement, the Governor quoted from the speech of Dr. William H. Welch delivered at the recent celebration of his eightieth birthday in Washington: "While public health is the foundation of the happiness and prosperity of the people and its promotion is recognised as an important function of government, how wide is the gap between what is achieved and what might be realised; how inadequate is the understanding of the public concerning the means adopted to secure the best results." Mr. Roosevelt said that it was his intention to reduce this gap.

The chairman of the new commission is Dr. Livingston Farrand, the President of Cornell University. He is supported by a very strong commission composed not only of prominent medical men such as Dr. Linsly Williams and Dr. Simon Flexner but also by lay experts in public health administration and successful business executives. The commission is charged to submit "any conclusions and recommendations which it may deem wise relating either to the legislative or administrative aspects of public health."

Prevention of Blindness.

On May 24th the Leslie Dana Gold Medal, which is awarded annually in recognition of "the most outstanding work in behalf of prevention of blindness," was presented to Dr. George E. de Schweinitz, of Philadelphia. The presentation address was made by Dr. Franklin Royer, medical director of the National Society for the Prevention of Blindness, which has just published its fifteenth annual report. Its efforts now seem to be very largely directed to removing the handicap of defective vision. Forty-five sight-saving classes have been inaugurated during the year, making a total of 350 such classes now in existence, in 95 cities of 21 States. Through the use of large type books, movable desks, ideal lighting, and special teaching methods children with visual defects are given a full education and at the same time learn how to conserve their remaining sight. The Society estimates that approximately 5000 such classes are needed. To train teachers for this work special courses will be given during the coming summer term at various universities.

A Competition for Cities.

The awards are announced of the first annual health contest sponsored by the U.S. Chamber of Commerce. The 108 competing cities were divided into five classes according to population, and the five winners are Milwaukee, Syracuse, N.Y., East Orange, N.J., White Plains, N.Y., and Sidney, Ohio. The primary object of this competition was to assist in reducing economic losses in the United States due to unnecessary illness and death, through the activities of local chambers of commerce or similar associations in cooperation with their official health agencies. The ratings were based upon the answers to a fact-finding schedule, copies of which were sent to the health officers of the contesting cities. The main factors considered in grading were the organisation and equipment of local health departments; financial support of health work, both official and voluntary; facilities for health information and education; water-supply; milk-supply; sewage disposal; and health laws and ordinances. The United States Chamber of Commerce hopes to continue the contest from year to year. From the local standpoint this offers a helpful yardstick for

the measurement of actual accomplishments with the possibility of gaining national recognition and is of special benefit in enlisting the interest of the leading business interests in promoting efficient city health administration.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

B C G.

IN Ujpest, a factory town adjacent to Budapest where hygienic conditions leave much to be desired, there is a considerable death-rate from tuberculosis. About two years ago, encouraged by the good results obtained with Calmette's vaccine, Dr. Rudolf Dvorcsák, senior physician of the tuberculosis dispensary of the Social-Political Institution, began to give it to selected infants in the town. Only those children were chosen who undoubtedly lived in an infected environment, and could easily contract the disease. Of several hundred infants treated five or six have died with manifest tuberculosis. In one case where both father and mother were tuberculous the six eldest children are alive, whereas the seventh, who received B C G, has succumbed to a virulent infection. Although the medical staff of the hospital and dispensary never suggested that these deaths were caused by the vaccine, the lay press, on hearing of the Lübeck fatalities, has given ear to unauthorised rumours and has alarmed the Hungarian public by asserting that the five or six fatal cases at Ujpest were due to B C G. Dr. Dvorcsák states resolutely that this is not so, and that Calmette's vaccine has proved efficacious in very many cases under his control. He is going to report to the Royal Medical Society, but meanwhile the use of B C G. has been discontinued.

Compulsory Baths in Poland.

The Polish Chamber of Deputies will shortly consider a new Bill on obligatory bathing. The object of the Bill is to enforce bathing on people who have no bathrooms in their houses, and for the time being the law will only run in cities and towns where there are bathing establishments. It is proposed that the Government should put up bathing plants in the smaller towns and large villages, so that poor people will have access to bathing during the winter months. They will have nothing to pay for their bath excepting soap and towel, which they may bring themselves. The public health magistrates will employ controllers to supervise the bathing booklets, each of which will contain 12 tickets to be used within three months. Exemption from bathing will be granted to people suffering from infectious or contagious diseases, skin troubles, tuberculosis, &c. It is not without interest that party politics has managed to raise objection even to such an obviously useful Bill. Certain opposition papers say that the soap trust has paid the Government to introduce it, and argue that it violates personal freedom since nobody should be forced to bathe when he has no mind to do so.

GLASGOW HOSPITAL FOR SICK CHILDREN.—In 1929 3359 patients were admitted to this hospital, which Dr. J. F. Fergus, President of the Royal Faculty of Physicians and Surgeons of Glasgow, described at the annual meeting as having gained "a European and almost a world-wide reputation." They came from every part of Scotland and were all under 15 years of age. Of the 29,000 children under 5 who annually join the Glasgow schools, 85 per cent. suffer from decayed teeth, 6 per cent. from rickets, 5 per cent. from enlarged tonsils, and 2 per cent. from discharging ears. The directors appeal for a research fund of £20,000 to investigate the causes and best means of preventing and curing the diseases of infancy and childhood. The corporation of Glasgow has granted the hospital exemption from parochial and education rates in virtue of the powers recently acquired from Parliament.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

The following are 1929 statistics of two county boroughs, one borough, and five urban districts. All the reports refer to the exceptionally severe epidemic of influenza, which increased the mortality from respiratory diseases in varying degrees.

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1-5 yr.) mortality.
Sunderland C.B. (184,000)	22.3	17.0	1.54	1.36	4.6	2.1	109/33	105
Eastbourne C.B. (58,570)	11.0	13.5	0.65	1.83	2.9	2.5	53/20	29
Edmonton U.D. (73,547)	17.6	10.8	1.17	1.20	2.0	2.4	62/—	23
Worcester C. and U.D. (52,320)	15.0	15.3	0.84	1.89	3.3	3.2	60/22	29
Pontypridd U.D. (45,320)	17.8	12.4	0.86	1.06	2.0	2.4	67/35	—
Bentley-with-Arksey U.D. (16,320)	18.5	10.2	0.86	0.55	2.6	1.2	119/—	—
Margate B. (29,580)	14.2	13.0	0.74	1.65	1.6	2.1	46/—	—
Ilfracombe U.D. (8,906)	14.0	14.6	1.01	1.34	2.6	4.6	56/—	—

Registered stillbirths per 100 live births:—Sunderland 4.1, Edmonton 3.6, Worcester 4.2, Pontypridd 8.0, Bentley-with-Arksey 3.6, Margate 3.2.
C.B. = County Borough. B. = Borough. U.D. = Urban District.
C. = City.

Sunderland.

Dr. A. S. Hebblethwaite gives a photograph and plan of the 20-bedded pavilion which has been added to Grindon Sanatorium, and was opened by the Duke of York on Oct. 31st. This brings the accommodation for surgical tuberculosis in children up to 50. The new pavilion has six two-bed cubicles and two four-bed wards. The maternity and child welfare scheme has been extended by the institution of two new infant welfare centres in outlying districts and one new antenatal centre. There are now four antenatal clinics, including one at the maternity home, for mothers, who intend to be confined in that institution. The births numbered 4111, and 1463 women attended the antenatal clinics. The medical functions of the board of guardians are to be dealt with by the public assistance committee for a period of 12 months, after which the health committee will deal with these transferred medical services. During the transition period the medical officer of health will act as medical officer to the public assistance committee.

The housing problem remains unsolved, although much renovation work has been done. During the year 410 new houses were erected as compared with 725 in the previous year. Overcrowding notices cannot be followed up owing to the lack of alternative accommodation. The measles death-rate was the highest since 1909. The deaths numbered 151, of which 25, 69, 27, 15 and 10, occurred during the first to the fifth year of life respectively. Deaths of children under two years from diarrhoea and enteritis were also high, giving a rate of 21.2 per 1000 births

as compared with 8.1 in England and Wales. As shown in the table, the death-rate from respiratory diseases with influenza was unusually high, and 424 deaths were ascribed to pneumonia, giving a death-rate from this cause alone of 2.3. Of the 424 pneumonia deaths, 108 were those of infants, 90 occurred in the second year of life, and 54 at the age-period 2 to 5. An attempt is being made to raise funds for the establishment of a central institution for the radium treatment of cancer, but up to the present the response to the appeal has been disappointing. Both hospitals, however, have agreed to increase their facilities for the earlier detection and earlier admission of cancer patients.

The water-carriage system has now been generally adopted and extended to the area added in April, 1928. There is only one swimming bath in the town, and better facilities are needed. The chief smoke offenders in the borough are laundries, breweries, public baths and washhouses, and small vertical boilers connected with locomotives or travelling cranes at the North dock; the latter are a nuisance to the seaside resort of Roker. The 14 houses in the Newcastle-road area, which are "all electric," with the exception of one coal fire in the living room, continue to be satisfactory to the tenants. A certain amount of difficulty is found in enforcing the orders made under recent Acts for informing the purchaser of the country of origin of produce. The chief difficulty appears to be the liability of fruit labels becoming displaced. There are now only 381 cows kept in the borough, and among these the veterinary inspector discovered two which were giving tuberculous milk. Of 106 samples of outside milk examined biologically, three were found to be tuberculous.

Eastbourne.

Dr. W. G. Willoughby reports that the birth-rate was the lowest on record, and that there were 151 more deaths than births. The council has continued its policy of allotting municipal houses only to persons with families. Since 1921 houses have been built at double the pre-war rate, and the population is better housed. Nevertheless there are still nearly 200 instances where the council could have good tenants and very considerably improve existing uncomfortable conditions. A feature of the year 1929 was the end of the hut-dwellings. The last was vacated in January and the site is now practically covered with permanent dwellings. The huts were a boon when adapted in May, 1919, but became a burden by 1926. There are now 795 municipal houses and 18 more in course of construction. The council have accepted a number of unsatisfactory tenants with children, and comparatively few have failed to repay this consideration.

The births in the borough numbered 643; of these, 221 took place in the municipal maternity home and 84 extern cases were attended by the midwife from the home. The antenatal clinic at the home was attended by 318 expectant mothers. General practitioners are invited to use this clinic for their patients, and did so in 110 instances. There were no maternal deaths attributed to childbirth in the borough, but one maternal death unconnected with maternity occurred in the home from acute nephritis and heart disease. The municipal home-help is paid a salary of 35s. per week, and attended 48 homes for household duties in maternity cases, and eight homes for the relief of expectant or nursing mothers or mothers with children ill.

Edmonton.

Dr. H. W. Harding doubts if his urban district gets its moneys' worth from an expenditure of £10,000 annually on the Enfield and Edmonton Joint Isolation Hospital. Scarlet fever is so mild nowadays, and when epidemics do occur there is a tendency to overcrowd the wards and cause return cases. The majority of the fatal cases of diphtheria are doomed before admission because they come in too late. During epidemics the hospital cannot accom-

modate carriers because there is no room, and the virulence of diphtheria and the presence of carriers, especially nasal carriers, appear to go hand-in-hand.

The council has an arrangement for maternity beds at the North Middlesex Hospital, and is responsible for fees at the rate of 6s. per day, which are collected from the patient before admission. The admission order is signed by Dr. Margaret Outram, who is in charge of the antenatal clinic, and sees each case before admission. The council patients admitted during 1929 numbered 19, of whom 9 paid for themselves and 10 were assisted by the council to the extent of £33 14s. The births numbered 1209, and 164 women made 833 attendances at the antenatal clinic. Two motor ambulances for non-infectious cases are run by the fire brigade, and carry a Novita resuscitating apparatus, which has been used successfully in cases of gas poisoning and drowning. The brigade also keep a bedside oxygen apparatus which can be obtained by local doctors at a cost of 5s. per cylinder. Dr. Harding records with pleasure that building operations in the district have lessened the facilities for the encampment of van-dwellers.

The new schools are a great improvement on the older ones. A new school is shortly to be erected and on the same site an open-air school, which will accommodate not only cases of malnutrition but also physically defective and partially blind children. In 1928 there was a plague of flying beetles which was thought to be due to migration caused by the exhaustion of the natural food of these insects, which are carnivorous in habit. The plague did not recur in 1929. The arrangement made with the guardians for the treatment of rickets and marasmus by ultra-violet rays at the North Middlesex Hospital at a cost of 1s. per exposure, has been continued. Sixteen cases are reported as cured, but 26 discontinued treatment against medical advice. Dr. Outram makes a special report on the cases treated at the centres with irradiated milk. Good results are claimed. The cases included 28 nursing mothers, 3 debilitated mothers, 9 expectant mothers and 29 "toddlers," and two sets of twins. The "Sun-ray"—Scheidl's Cold Process-Milk was used, and the Foodstuffs Irradiation Co., Ltd., helped by providing free sun-ray milk for necessitous cases. The Express Dairy Co. provided the milk at a cost of 3d. per half pint, and in no instance was more than half a pint given daily.

Worcester.

Dr. Mahyn Read in his thirty-ninth report says that better housing of the poorer citizens is still the most urgent of the problems in the city, and goes on to refer to the great changes by the removal of the worst of the slums during his 39 years' term of office. Overcrowding, he says, as a factor inimical to good health, is second only in importance to insufficient food. Of the 268 council houses erected during 1929, 80 have been allotted to overcrowded families, but there are still 107 overcrowded families on the register. The majority are in poor circumstances, and more houses at a rental not exceeding 7s. per week are needed. The city has many old houses and crowded courts, and the only new application under the Housing (Rural Workers) Act, 1920, could not be entertained because the alterations involved a sacrifice of light and air.

The new small-pox hospital on the site of the old City Hospital has been completed, and provides excellent accommodation for the city and the adjacent area of the county. The treatment of the city water-supply by chlorine has been a great success. The refuse-tips of the city have again proved a nuisance to adjacent houses. One has been closed in consequence, and the others are to be periodically sprayed, but Dr. Read points out that it is necessary to deposit the refuse in smaller layers and to keep the tips covered with a sufficient quantity of earth. The Cash captive bolt pistol is in general use for stunning cattle and calves before slaughter at the public slaughter-houses, and at the

22 registered and one licensed private slaughter-house, and the slaughtermen would not like to go back to their old methods. The meat regulations are well observed. Many of the local butchers do a large retail trade in the villages and hamlets in the county, and one firm has a fleet of motors fitted with hooks, glass shutters, and electric light, wherein to display their goods. Two retailers and a wholesaler were fined for selling sausages containing sulphur dioxide without declaring the presence of a preservative. In the last annual report (see THE LANCET, 1929, ii, 570) the difficulty experienced in discovering the offending cow of a herd of 21, which was giving tuberculous milk, was described. Ultimately, in August, 1929, a cow with udder tuberculous from this herd was slaughtered at the knackers' yard.

An ancient city like Worcester is specially liable to rat-infestation, and the rat campaign is continued. All the year round, and not only in rat week. The report to the Ministry of Agriculture shows that wire-cage traps are largely used. Examples are given of the capture of 24 and 18 live rats in single cages in one night. During "rat" week the first prize was won by a ratcatcher with a total of 48, and the second with 44. One ratcatcher held a post-mortem upon a doe-rat, and found she would shortly have had a litter of 16.

Pontypriid.

Dr. A. G. M. Severn describes his district as typical of the distressed coal-mining area of South Wales. There has been an increased supply of free milk through the maternity and child welfare scheme and the schools. For the 12 months ended March 31st, 1930, £945 was spent, as compared with £380 in the previous year on milk and foods supplied through the centres. There are 8940 children on the school registers, and 606, or 6·8 per cent., were granted milk and biscuits on the recommendation of the school medical officer. This again is an increase on the previous year. The scheme for discovering the cases of malnutrition among the scholars is described. All children are weighed before beginning school meals and again at intervals of three months. The scheme has been much facilitated by the school teachers' help. The low-lying part of the town was flooded in November and December, owing to the unprecedented rainfall. The total fall for the year was 59·41 inches, and of these 28·63 fell in November and December. Effectual relief measures were adopted. There is still a shortage of working-class houses, but the 40 municipal houses built during the year, and the additional 40 sanctioned will do much to alleviate overcrowding. Mr. C. L. Saies, formerly part-time, has been appointed full-time dental surgeon, thus improving the dental service of both welfare centres and schools. A new health centre is to be erected, which will provide accommodation for all the usual clinics, with ultra-violet light, ionisation, and increased facilities for orthopaedic treatment. In referring to the unusually high maternal mortality, Dr. Severn mentions that facilities have been provided for hospital treatment, specialists' consultations, and for free supply of antiserum to medical practitioners desiring it. One of the nine childbirth-deaths was assigned to sepsis and eight to "other causes." The Public Health and School Medical Services are well coordinated, and the pre-school children are effectively followed up from infancy up to school entrance.

Bentley-with-Arksry.

Dr. A. B. Dunne shows that the "all causes" death-rate of 10·2 becomes 12·0 when standardised. Measures have been taken to prevent the recurrence of flooding in the Bentley moor district. The council has erected about 800 houses since the war. They are of a good class, of brick, built usually in pairs, and not more than 12 to the acre. Each house has a good-sized garden. The dirty and verminous tenant, says Dr. Dunne, has not been so much to the front as in previous years. There are about 270

cows in the district, and amongst these one was found to be giving tuberculous milk, while six were slaughtered on account of pulmonary tuberculosis and three on account of tuberculous emaciation. One case of small-pox was notified. The rash appeared on April 19th; the patient was delivered of a child on April 22nd; no one suspected small-pox until April 28th. The woman bore no signs of vaccination. The baby was born apparently healthy, but subsequently developed the disease and died. Neighbours and young children had been freely in and out of the house, but no secondary cases occurred—an illustration, says Dr. Dunne, of the very slight infectivity of this type of small-pox.

Margate.

Dr. Rowan McCombe says the population at the height of the season exceeds 100,000. There are four midwives in practice, two being municipal. The latter are paid by salary, and earn the greater part of it in fees. Dr. McCombe considers the very small cost to the ratepayers is amply justified. Extensions of the water-supply and sewerage system are in progress, and the arrangements for the discharge of the sewage are so satisfactory that "no trace of sewage has been seen on the Margate foreshore for very many years." The erection of a total of 356 municipal houses has alleviated the housing problem, but there is still a demand for small houses that could be let at an inclusive rent of not more than 12s. per week. A considerable number of underground rooms are used for sleeping during the summer months. The rainfall was only 16.85 inches during 1929, whilst the hours of bright sunshine were 1942.4.

Ilfracombe.

Dr. D. C. Adam says the population during the height of the season is about 40,000. One of the events of the year was an outbreak of diphtheria, chiefly affecting the scholars in Standards 1 and 2 of Hermitage School. There was no reason to suspect milk. There were 50 cases in all, mostly in the month of March. There had been five cases of diphtheria in December, 1928, traceable to a carrier, and Dr. Adam thinks that he found another carrier to connect the December cases with the March outbreak. One case proved fatal—a boy of 7, who died of heart failure on the tenth day of the disease. Owing to the shortage of houses many poor families are paying exorbitant rentals for rooms in houses constructed for the use of one family. The public abattoir has been reconstructed and enlarged, and the new buildings were formally opened on August 29th by Sir Robert Gower (Chairman of the R.S.P.C.A.). A description of the new building is given. There are also three private slaughter-houses near the centre of the town, "and their presence in such situations is very undesirable." Of the 860 cattle slaughtered and inspected only 21 showed evidence of tuberculosis, and "this exceptionally low percentage" is thought to be due to the youth and quality of the cattle slaughtered, and the fact the animals, owing to the mild climate, are only housed for a very short period during the year. The rainfall for the year was about 45 inches, and the hours of bright sunshine 1748.3.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

MAY 31st, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 327 (last week 304); scarlet fever, 1939; diphtheria, 1088; enteric fever, 73; pneumonia, 975; puerperal fever, 52; puerperal pyrexia, 99; cerebro-spinal fever, 11; acute poliomyelitis, 4; acute poliomyelitis, 1; encephalitis lethargica, 15; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 97. No case of cholera, plague or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 3rd–4th was as follows:—Small-pox, 449 under treatment, 15 under observation (last week 462 and 13 respectively); scarlet fever, 2016; diphtheria, 2266; enteric fever, 25; measles, 712; whooping-cough, 77; puerperal fever, 26 (plus 17 babies); encephalitis lethargica, 121; poliomyelitis, 1; "other diseases," 18. At St. Margaret's Hospital there were 14 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 48 (14) from measles, 5 (2) from scarlet fever, 24 (5) from whooping-cough, 32 (8) from diphtheria, 37 (9) from diarrhoea and enteritis under two years, and 29 (4) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred at Sunderland. Five deaths from measles were reported from Warrington; not more than 2 from any other great town. Liverpool reported 6 deaths from diphtheria and 5 from diarrhoea.

The number of stillbirths notified during the week was 307 (corresponding to a rate of 43 per 1000 births), including 68 in London.

BLOOD CULTURE IN DIAGNOSIS OF ENTERIC INFECTION.

To the Editor of THE LANCET.

SIR,—To Dr. Eustace Thorp's further remarks (in your last issue, p. 1235) on enteric and the Widal test I should like to add some remarks of my own. The Widal agglutination test is an estimation of antibody formation on the part of the patient, either in response to actual infection by *B. typhosus* or *paratyphosus*, or as the result of prophylactic inoculation with a vaccine of these organisms. In the early stages of enteric infection there is probably present in all cases a bacillæmia, which is accompanied by a leucopenia—indicating an inhibition of the hæmopoietic centres as a result of this blood infection.

(1) In one group of cases this bacillæmia, either on account of a mild type of infection, or a good resistance on the part of the patient, may be transitory, and in such a satisfactory antibody response and a positive Widal reaction develop comparatively early.

(2) In a second group the infection may be more intense, or the patient's ability to respond less satisfactory with the result that antibody formation is delayed and the Widal reaction only obtained from the blood serum later than the normal time.

(3) In a third group of cases, either on account of the intensity of the infection or the total lack of an immunising response on the part of the patient, and in spite of definite clinical evidence of a typical typhoidal infection, a fatal issue may result without the appearance in the blood serum of a positive Widal reaction.

Frequently in such cases a blood-count estimation showing the presence of a leucopenia and a deficiency in the polymorph response may be as definite a sign of typhoidal infection as the Widal reaction. But in all three groups of cases the earliest and most helpful test is a blood culture taken into sterile bile. Three to five c.cm. of blood (with sterile precautions) are introduced in 10 c.cm. of bile, and the recovery of the infecting organism, whether typhoid or paratyphoid, is usually obtainable within 24 hours.

In three recent cases of pyrexia of four to five days' duration, in which a typhoidal infection was suspected but where there was little clinical evidence to support the diagnosis, the bile blood culture in each case gave such a positive result. In one case for typhoid, and in the other two for paratyphoid B, and in each case a Widal was not positive from seven to ten days subsequent to the definite diagnosis having been made by this means.

The technique is in no way difficult, and the bile easily sterilised and kept on hand for such emergency use, and this

is a method one feels should be used more promptly and in all suspicious cases of typhoidal infection. Ordinary broth cultures, although occasionally successful, are not nearly as reliable as the simple bile blood culture above referred to, probably because a certain degree of agglutination of the organisms present in the cultures takes place during incubation of the blood, and prevents satisfactory growth, while in the bile culture through a physical alteration of surface tension, agglutination is prevented and growth of the infecting organism if present is encouraged.

(4) A fourth group of cases are those in which relapse occurs after the development of a definite Widal reaction through some intercurrent depression of the patient's resistance, or the development of an ecphy-lactic focus, reinfection of the blood stream takes place accompanied by marked reduction or disappearance of the Widal reaction, which may later again develop. During this period of relapse the blood culture may again be found positive, and the condition thus proved to be a real typhoid relapse and not due to a secondary septic infection.

The Widal reaction must obviously depend not only upon the virulence of the infecting organism, but perhaps even more upon the ability of the patient to produce a satisfactory immunity response, and this will account for the variable findings which have been recorded, and which do not justify the conclusion that the Widal test as such is unreliable, but that the patient's immunity responses to a definite infection cannot be guaranteed, for without the development of protective agglutinins in the patient's serum the test cannot give a positive result. A marked positive Widal after 10 to 14 days' pyrexia indicates a satisfactory prognosis as far as the typhoid infection is concerned, although it gives no guarantee that secondary infection may not develop, or an intestinal perforation or hemorrhage occur. A mild and delayed Widal reaction in a severe case of infection probably gives evidence of a less satisfactory prognosis from a typhoidal point of view.—I am, Sir, yours faithfully,

E. CRONIN LOWE, M.B.E.

Liverpool, June 6th, 1930.

THE MECHANISM OF PULMONARY COLLAPSE.

To the Editor of THE LANCET.

SIR,—Dr. Watson-Williams's quotation from "All Quiet on the Western Front" has an interesting bearing upon the nature of pulmonary collapse. Experience in surgery of the chest indicates three facts:—

1. When one side of the chest is *opened freely*, as for the removal of an osteo-chondroma of the ribs, the lung collapses momentarily but is blown out forcibly to the chest wall with every expiration, the later expansions being more distinct than the first.

2. When *dissection* of a thickened pleura is done for chronic collapse of the lung, provided that the incisions are numerous, cross-cut, and deep enough to reach the reddened surface of the lung proper, the cuts open up as spaces, followed by expansion of the lung in proportion to the thoroughness of dissection.

3. When *decoritication* is performed (a more serious and sanguinary operation) the decoriticated lung comes up to the surface like a piece of soft red sponge.

The inherent tendency is for the exposed lung to expand or be blown out to the chest wall.

I am, Sir, yours faithfully,

THOMAS CARWARDINE.

Clifton, Bristol, June 6th, 1930.

FATAL AND MEDICINAL DOSES.

To the Editor of THE LANCET.

SIR,—In an annotation last week (p. 1240) entitled "The Object of a Pharmacopoeia you note a very unsatisfactory position in regard to drugs producing general anaesthesia—namely, that the effective anaesthetic doses of the drugs in use are more than 50 per cent. of the fatal doses, "a smaller margin of safety

than with any other class of important drugs." In the case, however, of at least one anthelmintic this unenviable record is completely broken. For carbon tetrachloride whose structure and pathological effects are similar to those of chloroform, the fatal dose is 1.5 c.cm.; while the dose advised as effective and used in tens of thousands of hookworm infections is 3 c.cm., or twice the fatal dose! This advised dose has naturally killed a varying proportion of those who have taken it. Further, it has been freely administered without troubling to discover whether any particular recipient was infected, in which case it remains unknown whether individuals so sacrificed should have been treated at all. We were next confronted with the statement that such herd treatment, which used double the minimum lethal dose and which had killed, had justified itself because with a minimum of trouble it had much reduced the worm load of a community. Those who receive herd treatment are certainly among the lowly, yet no advocate of such treatment has contended that they should be held no higher than cattle. Surely they should receive no treatment without previous diagnosis, and unless it is based on that humane principle of close attention to the fatal dose which your annotation, justifiably but wrongly, assumes to be always and everywhere accepted by medical men.—I am, Sir, yours faithfully,

Eating, W., June 7th, 1930.

CLAYTON LANE.

AREA OF PRIMARY INVOLVEMENT IN PULMONARY TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Hanan's letter in your last issue, there appears to be no doubt that several different opinions have been expressed as to which portion of the lungs is first affected in pulmonary tuberculosis. In my experience, there appears to be a difference in the two sexes, definite signs appearing first more frequently on the right side in males and on the left in females. Some years ago I took out figures in respect of 1232 sputum-positive cases, and after eliminating 152 instances in which it was impossible to decide which lung was more extensively affected. I found that 59 per cent. of males showed more advanced disease on the right side when first examined and 61 per cent. of females on the left side. These figures refer to the days before X ray facilities were available locally, and I am proposing to take out further figures relating to X ray films only. I am convinced that there is a definite difference according to sex.

I am, Sir, yours faithfully,

W. H. DICKINSON.

Newcastle-upon-Tyne, June 7th, 1930.

DISCOVERY OF BLOOD GROUPS.

To the Editor of THE LANCET.

SIR,—In your issue of May 3rd (p. 977) S. C. Dyke reviews the history of the discovery of the blood groups in a way which inadvertently does such injustice to the discoverer of the groups that I am sure Dr. Dyke will himself welcome a correction of the mistake.

Dr. Dyke states that "the first steps towards the identification of the blood groups were made by Landsteiner," and further, that "the existence of certain differences in the blood of human beings, differences which enabled them to be classed into four groups, was discovered and reported independently in Europe by J. Jansky and in America by W. L. Moss." The facts are that Landsteiner, in 1900, reported his discovery of the three more common groups, at the same time correctly recognising the underlying serologic constitution of the different bloods and pointing out the significance of his findings

¹ Landsteiner, K.: Wien. klin. Woch., 1900, xiv., 1132.

with respect to blood transfusion. Shortly thereafter, Decastello and Sturli,² the latter a co-worker of Landsteiner, with Landsteiner's permission, continued the study and they reported, in 1902, the existence of the fourth group. Landsteiner's review in Oppenheimer's *Handbuch* (1908-09) briefly describes the four groups. Jansky's study, reported in 1907, was undertaken merely with the purpose of seeing whether there was any special relationship between the blood groups and neuropathology; no such relationship was found, and Jansky simply numbered the groups in the order of their frequency, contributing nothing further to the general knowledge of the blood groups. Moss, in 1909-10 reached the mistaken conclusion that the blood groups depended upon three pairs of iso-agglutination elements.³ He numbered the groups without reference to frequency, and pointed out the difference between his numbering and that of Jansky. He referred to Landsteiner's original paper but omitted mention of the report by Decastello and Sturli and of Landsteiner's review. Von Dungern and Hirschfeld, in 1910, confirmed Landsteiner's logical conclusion regarding the serologic constitution of the different bloods and made the important discovery of the inheritance of the agglutinable substances A and B. Upon Landsteiner's suggestion, made through the Committee on Blood Groups of the National Research Council, the designation of the groups by letters has been adopted by important societies in this country and by the United States army and navy.

I am, Sir, yours faithfully,

ARTHUR F. COCA, M.D.,
Formerly Chairman of the Committee on Blood
Groups of the National Research Council.

June 7th, 1930.

THE POSITION OF THE MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—During the next two weeks the Society of Members of the Royal College of Surgeons of England will circularise all Members resident in the United Kingdom and Ireland soliciting a postal vote on the question of some representation of the Members on the Council of their College. Having regard to the great amount of work and expense entailed thereby, it is earnestly hoped that all Members will respond promptly and thus make their views known.

I am, Sir, yours faithfully,

ERNEST E. WARE, President.

60, Welbeck-street, W., June 10th, 1930.

VICTORIA PARK HOSPITAL.—Last year the City of London Hospital for Diseases of the Heart and Lungs treated 11,982 patients at a cost of £37,714. Of these 1094 were in-patients who stayed on an average 53 days, and their weekly average cost was £3 9s. 4-50d., an increase of 5s. 6d.

EPHING FOREST HOSPITAL.—The Marquis of Carisbrooke recently opened extensions to this hospital which have cost £9000. The enlargements include a ward as a memorial to the late Lord Lambourne, provided by the Freemasons of West Essex, who raised £2000 for the purpose.

SHEFFIELD AMBULANCE SERVICE.—Last year the Sheffield ambulances carried 31,000 patients and travelled 134,000 miles. It is complained that the number of ambulances is insufficient; at present there are six. In future persons of opposite sexes are not to be carried in the same ambulance.

Obituary.

JOHN BUCKLEY BRADBURY, M.D., F.R.C.P.,
DOWNING PROFESSOR OF MEDICINE, CAMBRIDGE.

THE death took place at Cambridge on Wednesday, June 4th, of the veteran Downing professor of medicine who was personally known to three generations of Cambridge medical students.

John Buckley Bradbury was a Yorkshireman, who received his education at King's College, London, whence he entered Gonville and Caius College, Cambridge. But while an undergraduate there he migrated to Downing where he obtained a science scholarship, and was eventually placed in the first class in the Natural Science Tripos in 1864. He completed his medical curriculum, and spent the whole of his academic and professional life in Cambridge. Over 60 years ago he was elected physician to Addenbrooke's Hospital, and for more than 30 years he superintended the medical training of students at Downing, while at Caius he was a lecturer on subjects ancillary to medicine. He was appointed Downing professor of medicine in 1894 on the resignation of the late Dr. P. W. Latham, and was by far the oldest man in the University of Cambridge to hold professorial rank. He was also the senior Fellow of the Royal College of Physicians of London where he became a Fellow in 1874, and served on the Council; he delivered the Bradshaw lectures in 1895 on the pharmacology of the vasodilators, and the Croonian lectures in 1899 on hypnotics. These lectures were the foundation of a volume, published shortly afterwards, on the treatment of sleep and sleeplessness, a subject which he made particularly his own. He acted as an examiner in medicine both at Oxford and Cambridge, and at his own University as an examiner in the Natural Science Tripos. He was one of the best known inhabitants of the city, and was devoted to the interests of Addenbrooke's Hospital to which institution he was physician for 50 years—viz., from 1869 to 1919, when he became consultant. He gave for many years clinical demonstrations in the hospital, while he lectured in his official capacity mainly on therapeutics.

Prof. Bradbury was twice married, first to Sarah, daughter of Mr. James Openshaw, and secondly to Jane, daughter of the Rev. R. Gwatkin.

HARRY COOPER PATTIN, M.D.CAMB., D.P.H.,
LATE MEDICAL OFFICER OF HEALTH, NORWICH.

WE regret to record the death of Dr. Cooper Pattin, lately medical officer of health for the city of Norwich and an ex-president of the Society of Medical Officers of Health, which occurred at Torquay on May 30th.

Harry Cooper Pattin received his medical education at Jesus College, Cambridge, and St. Thomas's Hospital, and graduated in medicine at Cambridge in 1890, having taking the double diplomas of the English Conjoint Board a year previously. His whole professional life was spent in Norwich, and for 33 years he had charge of the public health of the city, where his scientific qualifications and his great social gifts were equally recognised. Norwich is a city medieval in history and in much of its architecture, and modern in its developments and amenities, so that a man who could hold a public position for so long a period, while secure in the approval and support of official authority and popular esteem, may be said to have proved himself a practical success. Cooper Pattin was a great medical officer of health. The structural transformations in the old yards and courts, and the institution of special hospitals, which were brought about by the town council of Norwich and its health committee by Cooper Pattin's organisation, were reflected in remarkable improvements in the health of the city, but they could not come into being without much interference with vested interests,

and it required a man of his energy and integrity to make the reforms acceptable. When he retired from office four years ago he was able to quote figures showing remarkable improvements in death-rate and mortality and to hand on a successful health department which had practically been created by himself.

In private life Cooper Pattin was a man of high culture, a good judge of music and painting, a versatile and sometimes brilliant writer, a witty public speaker, and throughout his life a great traveller.

JOSEPH BIRT, M.R.C.S. ENG., L.R.C.P. EDIN.,

ANÆSTHETIST TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON.

ON May 20th last Dr. Birt, the well-known anæsthetist died, at the age of 67, and his death has been the occasion of our receiving an extraordinary testimonial to his character and worth from his intimate fellow workers.

Joseph Birt was educated at Brighton College, intending to become an engineer, but he entered the medical profession at the wish of his mother and joined the medical school at St. George's Hospital, whence he qualified as M.R.C.S. Eng. in 1886. He later acquired the L.R.C.P. Edin. in 1887 and for a time worked at the Sussex County Hospital. He then established himself in general practice at Uckfield, where he quickly earned the confidence and esteem of a large range of patients, rich and poor alike. He himself attributed to the late Mr. Pickering Pick, who had perceived his professional qualities and ability, the encouragement necessary to enter medical practice in London, and ten years later he established himself in the neighbourhood of St. George's Hospital, became medical officer to the Royal Pimlico Dispensary, and soon gathered round him an extensive practice to whom his personality made a particular appeal.

We owe to Mr. Tyrrell Gray, one of Birt's colleagues at Great Ormond-street, the following account of how this successful general practitioner, already in middle age, developed into a fine exponent of a difficult speciality. "In his search for some field of usefulness to his country during the war," says Mr. Gray, "Joseph Birt, with rare insight, decided that, at his age, anæsthetics offered him the best opportunity to help. His genius in this speciality was so quickly recognised that he was not only appointed anæsthetist to seven hospitals, but was unofficially co-opted to numerous hospitals to deputise for absentees in emergency. As a result his services were everywhere available both day and night, for refusal never occurred to him, and there is no doubt that his unflinching and willing response to every request for his services (both during the war and subsequently) was responsible for the long and intermittent illness which ultimately led to his death. But it was at Great Ormond-street that everyone realised his extraordinary flair for anæsthetising children and babies. There his colleagues quickly appreciated that study, knowledge, and experience could not alone be responsible for that outstanding command of a child's confidence which he invariably displayed. His gentle and affectionate disposition, together with the innate love of and compassion for anything young (especially in suffering)—these were the qualities which inspired the trust and affection of all children with whom he came in contact; and these were essentially the qualities which won him his special niche at Great Ormond-street. In the profession he will be remembered for his pioneer work in anæsthetising children—particularly for the standardisation of gas and oxygen anæsthesia as the method of choice for Rammstedt's operation. Living with his sister in a contented simplicity, he will be remembered by his colleagues as the embodiment of the dignified courtesy of a past age; for his love of everything young and beautiful; for a sense of humour which never hurt any feelings; and for his devotion to Great Ormond-street Hospital, where he could usually be found on Sunday morning playing with the children.

In his daily life he impoverished himself by his indiscriminate generosity though this never occasioned him any regrets—indeed, he was not conscious of it. One or other of these characteristics is reflected in all of the numerous letters written by patients and friends. To quote from three of them: In one: 'Such a personality can never die'; in another: 'He must be somewhere on ahead, waving an encouraging hand'; or again: 'I think he knew more of all our troubles than anyone.'

We have received from the surgical staff and the senior anæsthetist at the Children's Hospital individual letters setting out the reasons for the esteem with which they regarded Joseph Birt, to whom they one and all attribute the personality which is brought before us by Mr. Tyrrell Gray. The affection which this good man inspired among all he came in contact with was truly remarkable.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

WHITSUNTIDE ADJOURNMENT.

ON Wednesday, June 4th, the House of Lords adjourned for the Whitsuntide recess until Tuesday, June 17th. The House of Commons adjourned on Friday, June 6th, until the same date.

HOUSE OF COMMONS.

WEDNESDAY, JUNE 4TH.

Tuberculosis (Calmelle Treatment).

Mr. FREEMAN asked the Minister of Health whether the Calmette prophylactic treatment in regard to tuberculosis which had been followed by the death of 10 infants in Lübeck, Germany, was being advocated or employed in this country with the permission or under the instructions of the Ministry of Health.—Mr. GREENWOOD replied: The answer is in the negative. I may, however, add that the Medical Research Council has been engaged since 1925 in investigating the statistical and bacteriological evidence relating to this treatment and I am kept informed of their researches. I am informed that two representatives of the Medical Research Council have gone to Germany to obtain further information concerning the deaths at Lübeck.

Psychotherapeutic Treatment.

Mr. MANDER asked the Minister of Health the number of beds available in this country for cases receiving psychotherapeutic treatment.—Mr. GREENWOOD replied: Psychotherapeutic treatment is available in the normal course at many institutions under the jurisdiction of the Board of Control for such patients as are likely in the opinion of the medical staff to benefit from it. But beds are not specially set aside for such cases in these institutions.

Insanitary Conditions in London Boroughs.

Mr. GOULD asked the Home Secretary whether he had now received any report respecting his investigations in certain London boroughs arising out of the report prepared by Mr. A. D. Denning; and what steps he proposed to take regarding it.—Mr. CURRIE replied: I have now received a report which covers 67 factories and workshops, including all classes and sizes of works, and gives detailed particulars as to the actual conditions. Its general effect is to confirm the opinion previously expressed that Mr. Denning's report gives a very exaggerated account. While poor or bad conditions were found in some half-dozen cases, about one-half of the whole number are definitely reported as good, and the remainder reached on the whole a satisfactory standard. Action has already been or is being taken to bring the conditions in every case into conformity with the Act, and I propose to call for a further report in due course as to the results of this action. I also propose to communicate a copy of the report to the Joint committee of the industry for whom Mr. Denning's report was prepared, and shall be glad to consider any observations they may wish to make.

Extensions to East Ham Isolation Hospital.

Sir ASHSTON POWELL asked the Minister of Health whether he had recently sanctioned a loan to the East Ham town council for extensions to the local isolation hospital;

and, if so, what was the amount sanctioned.—Mr. GREENWOOD replied: I sanctioned on May 19th loans amounting to £40,663 to the East Ham town council for extensions to their isolation hospital.

Grading of Milk.

Dr. VERNON DAVIES asked the Minister of Health if his attention had been drawn to the recommendation of the Council of Agriculture for England that the grades of new milk recognised under the Milk (Special Designations) Order, 1923, should be altered—viz., that Certified should be altered to extra special, Grade A (T.T.) to special, and Grade A to standard; and, seeing that the standard milk for this country would thus be the lowest grade milk, that it was not produced from tuberculin tested cows, and that the new designations were not self-explanatory to the consumer, what action, if any, he proposed to take with regard to this recommendation.—Mr. GREENWOOD replied: I have received a copy of the report embodying the recommendation to which the hon. Member refers. I will consider the recommendation as well as the hon. Member's criticism, but I cannot contemplate the introduction of legislation on this subject in the immediate future.

Ultra-violet Ray Treatment.

Viscount ELMLEY asked the Minister of Health whether there was any provision made for the treatment of National Health Insurance patients by means of ultra-violet rays; and, if so, by whom the cost was borne.—Mr. GREENWOOD replied: Any question whether in a particular case this form of treatment is within the scope of medical benefit has to be decided in accordance with Article 43 of the Medical Benefit Regulations, and the method of payment depends upon the decision so arrived at.

Smoke Abatement By-laws in London.

Mr. D. G. SOMERVILLE asked the Minister of Health which authorities in the London area had made by-laws under the Smoke Abatement Act, 1926.—Mr. GREENWOOD replied: Seventeen local authorities in the Greater London area have made by-laws under this Act. The following are their names: Town Councils of Acton, Croydon, Kingston-upon-Thames, Leyton, and Richmond (Surrey); Urban District Councils of Brentford and Chiswick, Finchley, Hampton, Hayes, Heston and Isleworth, The Maudslays and Coombe, Mitcham, Surbiton, Wembley, and Willesden; Rural District Councils of Epsom and Hendon.

Certification of a Mental Patient.

Mr. GOULD asked the Minister of Health if he was aware that a lady, M. H., was placed in Camberwell House on the petition of her husband in December, 1903; that this lady was discharged in August, 1920, but was debarred from taking legal action against the doctors who certified her, owing to the Statute of Limitations, which required such action to be taken within six years of certification; and whether he would introduce legislation to prevent persons in such cases being deprived of redress on such grounds.—Mr. GREENWOOD replied: I cannot properly comment upon an individual case, but I understand that the effect of a decision in the House of Lords is as stated by my hon. friend. I cannot, however, undertake at present to introduce legislation on the point.

Exchequer Grants to Voluntary Societies.

Mr. DAY asked the Minister of Health the total amount of Exchequer grants of all kinds paid to voluntary societies in England and Wales to maternity and child welfare, welfare of the blind, and tuberculosis for the 12 months ended to the last convenient date.—Mr. GREENWOOD replied: The grants paid to voluntary societies in England and Wales in respect of the services mentioned during the year ended March 31st, 1930, were as follows: Maternity and child welfare (including grants for the training of midwives and health visitors), £264,354; welfare of the blind, £124,007; treatment of tuberculosis (paid to the Welsh National Memorial Association), £112,190.

Factory Inspectors and Cancer Research.

Mr. PHILIP OLIVER asked the Home Secretary whether, and to what extent, the medical inspectorate of the factory department had been able to assist in the investigation at present being carried out by the London Cancer Hospital into the incidence of the disease of cancer of the bladder among workers in aniline factories; and whether and to what extent the Registrar-General had been able to supply the statistical information required for the investigation.—Mr. CLYNES replied: The precise manner in which the Factory Department could best assist in this investigation has been explored, and it was decided that they should co-operate more particularly in tracing, so far as is necessary and practicable, the exact occupations of persons who have

died of cancer of the bladder. For this purpose the Registrar-General is extracting information from his records, and the first Return is, I understand, practically ready. As I have warned the hon. Member, the research is a complex and difficult one, and I am afraid it is impossible to forecast when we may expect any conclusive results.

Diagnosis of Silicosis.

Mr. HOPKIN asked the Home Secretary if he was aware that the late Thomas Davies, of Gorslas, Carmarthenshire, was certified in June, 1920, by his family doctor to be suffering from silicosis and was a few weeks later declared by the medical referee not to be suffering from silicosis; that in April, 1930, the post-mortem examination showed that he died from silicosis; and that at the inquest the verdict was returned in accordance with the medical evidence—viz., that Thomas Davies died from silicosis; and if he was now prepared to change Order 975 so as to obviate the effects of such mistakes to the miner or his dependants.—Mr. CLYNES replied: I have received reports on this case, and the facts appear to be as stated in the question. I am advised that, owing to the presence of the condition known as anthracosis, the diagnosis of the disease in this case would, during the workman's lifetime, be one of peculiar difficulty, and the case affords a very good illustration of the need for improved medical arrangements by the setting up of an expert Medical Board for the whole country as recommended by the Departmental Committee. I am seeking to obtain the necessary powers for this purpose in the Workmen's Compensation (Silicosis) Bill which is now before this House, and which I hope will be proceeded with immediately after the Recess, and I can assure my hon. friend that as soon as the Bill becomes law steps will be taken to establish the new medical organisation with the least possible delay.

Experiments on Living Animals.

Mr. FREEMAN asked the Home Secretary whether he was aware that experiments upon living animals had been conducted at the physiological laboratory, Cambridge, by Mr. B. H. C. Matthews, the purpose of which was to measure pain; what species of animals were used in this investigation; and under what certificates were the experiments conducted.—Mr. CLYNES replied: I have made inquiry into the circumstances. The purpose of the experiments was not to measure pain, but to measure electrical impulses, and they were not performed on living animals. No licence is necessary for this, and Mr. Matthews does not hold one.

FRIDAY, JUNE 6TH.

Pensions and Conditions of R.A.M.C. Officers.

Lieut.-Colonel FREMANTLE asked the Secretary of State for War (1) if he was aware that whereas combatant officers' pensions had increased in value since the war, the pensions of officers of the R.A.M.C. had decreased; that the pension earned by a major, R.A.M.C., at 20 years was now £368 per annum, which, having regard to the increases in income-tax and the cost of living was worth little more than half the pre-war rate of £365 per annum, fixed in the reorganisation of the Army Medical Service in 1902; and if it was proposed to reduce or increase this pension this year; (2) if he could give any undertaking that the maximum pension for a lieutenant-colonel of the R.A.M.C., attainable after 28 years' service, would not be further reduced from its present amount of £558; and (3) if he was aware that the officer strength of the R.A.M.C. was inadequate for requirements, resulting in the employment of civilian practitioners, and the re-employment of retired officers, all of whom did home service only, and that the average period of foreign service undertaken by regular officers, R.A.M.C., had increased in consequence; and whether, seeing that this prospect was bound adversely to affect the recruitment of young medical officers to the service, he would consider how these conditions of service could be improved.—Mr. T. SHAW replied: I have under my personal consideration at the present time the whole question of the supply of officers for the R.A.M.C. As regards the detailed information for which the hon. and gallant Member asks, last year special steps were taken to render conditions of service in the Corps more attractive. Certain concessions have been made regarding the counting, for purposes of promotion, increase of pay and pension, by officers appointed to permanent commissions in the Corps, of temporary service in the Corps, or of time spent in a civil hospital appointment. The Army Council are also in touch with civil hospitals at the present time to see whether arrangements can be made by which R.A.M.C. officers may be enabled to secure experience in civil hospital appointments. As regards retired pay, the retired pay of majors and lieutenant-colonels of the R.A.M.C. in receipt of post-war scales is subject, like that of other officers, to revision next year in the light of the cost of living figure. I cannot anticipate what the result of that revision will be.

Vaccination of Small-Pox Contacts.

MR. GROVES asked the Minister of Health whether he was aware that pyæmia, referred to in the death certificate of the infant which recently died from small-pox and pyæmia at the Joyce Green Hospital within five days after being vaccinated, was attributable to the operation of vaccination; and whether, in view of the fact that in this case and other similar cases there was strong ground for believing that vaccination after small-pox had commenced to incubate merely added to the patient's troubles, he would direct his medical officials to discourage as far as possible the vaccination of small-pox contacts. MR. GREENWOOD replied: If, as I assume, my hon. friend is referring to the case of Frank George Young, I am informed that death took place 25 days, and not 5 days, after the infant was vaccinated. I have caused inquiries to be made into the case, and am advised that the pyæmia referred to in the death certificate supervened on the small-pox, and that the death is not in any way attributable to the vaccination. As regards the second part of the question, I would refer my hon. friend to the answer given to him on this subject on April 3rd.

Medical News.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR M.B., B.S.

With Honours.—P. B. Ascroft (d), Middlesex Hosp.; Margaret E. Cook (b), L.S.M.W.; K. M. Robertson (a), St. Thomas's Hosp.; and Ursula Shelley (c), d) University Medal, L.S.M.W.
(a) Distinguished in Medicine. (b) Distinguished in Pathology.
(c) Distinguished in Forensic Medicine. (d) Distinguished in Surgery.

Pass.—E. F. D. Baker, D. A. Beattie, and A. C. H. Bell, St. Bart.'s Hosp.; J. R. Buchanan and C. W. F. Burnett, Univ. Coll. Hosp.; E. J. Butterworth, St. Mary's Hosp.; Charlotte A. G. Conway, L.S.M.W.; E. T. Conybeare, Guy's Hosp.; W. W. Craner, London Hosp.; H. B. A. R. Denham, Guy's Hosp.; D. C. L. Derry, St. Thomas's Hosp.; P. C. C. de Silva, King's Coll. Hosp.; F. B. P. Evans, Univ. of Birmingham; Rees Evans, Univ. Coll. Hosp.; S. N. Evans, Guy's Hosp.; E. M. Golstein, Univ. Coll. Hosp.; C. S. Gross, Guy's Hosp.; Ernest Grundy, Univ. of Leeds; A. G. Harsant, London Hosp.; J. C. Hatrick, Univ. Coll. Hosp.; J. J. Heather, Guy's Hosp.; H. B. Hodson, St. Thomas's Hosp.; A. S. Hoesason, St. George's Hosp.; C. C. H. Huss, St. Bart.'s Hosp.; Phyllis Hutchinson, King's Coll. Hosp.; John Ives, St. Mary's Hosp.; A. N. Jones, Guy's Hosp.; O. V. Lloyd-Davies, Middlesex Hosp.; Laura H. Macfarlane, L.S.M.W.; H. G. McGregor and B. R. Medycott, Univ. Coll. Hosp.; St. Thomas's Hosp.; C. L. Oakley, Guy's Hosp.; C. M. Oakwell, Guy's Hosp.; Ralph Oliver, Univ. Coll. Hosp.; R. A. H. Pearce, Middlesex Hosp.; G. F. Peters, Guy's Hosp.; R. K. Price, St. Bart.'s Hosp.; J. C. Pumphrey, Univ. Coll. Hosp.; D. R. Rann, St. Thomas's Hosp.; Henry Richards, Guy's Hosp.; Margaret P. Rosevear and R. M. Sargent, Univ. Coll. Hosp.; J. G. Scadding, Middlesex Hosp.; J. M. Scott, St. Bart.'s Hosp.; M. D. Sheppard, Univ. Coll. Hosp.; L. A. H. Snowball, King's Coll. Hosp.; Sybil Stamm, Guy's Hosp.; Brian Stanley, Univ. Coll. Hosp.; T. P. Steel, L.S.M.W.; W. D. Steel, Univ. of Birmingham; J. H. Watkin, St. Bart.'s Hosp.; Margaret M. White, L.S.M.W.; G. P. B. Whitwell, Guy's Hosp.; Joyce M. Wigram, L.S.M.W.; R. N. Wilcox, St. Thomas's Hosp.; E. W. Watkins, Middlesex Hosp.; and Margaret D. Wright, Univ. Coll. Hosp.

The following candidates passed in the undermentioned parts of the examination:—

Group I.—Frederick Back, St. Thomas's Hosp. and London Hosp.; E. F. Barnardo, Univ. Coll. Hosp.; G. L. Barnes, St. Bart.'s Hosp.; A. C. Byles, St. Mary's Hosp.; W. H. P. Cant, Univ. of Birmingham; Rosa E. Chamings, L.S.M.W.; E. E. Claxton, St. Bart.'s Hosp.; J. J. Croft, Guy's Hosp.; C. E. Dolman, St. Mary's Hosp.; Beryl M. Furlan, St. George's Hosp.; and Honor E. C. Harvey, L.S.M.W.; H. B. Jackson, Grace, and Honor E. C. Harvey, L.S.M.W.; H. J. Knight, St. Mary's Hosp.; Nellie I. Luckenau, Univ. Coll. Hosp.; I. W. Lazarus, London Hosp.; Annie M. McGrath, Westminster Hosp.; Joyce MacInnes, L.S.M.W.; Eileen M. Massey, King's Coll. Hosp.; Elizabeth M. May, L.S.M.W.; Ruth Milne, L.S.M.W.; Douglas Stanley Jones, St. Bart.'s Hosp.; H. H. Steadman, Guy's Hosp.; Muriel H. Steven, King's Coll. Hosp.; Olive G. Watkin, Charing Cross Hosp.; and T. H. Wilson, St. Thomas's Hosp.

Group II.—W. L. M. Bieby, Guy's Hosp.; Anthony Caplan, St. Bart.'s Hosp.; A. G. Carmichael, Middlesex Hosp.; J. D. George, St. Thomas's Hosp.; Brynley Griffiths, Univ. Coll. Cardiff, and Charing Cross Hosp.; Eric Gwynne-Evans, Univ. Coll. Hosp.; Mary W. Hamlyn, L.S.M.W.; P. Y. Hicks, St. Thomas's Hosp.; R. E. Holmes, London Hosp.; S. W. Holmes, St. Mary's Hosp.; Mohnaber, Luckenau, Univ. Coll. Hosp.; N. S. Mary L. Marsh, Charing Cross Hosp.; V. C. W. Nixon, St. Mary's Hosp.; A. P. M. Page, St. Bart.'s Hosp.; Oliver Plow-

right, Guy's Hosp.; D. C. Price, St. Bart.'s Hosp.; J. D. Ritchie, St. George's Hosp.; E. B. Rogers, Guy's Hosp.; Violet R. Sharp, L.S.M.W.; and T. S. Stone, London Hosp.

L.S.M.W.—London School of Medicine for Women.

At a meeting of the Senate on May 7th it was resolved to institute a university readership in biochemistry tenable at the London School of Hygiene and Tropical Medicine.

UNIVERSITY OF OXFORD.—Sir William Morris has offered to vest the Radcliffe Observatory site and buildings in the hands of a body of trustees, to be used for the benefit of the Radcliffe Infirmary and the Medical School of the University.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—On June 2nd Dr. Robert Grievie Hutchison and Dr. James Sharpe were admitted Fellows of Faculty.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—Mr. A. R. Melhuish, of London, has been elected president of this society.

MEDICO-LEGAL SOCIETY.—At a meeting of this society at 11, Chandos-street, London, W., on June 20th, Prof. J. S. Haldane, F.R.S., will read a paper on Carbon Monoxide Poisoning.

BIOCHEMICAL SOCIETY.—A meeting of this society is being held on Saturday, June 14th, in the department of biochemistry of the University of Oxford.

UNIVERSITY OF LIVERPOOL.—Dr. Walter Ramsden has resigned from the Johnston Chair of Biochemistry. His resignation will take effect at the end of the year.

Colonel Alfred William Sheen, C.B.E., and Lieut.-Colonel Sir Ewen John Maclean have been appointed Deputy Lieutenants for the county of Glamorgan.

HOSPITAL OF ST. JOHN AND ST. ELIZABETH.—A new wing of the nurses' home at this St. John's Wood hospital was opened last week. It is a memorial to the late Hon. Sir Charles Russell, who was chairman of the institution from 1919 to 1928. It has cost £15,000.

PADDINGTON MEDICAL SOCIETY.—A new regional medical society was inaugurated at a meeting held on June 10th at Paddington Town Hall. Dr. Howard Stratford took the chair, representatives were present from central medical associations, and apologies for absence were received from Dr. Christine Murrell and Dr. H. B. Morgan, M.P. for the borough. Dr. Julius Cohen, to whose initiative the society owes its origin, briefly outlined its aim which is to provide opportunity for the practitioners in the area to meet each other, to meet consultants away from the bedside, and to get to know the public officers of the health department and its associated clinics. It was intended not merely to register pious opinions but to discuss and agree upon medico-political questions of the day such as State medical service, contributory schemes, and the like. A constitution for the society was then adopted. Membership is open to all medical practitioners residing or practising in Paddington; six of the seven office-bearers must be actively engaged in medical practice in the borough itself. Dr. G. Swietochowski was then unanimously elected president, Dr. A. Balde vice-president, and Dr. Cohen hon. secretary and treasurer; after a card vote the four additional committee members chosen were Dr. W. G. Bendle, Dr. G. E. Oates (medical officer of health), Dr. R. G. Murray, and Dr. Isabella Stewart. Dr. Swietochowski, having been inducted to the presidential chair, outlined the future work of the society, making it clear that there would be no attempt to run counter to any existing group. The growing tendency within the medical profession, for better or worse, to become a branch of the civil service, made it essential, he said, to preserve a strong local organisation to act as a middle-man between the central authority and the individual practitioner. Paddington doctors would, he hoped, use the society precisely as the Romans treated their forum. At each meeting a 20 minutes paper would be read, and discussed; they would then pass to debate on current medico-political matters. At the close of the meeting most of those present enrolled as members. Meetings are to be held at 9 P.M. on the second Tuesday in the month at the Great Western Hotel, Paddington.

THE LANCET: SUBSCRIPTION RATES.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, June 17th.—5.30 P.M., Ballot for Election to the Fellowship.

THURSDAY.—5 P.M., DERMATOLOGY (Cases at 4 P.M.). Dr. W. N. Goldsmith: 1. Congenital Ichthyosiform Erythroderma in Mother and Son. 2. Case of Juvenile Spontaneous Bullae. Mr. Stanford Cade (Introduced by Dr. S. E. Dore): 3. Demonstration on Carcinoma of the Skin Treated by Radium. Dr. H. W. Barber: 4. Ichthyosiform Nævus. 5. Psoriasis. Dr. G. B. Dowling: 6. Urticaria Pigmentosa of Infantile Type Persisting into Adult Life. 7 and 8. Two Cases of Urticaria Ophryogenes (Unna). 9. Angioma Serpiginosum. Dr. Knowlesley Sibley: 10. Case for Diagnosis. Dr. S. E. Dore (for Dr. R. Oddie): 11. Case of Urticaria Pigmentosa. Other cases will be shown.

FRIDAY.—10 A.M., LARYNGOLOGY: Summer Meeting. Papers will be read by Dr. Douglas Crow, Dr. A. Brown Kelly, Dr. Dan McKenzie, Mr. W. S. Thacker Neville, Mr. E. Watson-Williams, and others. 5 P.M., Clinical Meeting. Cases will be shown by Dr. Norman Patterson, Dr. H. Bell Tayse, Mr. Mortimer Woolf, Dr. Dan McKenzie, Dr. E. A. Peters, Mr. J. F. O'Malley, Mr. Michael Vlasto, and others. The Annual Dinner of the Section with the Section of Otolaryngology will be held at the Langham Hotel, Portland-place, London, W., at 7.30 P.M. for 7.45 P.M. 8 P.M., OBSTETRICS AND GYNÆCOLOGY. Mr. A. J. Wrigley: Puerperal Infection by the Pathogenic Anaerobic Bacteria. Short Communications: Dr. H. K. Griffiths: 1. A Lithopedion. 2. A Short Account of a Pregnancy in one Horn of a Bicornate Uterus. Pathological Specimens: Mr. Eardley Holland: 1. A Case of Secondary Melanotic Sarcoma of the Placenta with Transmission of the Growth to the Fœtus; with specimens and drawings. 2. Six specimens of Recent Interesting Cases of Fibromyoma of the Uterus. Dr. J. Bamforth: 3. An Unusual Tumour of the Uterus. 4. Early Carcinoma of the Endometrium. 5. Endometrioma of the Abdominal Wall. Dr. Ivens Knowles: 6. Recurrent Melanotic Sarcoma of the Clitoris. Other specimens will be shown.

SATURDAY.—DISEASE IN CHILDREN: Annual Provincial Meeting at Norwich.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, June 19th.—8.15 P.M., General Meeting; preceded by a Demonstration at 7.45 P.M. to illustrate a paper by Dr. N. Hamilton Fairley: Spruce—its Applied Pathology, Biochemistry, and Treatment.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

TUESDAY, June 17th.—8.15 P.M., Professor de Quervain (Berne): Cretinism and its Relation to Thyroid Physiology. (Cavendish Lecture.) Reception at 7.45 P.M.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, June 17th.—5 P.M., Sir Charles Martin: The Thermal Adjustment of Man to External Conditions, more particularly those pertaining to Warm Climates. (2nd Croonian Lecture.)

THURSDAY.—5 P.M., Sir Charles Martin. (Last Croonian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, June 16th to SATURDAY, June 21st.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W., Special M.R.C.P. Lectures at 8.30 P.M., as follows: Tues., Dr. O. L. V. De Wesselow, Hypotension and Renal Disease; Fri., Dr. O. L. V. De Wesselow: Diabetic and other Acidoses. BOLINGBROKE HOSPITAL, Wandsworth Common, S.W.: Tues., 2 P.M., X Ray Demonstration by Dr. E. U. Williams. No fee. EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.: Wed., 11 A.M., Demonstration on Ear, Nose, and Throat Cases, by Mr. G. H. Howells. No fee. BLACKFRIARS SKIN HOSPITAL, Blackfriars-road, S.E. Afternoon Course. CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W.: Mondays and/or Afternoons. PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N.: Intensive Course in Medicine and Surgery. Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, June 16th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations. 4.30 to 5.30 P.M., Mr. H. W. Carson: Abdominal Pain in Children.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations. 4.30 to 5.30 P.M., Dr. J. B. Alexander: Various Forms of Treatment of Pulmonary Tuberculosis.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear clinics. Operations. 4.30 to 5.30 P.M., Mr. Aubrey Goodwin: The Use of Pessaries.

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M., Medical, Surgical, and Children's Diseases Clinics. Operations. 4.30 to 5.30 P.M., Mr. E. Gillespie: Surgery of the Stomach.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, June 16th.—12 noon, Dr. Greenfield: Cerebro-spinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Varieties of Peripheral Neuritis.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Spinal Tumours and Compression Paraplegia.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Gordon Holmes: Lesions of the Cerebellum.

FRIDAY.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of the Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Disorders of the Motor System.

Appointments.

CLARK, J., M.D., Ch.B. Aberd., D.P.H., has been appointed Deputy Medical Officer of Health, Sheffield.

PATEY, D. H., M.S., M.B. Lond., F.R.C.S. Eng., Assistant Surgeon to the Middlesex Hospital.

ROBERTSON, E. M., M.B., Ch.B. Glasg., D.P.H., Assistant Medical Officer of Health for Hyde.

TAIT, A., M.B., Ch.B. Edin., Certifying Surgeon under the Factory and Workshop Acts for the Markinch District of the County of Fife.

WALTON, W. S., M.B., B.S. Durh., D.P.H., Assistant Medical Officer of Health for the City and Port of Plymouth.

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital. H.P. £120.

Birkenhead County Borough.—Asst. M.O.H. and Bacteriologist. £750.

Birmingham, City of.—1st Asst. M.O. £600.

Birmingham, Midland Hospital, East-rose.—H.S. £150.

Blackburn Royal Infirmary.—Res. H.P. £175. Also 4th H.S. £150.

Brighton, New Sussex Hospital for Women and Children.—Hon. Asst. Ophth. S. Also H.P. £50.

Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.

Cancer Hospital, Fulham-road, S.W.—Pathologist. £850.

Cardiff, Cefn Mably Hospital, Michaelstone-y-Vedau, near Newport.—Asst. Res. M.O. £250.

Cardiff Royal Infirmary.—Res. Reg. £100. Cas. Surg. O., and H.S. to Ophth. Dept. Each at rate of £75.

Chesler, East Lancashire Tuberculosis Colony, Barrowmore Hall, Great Barrow.—Asst. M.O. £275-£300.

Cheslerfield and North Derbyshire Royal Hospital.—Cas. O. At rate of £200.

Colchester, Royal Eastern Counties' Institution for Mentally Defective.—Clin. Research Worker. £600.

Countess of Dufferin's Fund, Women's Medical Service for India.—Two Medical Women. 550 and 750 rupees per mensem.

Coventry and Warwickshire Hospital.—Res. Asst. H.S. £125.

Derby, Derbyshire Royal Infirmary.—Asst. H.S., and Cas. O. Also Ophth. H.S., and Res. Anæsthetist. Each £150.

Doncaster Royal Infirmary.—Hon. Phys. and Pathologist. £250.

East London Hospital for Children, Shadwell, E.—Dermatologist. Gloucester, Gloucestershire Royal Infirmary.—2nd H.S. At rate of £100.

Golden-square Throat, Nose, and Ear Hospital, W.—H.S. £100.

Great Farmouth General Hospital.—H.S. £150.

Halifax Royal Infirmary.—3rd H.S. At rate of £125.

Harrow Hospital, Harrow-on-the-Hill.—Surgeon.

Hertford County Hospital.—H.P. At rate of £150.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150.

Hull Royal Infirmary.—H.S. At rate of £150.

Hyde, Borough of.—M.O., &c. £800.

Indian Medical Service.—Commissions.

Ipswich, East Suffolk and Ipswich Hospital.—H.P. £120.

Islington Dispensary, 303, Upper-street, N.—Asst. Res. M.O. £220.

Leamington Spa, Warneford General Hospital.—Res. H.S. £165.

Lincoln County Hospital.—Jun. H.S. at rate of £150.

Liverpool, Royal Southern Hospital.—H.P. H.S. Also M.O. to Spec. Depts. Each at rate of £60.

L.C.C. Mental Hospital Service.—8th Asst. M.O. £445.

London Female Lock Hospital, 233, Harrow-road, W.—H.S. £150.

London Panel Committee, 17, Russell-square, W.C.—Organising and Asst. Med. Secy. £600.

London University.—Graham Scholarship in Pathology. £300.

Also Externship Examinations.

Manchester, Ancoats Hospital.—H.S. At rate of £100. Also Clin. Asst. for Ear, Nose and Throat Dept. 10s. 6d. per clinic.

Manchester, Baguley Sanatorium.—Asst. M.O. £350.

Manchester Ear Hospital, Grosvenor-square, All Saints.—Non-Res. H.S. At rate of £150.

Manchester Royal Infirmary.—Asst. Surg. O., and Asst. M.O. Each £35.
Manor House Hospital, Golders Green.—Jun. Med. Officer. £200.
Margate and District Venereal Hospital.—Res. M.O. £125.
Mount Vernon Hospital, Northwood, Middlesex.—Gynaecologist. Newark General Hospital.—Res. H.S. "At rate of £150.
Northampton General Hospital.—Asst. H.S. At rate of £150.
Norwich, Norfolk and Norwich Hospital.—H.S. £120.
Parley District Asylum, Riccarton.—Clin. Asst. £200.
Portsmouth Hospital.—Cas. O. At rate of £100.
Prinfors Onderstepoort Veterinary Research Laboratory.—Three Research Fellowships. £800-£1000.
Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. M.O. £200.
Queensberry Hospital for the East End, Stratford, E.—H.P.'s and H.S.'s. Each £120. Also H.P. and Cas. O. £150.
Queen's Hospital for Children, Hackney-road, E.—Res. M.O. At rate of £200. Also Asst. Physician.
Reading, Royal Berkshire Hospital.—H.P. Cas. O. Also Res. Anaesthetist. Each at rate of £150.
Richmond, Surrey, Royal Hospital.—Hon. Asst. Radiologist, Hon. Surg. and Hon. Asst. P. to Out-patients.
Rotherham Hospital.—Sen. H.S. £220. Also H.P. £180.
St. Bartholomew's Hospital, E.C.—Surgeon to Throat Dept. Also Asst. Physician.
St. Johns County Borough.—Asst. M.O.H. £600.
Salford Royal Hospital.—Hon. Asst. S. Also H.P., H.S., and Cas. H.S. Each at rate of £125. Also Anaesthetist. 1 gn per session.
Sheffield Children's Hospital.—3rd Res. M.O. £100.
Sheffield Royal Hospital.—Res. Anaesthetist. At rate of £80.
Sheffield Royal Infirmary.—Cas. £30.
Southark Hospital, East Dulwich-grove, S.E.—Med. Supt. £1200.
South Shields, Ingham Infirmary.—Sen. and Jun. H.S.'s. £200 and £150 respectively.
Southampton Borough Hospital.—Res. M.O. £275.
Southampton, the South, Havant and Southampton Hospital.—Sen. H.S. £225. Also Asst. H.S. £180.
Southport General Infirmary.—Jun. H.S. £100.
Surrey County Council.—Asst. M.O. £600.
Sussex County Borough.—Asst. M.O. £600.
Torquay Royal Cornwall Infirmary.—H.S. £170.
University College Hospital, Gower-street, W.C.—Hon. Anaesthetist.
Walsall General Hospital.—Cas. H.S. At rate of £120.
Warrington Hospital, Grove-road, Bolham, S.W.—Jun. Res. M.O. £150.
West London Hospital, Hammersmith, W.—Res. Asst. Phys. £300.
Weymouth and District Hospital.—H.S. £180.
Wigan Royal Infirmary.—Res. Med. and Surg. O. and Registrar £250.
Wilkes General Hospital, N.W.—Clin. Asst. to Surg. Out-patient Dept.
Winchester, Royal Hampshire County Hospital.—Sen. Res. M.O. £200. Also H.P. and H.S. Each £150.
Worcester General Infirmary.—Jun. Res. M.O. £120.

The Home Secretary gives notice of a vacancy for a Medical Officer under the Workmen's Compensation Act for the Districts of the Boston, Holbeach, Sleaford, Spalding, and Spillbury County Courts (Circuit 17). Applications should reach the Private Secretary, Home Office, Whitehall, London, not later than June 28th.

Births, Marriages, and Deaths.

BIRTHS.

CRISP.—On May 30th, at Oakham, Rutland, the wife of G. H. Crisp, B.M., B.Ch., of a daughter.
FELDEN.—On June 6th, 1930, at 28, The Drive, Hove, the wife of Frederick E. Felden, F.R.C.S. Edin.—of a daughter.
ROPE.—On June 2nd, at Quenby-place, Shrewsbury, the wife of Dr. A. D. Rope, of a daughter.

MARRIAGES.

MACKENZIE-CAVE.—On June 3rd, at St. Andrew's Parish Church, Malahide, Co. Dublin, Kenneth Fitzgerald Mackenzie, M.B., B.S., F.R.C.S., to Miss Dorothea, only daughter of the Rev. Henry C. Cave, M.A., and Mrs. Cave, of the Rectory, Malahide, Co. Dublin.
ROTTIE-SCOT SKIRVING.—On June 7th, at the Parish Church, Cheltenham, Douglas James Rottie, M.B., B.S., F.R.C.S., to Miss Elizabeth, youngest daughter of Mr. and Mrs. E. Scot Skirving, of Kilehamon, Cheltenham.

DEATHS.

BRADY.—On June 4th, at St. Peter's-terrace, Cambridge John Buckley Brady, Downing Professor of Medicine.
CAMP.—On June 2nd, at Frouse, Snow Hill, Newport, Mon., Thomas Ignatius Candy, M.B., B.Ch., B.A.O., D.M.R.E., aged 38.
GER.—On June 2nd, at the Royal Northern Hospital, following an operation, Lieut.-Col. Ernest William Gee, I.M.S. ret'd., C.B.E., M.B., B.Sc., M.R.C.S., of Westmead, Cookham, Berks.
HAMMILL.—On May 30th, at Sydenham, suddenly, Donald H. Hammill, L.D.S., D.D.S., of Wimpole-street, W.
WAKEFIELD.—On June 6th, in the Robert Clark Wakefield, M.D., late of Maresbury-road, Bromsbury, aged 67.
WOOLDRIDGE.—On June 6th, at Camberley, Arthur Trice Wooldrige, M.R.C.S., L.R.C.P., L.S.A.
N.B.—A fee of 1s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Notes, Comments, and Abstracts.

ECONOMIC ASPECTS OF MEDICINE.

By LEONARD P. LOOKHART, M.D. CAMB.,
BARRISTER-AT-LAW.

THOSE who have watched the progress of social services since the war must have been greatly struck by Sir Arthur Keith's recent address to the Medical Society of London on the "Inexorability of the Law of Evolution as Manifested in Modern Medicine." While stating nothing that is not already accepted, Sir Arthur presented it to the reader in such a way that in his train of argument he exemplified that very law of evolution upon which he based his thesis. He comes finally to a conclusion, which from such a source cannot fail to prove arresting, that "we cannot escape State control on the long run." Certainly this may be the outcome of the series of events in which we are at now playing a part, but it would be fruitless to argue as to whether or no State control will ultimately prove beneficial to medical science because by the time it comes to fruition it will probably bear as much resemblance to our present conception of State control as the battle of Jutland bore to Trafalgar—a difference not only of degree but of kind. Our present conception of State control is dominated by the idea of an ever-increasing bureaucracy in Whitehall, but it is unlikely that the present system will expand indefinitely. Already it is becoming obvious that over-organisation is a malignant and ultimately fatal disease in any corporate body, so much so that in certain industries there is a tendency to organise small self-contained units in parallel rather than in series—a confederation of self-governing states rather than a centrally controlled empire.

The time factor in civil evolution is important, because it is evident from historical records that mere passage of time is not necessarily synonymous with progress, for in the sphere of civil and social growth the biological law is not by any means valid—violent retrogressions unknown in the animal world result from hasty and ill-considered forward rushes such as in nature never can take place—and it may be that Sir Arthur Keith has placed unwarranted confidence in the evolutionary value of time. Perhaps, after all, disintegration is as likely to be the outcome of our present system as continued integration, but no one would on that score presume to question Sir Arthur Keith's statement that the main feature of the law of evolution is its inexorability. One may, however, question the completeness of the analogy between physical and mental evolution, and there is at least a doubt whether the evolution of medicine and other social services is not liable to disintegrate the spirit of man and, even if such a setback should prove but temporary, the human mind is likely to seek some more trustworthy ladder of ascent once it has recovered its poise. At a time when the British Medical Association is presenting for criticism a policy for a general medical service for the nation, it may not be out of place to recall to the minds of our profession a point which is repeatedly lost sight of, and which has even escaped mention in Sir Arthur Keith's paper—namely, the interdependence of medicine and industry. Neither can exist without the other, and yet the intimate and vital connexion is so frequently lost sight of that disintegration at this very point might very easily prove the undoing of Sir Arthur's hypothesis.

Interdependence of Medicine and Industry.

Dr. Erwin Lick goes so far as to make a statement that Germany lost the Great War because the moral character of the nation had been undermined by the social insurance system. Supposing this statement to be no more than a mere personal opinion, it is at least one held in part by a great number of thoughtful persons in connexion with our own social system, and it follows that social insurance is at once a concomitant of evolutionary progress, and at the same time the very harbour of a disintegrating force, which is slowly sapping our moral fibre. It is clear that Sir Arthur visualises an idealised form of social service, while Dr. Lick only considers the uses and abuses of the present system, with a distinct bias towards the latter. It is probable that we have not yet learnt how properly to handle the social insurance problem, and that it is not the system which is at the root of the trouble but its faulty application. Misuse is by no means always intentional or negligent; more often than not it springs from a misconception, and it is impossible to avoid the conclusion that our profession as a whole is not adequately informed on the industrial situation as it affects not only the insured person but the nation as a whole. It needs but a little reflection for everyone to

realise the immense importance of a proper understanding of the inner workings of modern industry. We are without doubt in danger of producing an industrial population which is propped at every turn by social insurance, and unless everything possible is done to discourage excessive dependence on the props we shall find ourselves with a demoralised population and inevitable bankruptcy of the funds. A desire to use the funds as little as possible is essential in all insurance, and benefits should only be drawn on in emergencies, not at regular intervals as a prize for abstinence in the interim.

The American view on this matter is illuminating. It is widely held in the United States that wealth is not in industry, but that wealth is industry, and that every single thing which is given for nothing or in return for inadequate service is in effect so much actual poverty grafted on to the nation. Thus abuse of any system of insurance is wilful robbery of other people's livelihood and high treason against the State.

Abuse of the Insurance Principle.

A common form of abuse is exemplified by the additional benefit for ophthalmic treatment. A patient breaks his or her glasses or desires a newer type of frame, whereupon, withholding information regarding existing appliances, he asks some doctor (any doctor will do) for a certificate to the effect that the condition of his eyes is prejudicial to his health. A patient recently refused a certificate by the writer retorted that she had not "had anything out of the insurance for six years!"

A medical man who exercises his judicial function over certification in this and other matters stands to lose at the hands of disgruntled patients, and in an age of extensive certification for a multitude of purposes it is a matter serious enough to call for some form of protection for the doctor, for the economic pressure is great. If no benefit could be drawn except by the production of a certificate on a form previously obtained by the patient from the approved society or other interested body, and if every doctor who felt it his duty to refuse the certificate was called on to note that fact on the form it would be impossible for any other medical man subsequently approached to reverse that decision in ignorance of the previous refusal, and the spectacle of one medical man set off against another would be avoided.

On the other hand there is often a failure by the doctor to realise to the full the import of certain very innocent looking words when used on certificates. "Fit for light work" often causes a lot of trouble, because the patient knows full well that in modern industry the provision of light duty is, except in rare and isolated cases, next to impossible. There is not enough light work for 2 per cent. of any large staff; the reason being that in heavy industries there is little really light work, and in the big repetitive workshops there is a minimum of really heavy duty. A certificate bearing the words in question often means that a patient considers himself far worse than he really is, because his idea of light work and the doctor's are quite different. Many doctors still think in terms of coal, iron, and steel, and forget the enormous growth of light repetitive processes. Heavy work is being increasingly performed by machinery, and in the coming age of machine-tenders light work and ordinary work are very nearly synonymous terms. The team organisation of mass production prevents much individual laxity in hours for the convalescent employee, so that to-day one is either fit or unfit, and there is a tendency in certification to err on the side of excessive safety. An inside knowledge of local industrial operations is invaluable for arriving at a right decision.

The Off-work Neurosis.

A determined effort by the profession to eliminate from certificates, except in cases of absolute need, the words "nerves, neurasthenia, anemia, depression, cardiac debility, weak heart, &c.," would go a long way towards reinforcing that aspect of psychotherapy—suggestion—which is invaluable to the convalescent. There is a definite "off-work" neurosis, and it is certain that many patients wait for their doctors to suggest their ability to work, and that symptoms psychological in origin persist until that suggestion comes, but the doctor defers the urge to work because of the continuing symptoms. There is a danger, too, of our encouraging a tendency to introspection among young people when we allow them to become unduly preoccupied over conditions which are in the main environmental, and for which work is the best cure. Our social insurance has saved an immensity of suffering, but in the elimination of suffering may we not lose something of our moral fibre? It is on our shoulders that the responsibility will lie. Too many ailments, from chapped hands to constipation, are ascribed to occupation, and certificates given to this effect, often by certifying surgeons. The result in many cases is that employees lose their jobs because they are too expensive to keep, and the risk of a recurrence too great. Modern industry is the nation. We must help it, and not be always hampering it with restrictive charges which ought not to be placed on it. The Workmen's Compensation Act is a great measure of

social welfare, but it is a two-edged sword, and many employees have reason to doubt its beneficial action.

When our profession and the courts of law begin to take a wider view of this matter it will be possible to take steps to give better employment to the cripples and the partially disabled. At present restrictions and the threat of legal action make it essential for wise employers to select only the most physically fit. In this way the less fit are left in idleness or in the lower grades of employment, and any chances they might have of raising themselves and their offspring to higher levels are permanently dashed, to the great disadvantage of the nation. Old age pensions at 65 and the new proposal to raise the school age, even with its attendant costs and immoral maintenance allowance, both have good features, but they are not unmixt blessings, and though both are in reality an attempt to square the fall alike in birth- and death-rates with the passing phase of under-employment they both levy a toll of industrial victims.

Fair Play to Industry.

Industry is still looked on as a stalking horse. Big corporations fail to get justice in the medical man's mind merely because they are big and supposedly rich, but the margin between profit and loss under present-day conditions is often very small, and industry can only survive, prosper, and pay wages if everything is done to assist it to perform its function. Out of industrial profits our profession is supported directly and indirectly, and our social advances depend on the ability of industry to pay. Therefore we must not look on the industrial worker as one who is always in need of protection from his employer, and especially must we be on our guard against charging against the employer the costs of the ordinary risks of life—certifying them as occupational, and to that extent depleting the employing power of industry.

Every certificate is a fiduciary act, and can only be rightly given when all the facts are known. A wider inside knowledge of industrial and commercial procedure would enable our profession to render a service to British industry which would rank as a first-class measure of safeguarding.

SURGICAL NEEDLES.

To the Editor of THE LANCET.

SIR,—In view of recent correspondence in the press concerning the antiquity of the sewing needle, the following information may prove interesting to the readers of your journal. Mr. Harford Lowe, F.G.S., has investigated the use of the needle by primitive man in the Stone Age and has an enlightening theory that it may be considered as the lever which primarily lifted man above the condition of the brute.

The surgeon's needle can only be produced by old-fashioned hand processes owing to the large number of models designed to meet the special needs of modern surgery. This is undoubtedly well from the point of view of the surgeon as it ensures a degree of quality that only trained craftsmanship can give. Needles for surgical use devised from stone, ivory, and bone have been unearthed with collections of surgical instruments used by the early Romans and ancient Greeks, so one imagines that the Chinese, Japanese, and Egyptians during their development thousands of years ago must have fashioned needles from these same substances whether for some gorgeous embroidery to be worked, or the intricacies of a masterpiece in tapestry, or for the closing of a wound at a surgical operation in those pre-Lister days. So far as available records show it appears that the earliest steel surgeon's needles were made in the year 1810 by one Emanuel Shrimpton, whose son Emanuel in the year 1830 migrated to Redditch in company with other makers of various kinds of needles.—I am, Sir, yours faithfully,
June 6th, 1930. ACUS.

KING EDWARD'S FUND.

THE annual report of King Edward's Fund shows that the receipts for the last 12 months were £535,435, of which £115,000 represented the Thankoffering Fund for the King's Recovery. The ordinary distribution amounted to £250,000, and the special distributions brought the total expenditure to £378,000. Since the foundation of the fund in 1897 a total of £6,488,000 has been distributed. The year's expenses were £13,030—about 6½d. per £1 of the total received. The accompanying report of the Voluntary Hospitals (Parliamentary) Committee sets out the reasons for the clause in the Road Traffic Bill authorising payment to hospitals treating patients injured in motor accidents, and adds that "as the Bill provides that, by means of compulsory insurance, there shall be funds out of which legal charges for the cost of the treatment of such injured persons shall be met, it is equitable that provision should at the same time be made for meeting the cost of hospital treatment; and that it is reasonable that the cost of treating these cases should be borne by the insurance of motorists rather than by the funds subscribed by the charitable public for the support of their local hospitals."

Observations ON DIVERTICULITIS.*

By E. G. SLESINGER, O.B.E., M.S., F.R.C.S.,
ASSISTANT SURGEON TO GUY'S HOSPITAL.

DIVERTICULA of the colon were first described by Cruveilhier in 1849, and the first description in English was by Habershon, physician to Guy's Hospital in 1857, who published an excellent account of the condition as seen in post-mortem material. Guy's has a particular interest in this subject, for the first illustration of diverticula of the colon appeared in a paper by Arbuthnot Lane, published in *Guy's Hospital Reports* in 1855. In spite of these early and excellent accounts, however, it was not until some twenty years ago that the pathological and clinical importance of the condition came to be recognised, and it is only since the technique of radiographic examination of the colon has been perfected that the early stages have become known and its clinical features and appropriate treatment have been worked out.

Diverticula of the colon are very much commoner than is generally realised, and the figures from the Mayo Clinic show that they are to be found in roughly one person in every eight over the age of 45. Their commonest site is in the sigmoid, and in about 40 per cent. of cases they are confined to this region of the bowel. In a further 30 per cent. of the cases diverticula are found scattered throughout the colon, including, of course, the sigmoid, and in the remaining cases they are situated in the splenic flexure, transverse colon, cæcum, or rectum. The ascending colon is almost never involved. The important point to remember, however, is that the sigmoid is affected either alone or in association with other parts over 70 per cent. of cases; it is primarily as a disease of the sigmoid that we shall consider the matter to-day.

F. de Quervain and E. I. Spriggs independently have suggested that the term diverticulosis should be used to describe the mere presence of diverticula and that diverticulitis should be reserved for the cases with those additional inflammatory changes which are responsible for all the severe symptoms and complications which may ensue. The diverticula vary in size from almost microscopic dimensions to from 2 to 4 cm. in diameter, but they very seldom exceed that size. They occur in a part of the intestine which is usually loaded with fat, and frequently tend to grow into the appendices epiploice, with the result that in situ they are difficult to distinguish, and all that is visible is a tuberosus appearance of the bowel. When, however, the fat is stripped off, the diverticula are seen as typically bluish-black flask-shaped out-pouchings set roughly in two parallel rows. The blue-black colour is due to the fact that the mucosa and submucosa have herniated through the muscular wall and the colour of the fecal contents is seen through the thin wall. Usually a whitish strip or collar can be made out round the neck of the diverticulum which marks the limit of the muscular covering. The points in the circumference of the bowel at which the diverticula appear vary somewhat, but the commonest site is between the mesocolic and the antimesenteric longitudinal muscle bands, and as that is where the vessels pierce the muscular wall it seems probable that this point of entry of the vessels forms a weak point in the circular muscle layer.

The diverticula are usually full of fecal material and enlarge as more bowel content is forced into them, and as they do so they very often force their way into the appendices epiploice.

ORIGIN OF THE DIVERTICULA.

From the ætiological point of view the first point to consider is whether these diverticula are congenital or acquired. While occasional congenital diverticula do undoubtedly occur, there can be no doubt that the majority are acquired, as is proved by the fact that they almost invariably occur in middle and later life, while their development has often been watched for several years by X ray examination: 85 per cent. of a series of 100 cases examined by R. Mailer occurred between the ages of 40-70, and the condition is about twice as frequent in men as in women.

Spriggs and O. A. Marxer, as the result of careful radiological study, describe what they term a pre-diverticular state in which there is irritation and inflammation of the whole circumference of the bowel, and they believe that the hernie occur owing to damage to the muscle-fibres during this stage. There can be no doubt that diverticulosis is almost always associated with septic foci elsewhere—such as septic teeth, arthritis of the spine, or cholecystitis—which would provide a focus for infection. Other views of the cause of these hernie are that they are the result of the increased pressure resulting from constipation on a weak and degenerating musculature, or that they are due to weakness at the point of entry of the blood-vessels. R. Davies-Colley holds that they are the result of a muscle degeneration due to the pressure of an abnormal amount of fat round the colon, but Spriggs has shown that these patients are no fatter on the average than normal control patients, and many cases of diverticulosis have been found in thin and wasted individuals.

ORIGIN OF SYMPTOMS.

It is doubtful whether the presence of diverticula by themselves gives rise to any symptoms at all, except possibly those due to the hypothetical sigmoiditis which Spriggs suggests is responsible for their formation. The symptoms that do arise are due either to mechanical or to inflammatory changes in them.

The mechanical changes are the lodgment in the diverticula of fecal concretions. These gradually increase in size as more material is forced into the pouch from the constipated colon, and cases of so-called "pistol shot" perforation have been described by Murray where there is no inflammatory ulceration but where the concretion is forced through the thin-walled sac by the peristalsis of the bowel.

The inflammatory changes are, however, by far the commonest and most important, and may be either acute or chronic, while very frequently the case comes under notice because of an acute exacerbation of a chronic infection. In acute infections, which are very rare, the changes in the diverticulum are similar to those seen in acute appendicitis, and gangrene and perforation may ensue in a few hours, leading to generalised peritonitis.

Last year, in consultation with Dr. D. M. MacManus, I saw a woman of 65 who was quite well until 10 o'clock one morning, when she began to have severe pain in the left iliac fossa. This continued until noon when she had a collapse marked by sweating, fainting, coldness of the extremities, and a very feeble pulse. She rallied from this collapse, and when I saw her at 4 P.M. she had marked rigidity and tenderness of the lower abdomen on both sides, with pain more in the middle than it had been. I operated on her and found her peritoneum full of pus, and she had diverticulitis of the sigmoid with a perforation of one of the diverticula which was gangrenous at its tip. I closed this and covered it with fat, and instituted slow irrigation of the peritoneal cavity by means of Carrel tubes with saline, and she made a good recovery.

The commoner change is one of chronic inflammation which is associated with much thickening and rigidity of the bowel. The fat of the colon becomes coarse and granular, the mesentery is thickened and shortened, and the area of colon affected becomes hard and rigid and is very frequently mistaken for a growth on abdominal exploration. It is in the highest degree probable that the patients one sees

* Based on a lecture delivered at Guy's Hospital.

sometimes surviving for long periods after colostomy performed for growth of the sigmoid were really suffering from diverticulitis and not growth; for it is often impossible to tell the difference from the outside, and it is often difficult to do so even when the bowel has been opened.

As the result of this chronic inflammation there may be very various secondary pathological results, of which the commonest are peritonitis of varying grades—either generalised peritonitis, pelvic peritonitis, abscess formation, or the formation of adhesions to the bladder or small intestines or side wall of the pelvis where the adhesions not infrequently involve the iliac vessels and the ureter. Later still perforation of a diverticulum may give rise to fistulae of various types, of which the commonest is between the bowel and the bladder, though cases occur of fistulae communicating with other hollow viscera.

Diverticulitis is by far the commonest cause of vesico-colic fistula—a far commoner cause of this condition than is cancer. Such a fistula may be in the nature of a direct communication between a diverticulum and the bladder, or may take place by way of an abscess cavity formed between the bladder and the inflamed colon. It is an interesting fact that the presence of a hard tumour in the bowel, accompanied by the passage of gas and faeces per urethram, is in the great majority of cases due to diverticulitis, yet when one sees these cases the tendency to make a diagnosis of cancer is very strong indeed. Although this fact is well recognised by all those who have studied this condition, there are still many patients who are denied the opportunity of surgical relief owing to the diagnosis of cancer being made, so that I want to lay stress on this point.

CLINICAL VARIETIES.

When we come to consider the clinical features of diverticulitis we find a variety of picture depending on the stage of the disease with which we are dealing. As in so many other diseases, a good deal of confusion arises from the fact that the first cases to be described were late cases, cases with complications, and that for a long time the clinical picture was based entirely on these late cases. Symptomatology is probably the department of surgery which needs a complete overhaul more than any other. It needs an overhaul which will disentangle the symptoms of the disease from those of its results, and which will enable us to diagnose conditions capable of repair without having to wait for resulting destructive lesions to give us the so-called typical symptomatology. Cholecystitis and duodenal ulcer are two of the conditions which have been successfully rescued from this muddle of symptomatology, so that we can now diagnose them successfully without waiting for their complications, and consequently treatment, both medical and surgical, can be carried out with reasonable hopes of success because irreparable damage has not yet been done. To return to the question of diverticulitis, it should be and is possible to diagnose this condition in the early stages, and when that is done treatment is usually very successful. In any patient over the age of 40 who complains of discomfort in the lower part of the abdomen, and especially in the left iliac fossa, associated with constipation, irritability of the bladder, and occasional attacks of slight pyrexia, diverticulitis must be thought of as a probable diagnosis. In such a case there is nearly always tenderness in the left iliac fossa or over the pubis, and there may be thickening of the iliac colon or a definite tumour in this region. Examination by a competent radiologist will confirm the diagnosis.

In the later cases a variety of symptoms are present, and they can be grouped roughly into three types, according to the locality and extent of the inflammatory spread—namely, the inflammatory type, the obstructive type, and the genito-urinary type. In the first group acute inflammatory attacks may occur which are very similar to those of appendicitis, but situated on the left side. These attacks may begin quite suddenly with acute pain after a heavy meal,

when straining at stool, after an aperient, or during the administration of an enema, and in other cases the attacks have begun while at work or at play. Their severity varies as much as it does in appendicitis, from the severe case with a rapid generalising peritonitis such as the woman I mentioned, to milder types with abscess formation or merely resulting in the formation of adhesions. The local signs are similar to those in appendicitis, but on the opposite side, and patients often describe the pain as radiating into one or both testicles or to the vagina in women. If the rigidity is not great an elongated tender tumour may be felt in the region of the iliac or sigmoid colon, and this tumour can often be felt better on bimanual examination than from the abdomen alone.

If the tumour is present it is often found to diminish greatly or even to disappear after the attack, to reappear again in the next one. The obstructive type is the one most often mistaken for a carcinoma, and often the history and symptoms are strikingly similar. There is usually a life-long history of constipation, and this is found gradually to increase until the patient is completely obstructed. Associated with the obstruction there is a good deal of pain and tenderness in the left iliac fossa and often considerable pyrexia, which is, of course, unusual in carcinoma. There is seldom blood or mucus in the stool, even occult blood being usually absent. Patients often notice that their pain is better when their bladder is empty, and worse when it is full. A moderate polymorphonuclear leucocytosis is common and further helps to distinguish the condition from carcinoma.

In the third or *genito-urinary* group the main symptoms are referred to the bladder. In all types of diverticulitis frequency of micturition and a burning pain at the beginning or end of the act is common, but in the type of case I am speaking of now more acute symptoms are present. There is often a history of increasing constipation and intermittent pain in the left iliac fossa or the perineum for a week or so before the attack. Then there is a sudden attack of urgent burning and painful micturition, accompanied by the passage of small grape-seed-like faecal particles from the urethra and of audible gas at the end of micturition. The urine is heavy with sediment and has a faecal odour. The passage of gas relieves the severe pain, but frequency and urgency persist, accompanied by cystitis of varying degree until operative relief is given. In such a case cystoscopy will demonstrate the fistula usually situated on the lateral wall of the bladder.

DIAGNOSTIC METHODS.

In the diagnosis of diverticulitis, cases with acute complications, such as a general peritonitis, peritoneal abscess, or vesico-colic fistula will, of course, be recognised from the symptoms of the complication, and diverticulitis will be remembered as one of the causes of these complications. Whenever any inflammation has occurred round the diverticula, however, there will be pain and discomfort with associated tenderness, and often the inflamed area can be palpated through the abdominal wall. Irregular pyrexia, moderate leucocytosis, absence of blood from the stools, and irritability of the bladder help to confirm the diagnosis.

Patients with diverticulitis are usually but not always well covered with fat, and generally give a life-long history of constipation.

Sigmoidoscopic examination is useful in putting out the possibility of a carcinoma of the recto-sigmoid with faecal retention above it, but usually in diverticulitis the area affected is beyond reach. Nevertheless cases have occasionally been recorded where the mouths of the diverticula have been seen to open through the sigmoidoscope on inflation.

X rays, however, afford the only means of diagnosing the presence of diverticula with certainty. Both an opaque meal and an enema should be used, as though it is the latter which will usually demonstrate the diverticula, the former will give most help in esti-

inating the degree of their effect on the functions of the bowel. Usually typical rounded oval or crescentic shadows of the barium in the diverticula will be recognised, and often are best seen after the barium enema has been evacuated, when two rows of small rounded shadows with narrow necks connecting them with the bowel can be seen. They may be visible for several days after the enema has been given. Marxer has pointed out, however, that these shadows are not the characteristic features. These are the spike or palisade-like projections of barium shadows from the lumen of the bowel, the wall of which is thickened and fixed. A series of films taken at short intervals, when superimposed, shows no variation in the outline of these shadows, although there may be vigorous and irritable contractions of the bowel wall above and below. This method of examination of superimposed serial films is of great value in estimating the degree of diverticulitis as opposed to diverticulosis which is present.

There are two fallacies to be remembered in regard to X ray examination in these cases. One is that the degree of obstruction shown after a barium enema is often a considerable exaggeration of the true state of affairs, since a good deal of spasm is induced in these irritable colons by the stimulus of the enema. The other is that in the cases with much thickening from inflammation, the diverticula may not show in the radiogram at all, in which case reliance must be placed on the demonstration of an area of rigidity and on the irregular palisading of the contents of the colon.

There is considerable diversity of opinion as to the frequency with which carcinoma develops in a colon the subject of diverticulitis, if indeed it does so at all. W. J. Mayo reported the presence of carcinoma in 13 out of 42 cases, but Judd and Pollock, from an examination of specimens, believe that a patient with diverticulitis is no more liable to develop carcinoma than a normal patient, and that is the view I am inclined to agree with. The clinical distinction between carcinoma and diverticulitis may, as I have said, be very difficult; many cases have been operated on and the specimen removed under the impression that it was a carcinoma, and the mistake has not become apparent until microscopic sections were examined. Tenesmus and painful defecation are commoner in carcinoma, as is the passage of blood in the motions. Mucus may be passed in both conditions, but it is commoner in carcinoma. Pain is present in both diseases, but in carcinoma usually radiates through to the back which it very seldom does in diverticulitis. Pyrexia and leucocytosis are usual in diverticulitis and rare in carcinoma, and, as I have said, the presence of a vesico-colic fistula is very much more in favour of diverticulitis than of growth.

TREATMENT.

In regard to treatment we must consider the prophylactic, the medical, and the surgical treatment. As to prophylaxis, if diverticula are discovered accidentally during a routine radiographic examination of the colon, their significance must be explained to the patient and treatment must be directed to preventing the stagnation of hard faeces in them. Sufficient paraffin must be given to keep the motions soft, and a diet should be chosen which leaves the minimum of solid undigested residue. Salads, green vegetables, pips and skins of fruit, currants, raisins, &c., must be prohibited, and articles of diet which stimulate peristalsis chemically should be eaten freely. When actual diverticulitis is present, if the attack is a mild one and complications such as peritonitis are absent, medical treatment should be tried. This will consist in complete rest in bed until pain, tenderness, rigidity, and pyrexia have disappeared and the diet just mentioned should be instituted. Paraffin (8 to 10 oz.) should be slowly run into the bowel under low pressure every evening, and if possible be retained overnight, and should be slowly washed out with saline in the morning.

Atropine must be given, either alone or with hyoscyamus, either by mouth or hypodermically, to counteract spasm, and purgatives should be avoided. As soon as the attack begins to abate, paraffin by mouth should be given, and the rectal paraffin may be reduced in amount and frequency. By these means attacks will be found to subside in many cases, and even if surgery is called for in the treatment of some complication this type of medical treatment will often avoid a recurrence or the necessity of the severe procedure of resection.

In regard to surgical treatment, the first point I would like to impress on you is that any attempt at radical removal of the area of bowel affected should never be undertaken in the presence of peritoneal infection. Such a procedure is almost certain to kill the patient. In the cases with general peritonitis the treatment must, in the first place, be directed to that alone, and drainage with Carrel tube irrigation in my view holds out the best chance of recovery. In the less acute cases with abscess formation, the abscess should be drained and a colostomy or caecostomy performed. After a colostomy the inflammatory mass will often subside with surprising rapidity, and the colostomy may be closed, or resection of the affected area of bowel may be undertaken later. It is in the obstructive type of case, with tumour formation and gradually increasing stenosis, that resection is most often called for, and these cases are difficult and call for very careful surgical judgment if a disaster is to be avoided. In occasional cases a primary resection of the area affected with end-to-end union is possible, and should usually be done over a tube, but the temptation to perform this attractive method of relieving the patient often has to be resisted on account of the dangers of leakage from a junction performed low in the pelvis and often between inflamed segment of bowel. The safest way to resect these cases where possible is the three-stage method of Mickulicz. In this operation the first stage consists in bringing the diseased segment of bowel outside the abdomen and fixing it there over a glass rod. This is sometimes not so easy as it sounds, owing to shortness of the mesentery, but careful separation on the outer side of the mesentery will often make it possible. In a few days the affected bowel is cut off with a diathermy knife, and the third stage consists of restoring the continuity of the bowel either by one of the crushing methods or by suture. While this method is naturally unpleasant for the patient in that it entails two or three operations, it is far the safest, and an unpleasant procedure with a live patient at the end is better than the nearest of operations resulting in a dead one.

The most difficult cases of all to treat surgically are those with a vesico-colic fistula. As a rule a preliminary colostomy is required with spur formation so that no contents pass below the opening. The lower bowel can then be got reasonably clean, and the severity of the cystitis diminished before further operation is undertaken. If the colostomy can be performed just above the area of diverticulitis, it is sometimes of advantage, as the opening can then be resected with the affected area of bowel. At the second operation the bowel is separated from the bladder, and the opening into this organ is pared and inverted. The colon must be treated according to circumstances. Very occasionally the actual perforated diverticulum can be inverted into the bowel, but usually the condition is too advanced for that, and the affected bowel must be resected. If this is a moderately local area and situated not too low down, end-to-end union over a tube may be possible, but in many cases the lower end of the bowel will have to be closed and the patient will have to pay the price of a permanent colostomy for relief from his symptoms.

Such, then, is briefly the treatment we have to offer; and it is evident that much can be done for these patients provided a reasonably early diagnosis is made. Both medical and surgical treatment have

their part to play—a state of affairs which is common to many abdominal and other diseases. We hear far too much about people “believing” in either medical or surgical treatment for any particular condition. The truth is that the good physician will use surgery as freely as any of the other curative methods at his disposal, and the good surgeon, who should be a physician at heart, will not allow pride of craft to influence his judgment.

THE ACTIVATION OF SYPHILIS BY TREATMENT.

By JAMES H. SEQUEIRA, M.D., F.R.C.P. LOND.,
F.R.C.S. ENG.,

CONSULTING PHYSICIAN TO THE SKIN DEPARTMENT,
LONDON HOSPITAL.

THE object of this communication is to bring together facts which appear to demonstrate conclusively that not only may inadequate treatment by 914 and its allies produce an arsenic-resistant type of spirochæma, but that treatment, especially insufficient treatment, may actually activate latent syphilis.

It is now 20 years since Ehrlich and Hata announced the discovery of salvarsan. During the optimistic period which inevitably follows the introduction of an intensely advertised addition to the therapeutic armamentarium, a ritual of treatment was evolved and was widely followed. If we may judge from the opinions expressed by leading syphilologists in recent discussions and communications to the medical press, stereotyped routine has given place to a plasticity which indicates a tardy appreciation of accumulated experience. It is hardly an exaggeration to say that after 20 years' trial of the modern remedies there is an absence of unanimity as to the best method of treating syphilis. The introduction of bismuth into antisypilitic therapy by Levaditi and Sazerac in 1920 introduced a new and important factor, and those of us who were brought up in the old tradition are gratified to see that the claims of mercury are again receiving recognition.

Watrin, in an article on arseno-resistance, justly remarks that “whatever be the cause arsenical treatment is not so simple as it appeared to be some years ago.”¹ Now, so long ago as 1911, only a year after the debut of salvarsan, McIntosh and Fildes warned us of the possible production of strains of spirochætes “fast to 606,” and stated very definitely that “if such strains become general, the therapeutic value of the substance will be much diminished.” They pointed out that the survivors of sublethal doses acquire an immunity, and that “in practice . . . such strains, if they occur, will be produced by an initial treatment of too slight intensity.”² The warning of these writers has been amply justified. The conditions they foreshadowed have been completely fulfilled. For a long period it has been the custom to treat syphilis by small doses of the arsenicals repeatedly administered by intravenous injection in one or more courses. The very natural reluctance to give Ehrlich's effective doses to ambulant patients, who are under no control and may not be seen for a week, is an important factor not only in increasing the resistance of the spirochæma, but in actually stimulating it to activity, as I propose to show shortly.

An examination of recent pronouncements shows that there are extraordinary variations as to what are now deemed to be safe doses of the arsenicals. We also observe that while one authority advises alternate courses of 914 and bismuth, another insists on the imperative necessity of the simultaneous administration of these remedies, a third recommends an initial course of mercury, followed by arsenicals, then by bismuth, concluding with iodides. Another

school would, even in early syphilis, always add pyrotherapy (malarial treatment, &c.), to chemotherapy. This last contention makes it seem possible that, as I have suggested elsewhere, our early dramatic successes with 606 may have been partly due to the pyrexia with rigors caused by our giving the drug in 100 c.cm. of imperfectly sterilised normal saline.

Some of the differences of opinion may perhaps be explained by the impossibility of keeping accurate observation on large numbers of persons treated as out-patients. It is, however, obvious that our 20 years' experience of salvarsan therapy has resulted in agreement upon one point—that it is impossible to rely upon arsenicals alone to effect a cure, if we can still speak of a “cure” of syphilis. No one will, I think, contest the opinion of Warthin³ that the chief advantage of the arsenobenzols is “the more rapid reduction of the average case to a stage of latency.” “This latency,” he points out, “may last throughout the individual's life, or at any time exacerbations may take place and the disease arise above the clinical horizon.” As a pathologist he remarks upon our ignorance as to whether these renewals of virulence are due to changes in the quality of the spirochæma or to changes in the resistance of the body. We are in complete ignorance of the state of the microbe in its latent phases, and we know little or nothing of the changes in the reacting power of the body. Milian, from the clinical aspect, appears to give adequate evidence that one of the factors which may determine an exacerbation is the direct stimulation of the dormant spirochæma by antisypilitic treatment.⁴ To such stimulation he gives the name of “biotropism.” It is, of course, not suggested that this explanation accounts for more than a part of the exacerbations, but it evidently demands close study. That different doses of drugs produce different effects is common experience and is recognised in elementary therapeutics. It is hardly necessary to recall the stimulant effect of small doses of opium and the sedative influence of larger quantities.

Biotropism is the activation of microbes by chemical and other stimuli. Milian contrasts this process with Ehrlich's parasitotropism and organotropism, which conditions are *necro-tropic*—that is, they tend to the destruction either of the parasite or of the host. Biotropism is met with in many circumstances. I have personally seen a small dose of 914, administered as a gentle tonic, induce an acute attack of subtertian malaria, verified by the demonstration of the plasmodium in the blood, and by its rapid response to quinine. In this instance the patient had no idea that he was subject to malaria. The administration of 914 may stimulate to activity a latent streptococcal infection in the throat, with the result that at the end of nine days a tonsillitis and scarlatiniform erythema develop with pyrexia, the syndrome being indistinguishable from scarlet fever. This phenomenon has occurred more than once in my hospital experience, and it is commonly regarded as evidence of arsenical poisoning. It is obviously not so for it disappears under more intense treatment with arsenic and is quite different from the diffuse moist universal salvarsan dermatitis which only occurs after a course of arsenobenzol treatment. Mercury and bismuth, and occasionally arsenic, may stimulate septic organisms in the buccal cavity and thus cause grave stomatitis. Similarly, drugs may activate latent staphylococcal infection, &c., and the stimulation of the dormant viruses of herpes and zona by arsenic and other drugs is familiar. Arsenic, and particularly the trivalent arsenicals, such as 606 and 914, appear to be the commonest biotropic therapeutic agents, but both the other antisypilitic remedies, mercury and bismuth, are not infrequent offenders.

“Provocative” Injections of the Arsenobenzols.

The simplest example illustrating the theory of the activation of syphilis by treatment is afforded by the commonly used “provocative” injections.

In cases in which the Wassermann reaction has been rendered negative by treatment, a small dose of 914 given after an interval of some months is frequently followed by a positive reaction. The most satisfactory time for this examination is about the fourteenth day after the provocative dose: It is not too much to assume that such positive reactions indicate the activation of groups of spirochetes which have been lying dormant. Such a positive reaction may last for some days to some months, and often yields to further treatment by larger doses of the drug. It is also noteworthy that in cases where mercury has rendered a blood reaction negative, the administration of 914 without any interval may activate a focus not touched by the mercury and again give a positive reaction. These observations are commonplace, but they support the thesis.

There is evidence that not only drugs but also infectious diseases may activate a dormant syphilis and produce a positive Wassermann reaction. Milian quotes Neuda's case in which a negative blood reaction in an old syphilitic patient became positive during an influenza pneumonia, and Marini's case in which typhoid fever brought out a papular syphilide with a positive Wassermann in a patient who was not known to be luetic. It has been suggested that some of the positive reactions occurring in certain acute fevers may be examples of biotropism—viz., the activation of a latent syphilitic infection. "Protein shock" and the vaccines are also known to bring out a positive Wassermann reaction in rare instances.

Conflict Between Drug and Microbe: Jarisch-Herxheimer Reaction.

About 30 years ago Jadassohn and Jarisch described the intensification of a syphilitic roseola under the influence of injections of grey oil. The importance of this observation was not realised until the frequent occurrence of a temporary augmentation of the cutaneous and mucous membrane manifestations of syphilis after treatment by 606 focused attention upon it. Herxheimer's work led to his name being associated with that of Jarisch. These reactions are much more frequent under arsenobenzol therapy than with mercury, and they occur commonly at the beginning of a course—that is, with insufficient treatment.

Milian has shown in a striking manner that bismuth may cause a Herxheimer reaction. He has placed in the museum of the St. Louis moulages representing two gummatous ulcers of the skin before and after the administration of two intramuscular injections of bismuth. One lesion was the size of a franc and the other as big as a two-franc piece. Instead of the ulcers retrogressing under the treatment they doubled in size, becoming at the same time redder and with increased discharge.

No one doubts that such reactions occur in visible cutaneous and mucous membrane lesions, but it does not appear to be so generally realised that the same type of phenomenon occurs in syphilis of the brain and peripheral nerves, in the liver, and in the heart. This is the result of the common failure to appreciate the fact that in the stage of generalisation every organ is invaded by the spirochete and reacts more or less characteristically to it. Formerly the Herxheimer reaction was explained by the liberation of endotoxins from the microbes, but it is now recognised that it is evidence of a "therapeutic conflict" between the virus and the drug, and that the drug is insufficient to destroy the organism. Or, as Milian puts it, "it is a stimulation of the germ by a medication which is insufficient either as to dose or as to nature." Such therapeutic conflicts are accompanied by elevation of the temperature, with rigors, sweating, and general malaise, which may simulate malaria, but beyond the occurrence of vomiting and diarrhoea there is no evidence of arsenical intoxication. These reactions may occur without any visible cutaneous or mucous membrane manifestation.

The series of charts in "Le Biotropisme" recall reactions familiar to those who have had the oppor-

tunity of following cases under treatment in the wards of a hospital. In the simplest and commonest there is only one rise of temperature, perhaps to 102° or 103°, after the first dose of 914. In other cases a similar rise follows each increase in the dose. In some instances the temperature remains elevated with doses of 0.3 g. to 0.6 g., but after a profound reaction to one or more doses of 0.9 g. there is no further pyrexia. One striking chart shows intense reactions (T. 104°-105°) to doses of 0.3 g., and the production of a continued syphilitic pyrexia which was completely abolished by intramuscular injections of bismuth. The continued fever having been eliminated by bismuth it was possible to resume arsenical treatment without untoward symptoms. Another equally important chart shows repeated high temperatures (104°, 105°) after doses of 0.3 g. of 914, which were entirely absent with daily injections of cyanide of mercury (0.01 g.), whereby the resumption of treatment by 914 up to doses of 0.9 g. became possible. These observations show that in certain cases bismuth and mercury have a more powerful effect than arsenic, and demonstrate the great value of careful thermometric observations which unfortunately are impossible in an out-patient clinic.

Jaundice, Syphilitic or Toxic?

Warthin¹ tells us that the occurrence of a mild degree of atrophic hepatitis is very common in latent syphilis. The percentage of cases in his material in which the liver is involved appears to be on the increase, particularly in those given a modern treatment with arsenic. There may be no symptoms; for so large an organ as the liver may still retain a sufficiency of healthy tissue to carry on its functions. On the other hand, there is no doubt that arsenic itself may damage the liver, and such toxic action has long been a source of anxiety to all engaged in the modern treatment of syphilis. There are, therefore, two distinct types of jaundice, the more common syphilitic, the rare toxic, and it may be very difficult to distinguish them.

In a recent communication Schamberg² states that seven fatal cases of acute yellow atrophy occurred in one clinic during the past year, and states that such fatalities can only be avoided by small doses of the drug, the maximum for 914 being 0.6 g. Harrison,³ at the Medical Society in February last, is reported as saying "For syphilis affecting the liver arsenobenzol compounds were contra-indicated." (The italics are mine.—J. H. S.) On the other hand, Milian holds that 90 per cent. of the cases of jaundice which occur during antisyphilitic treatment are merely the awakening of a dormant syphilitic hepatitis and as such require intensive treatment. He cites the following case which appears to be incontestable:—

In consultation with Dr. Ravaut he saw a patient with secondary syphilis, in whom a well-marked jaundice had appeared during treatment with 914, a dose of 0.76 g. having been reached. In view of the jaundice, Dr. Ravaut had decreased the dose to 0.15 g., followed by 0.3 g. In spite of this reduction the icterus increased. The case is described as one of typical afebrile obstructive jaundice, with decolorisation of the stools, &c., but with no evidence of arsenical intoxication. On Milian's advice doses of 0.9 g. and 1.05 g. were given, diuresis was established, and the jaundice rapidly disappeared. He maintains that this was a case of syphilitic hepatitis aggravated by small doses of 914, but which yielded at once to more intensive treatment.

In this connexion it is interesting to mention that Lafoucade, J. Fougnet, and Nativelle⁴ report 23 cases of jaundice occurring during antisyphilitic treatment, of which only five were actually under treatment, the remainder being under mercury or bismuth, and none of them had recently had arsenical treatment. They therefore conclude that jaundice is not more frequent under arsenic than under mercury or bismuth (a conclusion not confirmed by my own experience). The sequel is important, as it strongly supports Milian's thesis. Thirteen of these cases had developed jaundice while having injections of grey oil. They each received a course

of arsenobenzol, and the icterus disappeared in every case, usually after the second or third dose.

It is obvious that very few clinicians would feel justified in following the admirable example of these observers, and the matter can hardly be further advanced until we have some reliable means of determining the relationship between indifferent excretion and toxic manifestations. Some work of N. L. Lloyd at Guy's Hospital⁸ tend to show that Abelin's reaction, which can be applied in out-patient practice, may prove of assistance in this respect. In any case the subject demands carefully controlled investigation.

Cardiovascular Syphilis: "Heart-block."

That syphilis is an important cause of disease of the heart and vessels is well recognised, and there seems to be little doubt that these affections are on the increase. It has been suggested that modern arsenical treatment alters the life-history of the spirochete in the body (Sarbo⁹). Langer's report states that while there was disease of the aorta in 33 per cent. of syphilitics seen in the post-mortem room in 1907 (that is before salvarsan), the percentage had risen to 63 per cent. in 1915 and 83 per cent. in 1925.¹⁰ These figures are supported by records from other pathologists. It may be argued that there is more care taken in investigating these cases, and that the technique has greatly improved, but my own experience, which I feel sure will be confirmed by others, is that as far back as 1907 pathologists of repute were fully alive to the occurrence of syphilitic endarteritis, &c., and the improvement in histological technique cannot account for the remarkable figures quoted above.

In addition to disease of the vessels and cardiac valves there is increasing evidence that the myocardium is frequently involved. Such involvement may be without symptoms, but tachycardia and arrhythmia are common and "heart-block" occasionally occurs. It is now evident that cardiovascular syphilis is responsible for more deaths than general paralysis and tabes.¹¹ Myocarditis may be primary or secondary to endarteritis of the coronaries. "Heart-block" may be caused by disease of the vessels supplying the bundle of His, or by actual gumma or fibrosis in that region. It is said that the trivalent arsenicals have caused "heart-block" in patients free from the condition, and it is suggested that these drugs act directly on the bundle of His. It, however, seems much more reasonable to explain the phenomenon as being caused by the arsenic stimulating dormant spirochetes in the involved area. It is stated that neither the pentavalent arsenicals nor bismuth produce this effect upon the heart.

Renal Conditions.

It is now understood in clinics that simple albuminuria, often of syphilitic origin, is no contra-indication to treatment. The albuminuria usually clears up. In grave arsenical intoxication suppression of urine may occur, and Milian has published a case of grave anuria during mercurial treatment. He believed this to be due to septic absorption from a severe stomatitis.

Nervous Affections: Neurorecurrences.

In the early days of salvarsan treatment it was noticed that symptoms of the affection of cranial nerves and of the central nervous system sometimes occurred after treatment by injection. These recurrences were certainly more frequent than under mercurial medication. Auditory and facial nerve paralyses were the commonest but the oculomotor nerves were also affected. I put on record cases of paraplegia, and have seen hemiplegia. It was soon established that these neurorecurrences were more frequent in patients who had been insufficiently treated by arsenic, and that they usually cleared up with further injections of the remedy.

Some of Milian's cases strongly support this view, and one is so instructive that I may be pardoned by giving a brief précis of the details.

A woman aged 35, the daughter of a general paralytic, suffered intensely from migraine which prostrated her for 24 to 48 hours at frequent intervals. Although her general health was otherwise very good, her doctor suspected the syphilitic origin of these headaches, and gave her a dozen intravenous injections of cyanide of mercury. The result was almost magical, and the migraine did not recur. The patient went for a holiday and treatment was suspended. On her being seen three months later, she was found to be suffering from grave hemiplegia with aphasia, which has since gone on to contracture. There appeared to be no doubt that the treatment had determined the more grave affection, and the medical man regretted his interference. In his comment on this case Milian insists that it is not the treatment but the insufficiency of the treatment which should be blamed. Not only was treatment stopped too soon but the patient was allowed to go away far from medical advice without even being ordered mercury by the mouth.

A case of paraplegia occurring in a young man during a moderate course of treatment is also detailed. In this instance the paraplegia seems to have been determined by a chill. It was complete, with retention of urine and incontinence of faeces. Here an intensive treatment by arsenicals and mercury cyanide in combination was followed by intravenous injections of arsenobismuth. The patient was completely cured of his paralysis in six months.

The author points out the importance of studying the methods of treatment which have been employed before the outbreak of fresh symptoms. An indication will often be thus obtained as to the advisability of increasing the dosage of the previously used drugs or what is often better, to change the *antisiphilic medication* (the italics are Dr. Milian's.—J. H. S.).

Conclusions.

The absolute cure of syphilis—i.e., the complete destruction of all the spirochetes in the body—is rare. The value of the arsenobenzols lies in their rendering an active syphilis latent more rapidly than any other form of medication. Ehrlich's therapeutic doses—0.015 g. per kg. of body-weight for the neosalvarsan group (914), and 0.01 g. per kg. for the salvarsan series (606), are usually quite safe; the parasitotropic and organotropic properties are in the approved ratio. The intravenous injection of these powerful drugs in adequate doses demands great care, and the proper preparation and competent observation of the patient—preferably in hospital. In a national scheme of treatment these ideal conditions, even if provided by private munificence, have to be surrendered to make the clinic attractive to, and wait upon the convenience of, a proletarian clientele. Ambulant patients, who are only seen once a week and rarely, if ever, make the acquaintance of the clinical thermometer, must be given smaller doses and the less active preparations.

This sacrifice of efficiency to expediency has led to the evolution of strains of arsenic-fast spirochetes and is attended with the risk of activating latent foci of infection. These risks may be modified, if they cannot be removed, by polytherapy—mercury, bismuth, and iodides being included with arsenicals in routine treatment.

Some of the early reactions hitherto thought to be evidence of intolerance to the drugs are merely activation of latent microbial (coccal, &c.) infections—e.g., the scarlatiniform, morbilliform, and other erythematous, or the stimulation of dormant viruses, such as herpes and zona. These all clear up with more active treatment. The most serious results of arsenical intoxication are salvarsan dermatitis and hepatitis. Neither are common. The dermatitis only occurs after a course of injections. Jaundice in the majority of cases is not an evidence of toxæmia due to arsenic, but is produced by the stimulation of a latent syphilitic hepatitis by inadequate treatment. The difficulty in distinguishing this has been discussed.

There is no question of the activation of latent syphilis by drugs, and this danger is greatest when the trivalent arsenicals are used, particularly in small doses. I entirely agree with Milian that it is better to leave these cases alone though they have a positive

Wassermann, than to submit them to inadequate treatment. By any combination of remedies we are not likely to eliminate infections of the nervous system, nor are we likely to approach the figures of Brugs-gaard,¹² who found only 0.6 per cent. of general paralysis in untreated cases, whereas the usual figure in treated patients is 4 per cent.

To diminish the risks of infection we must probably continue to treat all syphilis in the active stage, but in later cases it seems reasonable to ask whether we should not pay more attention to the condition of the patient than to his Wassermann reaction.

CLASSIFICATION OF FOUR THOUSAND EXPERIMENTAL OIL AND TAR SKIN TUMOURS OF MICE.

By C. C. TWORT, M.D. ABERD.,

AND

J. M. TWORT, B.Sc. LOND.,

PATHOLOGIST AND ZOOLOGIST TO THE MANCHESTER COMMITTEE
ON CANCER.

The tumours under consideration were produced in mice by the frequent application of pure and chemically treated carcinogenic agents having different degrees of potency. The number of benign and malignant tumours which have resulted from our experiments are:—

	Animals utilised.	Benign.	Malignant.
Coal gas tars	800	93	106
Synthetic tars	8,800	1,086	1,221
Shale oils	10,000	977	307
Petroleum oils	6,100	183	43
Other oils, &c.	500	0	0
Pure compounds	2,900	15	6
Totals	29,100	2,354	1,743

About 8000 animals, of which approximately 1000 are bearing or have borne tumours, belong to incomplete experiments and are not included in the above totals, but the tumours of approximately 500 of these animals which have died have been examined microscopically and utilised for classification purposes.

The pre-tumour or pre-cancerous stage of the epithelium we do not propose to discuss here. The only observation we wish to make is that the more specimens we examine the more are we convinced that the gap between the benign and malignant is bridged by innumerable transitional cells. A single really good specimen will reveal a picture of a series of cells which would seem to have reached different stages in the development from the benign to the malignant, while many widely separated groups of cells may have simultaneously reached an equal degree of malignancy.

The tumours which we have met with can be divided into:—

- (A) Tumours of the surface epithelium,
- (B) " " " follicular epithelium,
- (C) " " " sebaceous glands
- (D) " " " connective tissue, and
- (E) " " " comprised of mast cells.

In the first place the tumours are divided into benign and malignant. The classification of a tumour is, of course, not always easy. In difficult cases serial sections will sometimes permit one to make a definite diagnosis, but this procedure may fail to help, and in the latter case personal factors decide into which group a particular tumour shall fall. We have not deemed it necessary to institute an intermediary group of doubtful tumours because in the calculation of the carcinogenic potency of our agents due allowance is made for this contingency. Each group will now be briefly discussed, and in order to avoid repetition groups A and B will be considered together.

(A) and (B) Tumours of the Surface and Follicular Epithelium.

Benign tumours may be divided into: (1) tiny thickened areas of the epithelium which produce a small mound, just visible to the naked eye, on the otherwise smooth skin; (2) flat warts; and (3) papillomata, by far the commonest variety of benign tumour met with. The small foci of acanthotic epithelium which constitute the thickened areas of epithelium referred to in sub-group 1 we do not classify as true tumours on account of the tendency for regression of the epithelium to take place and leave again a smooth clean skin.

Malignant tumours.—These may be classified as follows:—

1. Spino-cellular, normal.
2. " " with cystic tendency.
3. " " " scirrhous "
4. " " " hyaline "
5. " " " basal-celled "
6. " " " medullary "

Medullary tumours may be: spindle-celled, endothelial-celled, or alveolar, and if in these tumours keratinisation is not obviously present we classify as pure spindle-celled, &c. If two different areas of a tumour have each different histological features the tumour is classified as "mixed." If two such histological features are present in a single small area the tumour is called "intmixed." If two or more primary tumours occur in a single animal the ordinary term "multiple" is used. Multiple tumours may be of one or more than one variety, and both benign and malignant tumours may be present on the same animal.

A few details will now be given with reference to several of the more interesting examples of this group of tumours. In the first place it is to be noted that what we call flat warts are very often the result of hyperplasia of the follicular epithelium. If the surface epithelium is sufficiently hyperplastic to give the appearances of a flat wart the microscope usually shows that the tumour is already malignant. The majority of experimental malignant tumours of the surface and follicular epithelium are of the ordinary spino-cellular variety, and they are classified as normal spino-cellular epitheliomata. It is only when special histological features are present to a marked degree that the tumour is classified as spino-cellular with cystic, basal-celled, spindle-celled, &c., tendency. If there is little indication of any relation to the spino-cellular type the tumour is classified as pure cystic, basal-celled, spindle-celled, &c. New growths of follicular origin seem to have a greater tendency to become cystic than those originating from the surface epithelium, while medullary tumours do not often appear to originate from the follicles. Nothing further need be said concerning cystic, scirrhous (Fig. 1*), or hyaline tumours (Fig. 2), except in so

* The photographs are by R. Combes, Manchester University.

far as they are related to basal-celled and medullary tumours, the last two varieties, however, requiring a more detailed description.

Among our tumours it would appear that some at least have their origin from the basal layer of cells, although in no instance have we seen a tumour which could be classified as what is called a basal-celled epithelioma. We have frequently observed in the early stages of epitheliomatous disease of mice that the processes of cells penetrating into the dermis are in appearance identical with the cylindrical or somewhat cubical cells typical of a basal-celled epithelioma (Fig. 3). This condition is, of course, not peculiar to mice. The inward growing, densely cellular, irregularly edged, papillomatous processes, although bearing a resemblance to a basal-celled tumour, in all cases appear ultimately to become differentiated into the spino-cellular type of tumour. It has been suggested that these tumours might be classified as mixed basal-celled spino-cellular, but we prefer to consider them as spino-cellular tumours with a tendency to the basal-celled type.

The most prevalent variety of pure medullary tumours is the non-keratinising, small spindle-celled epithelioma, which has occurred in about 2 per cent. of our experimental skin tumours. If mixed and intermixed spindle-cell tumours are included the percentage is about 10. The large spindle-celled tumour is not so frequently met with. A typical spindle-celled epithelioma is very cellular, and consists of bundles of interlacing smallish spindle cells which in a single section may be cut in all directions (Fig. 4). The deep margin of the tumour is usually fairly well defined (Fig. 4), although it may be infiltrative (Fig. 5). Laterally, however, the tumour tends to spread far beneath the sound epithelium, and finally it blends imperceptibly with the subcutaneous connective tissues so that it is impossible to define the limits of malignancy. In a typical specimen the tumour cells approach right against the basal cells of the laterally intact surface epithelium. The fading away, so to speak, of the infiltrative edge of the malignant growth is of interest in relation to the lack of spindle-cell metastases. In what we call the pure spindle-celled tumours the absence of the so-called cell nests is a special feature, but a careful study will at times reveal commencing keratinisation of some of the cells. In the mixed and intermixed tumours keratinisation is, of course, part of the microscopical picture.

It is a significant fact that in almost every instance where we have found a pure spindle-celled tumour it has been situated on the edges of a fibrosed sore or has a frankly ulcerated surface. The tumours may be provided with thin-walled vessels which, together with hemorrhages, are most numerous on the periphery. As the microphotographs show, the tumours are superficially not dissimilar to sarcomata, but that they have really originated from epithelial tissue is not usually difficult to demonstrate. Sometimes the spindle cells can be seen flaking as it were from the basal layer of cells (Figs. 6 and 7), and would thus appear to have their origin from the basal epithelium. This condition of affairs is, however, the exception.

Another special variety of the medullary tumour is the alveolar epithelioma (Fig. 8), wherein the tumour cells are divided into islets by strands of connective tissue.

The endothelial-celled tumour is the third variety of medullary epithelioma and like the alveolar tumour is only occasionally met with. While in the spindle-celled tumour the malignant cells blend and become indistinguishable from fibroblasts, so in the endothelial variety the malignant cells may become lost among the normal endothelial cells. It seems to us that both alveolar and endothelial varieties of malignant growth may be a stage in the metaplasia of the prickle cell to the resistant spindle cell, but in the majority of cases the metaplasia is direct.

With the onset of ulceration and concomitant sepsis complete healing of malignant tumours may

take place, but total destruction of the tumour appears never to occur in the absence of ulceration. We have failed to observe regression of a tumour the surface epithelium of which was intact, but before the malignant growth is visible to the naked eye the microscope provides evidence that in some animals tiny primary foci of malignant cells may keratinise completely, no living cells remaining, so that in such cases the nucleus of a tumour would appear to be destroyed before any advance in growth is able to take place.

With the advent of ulceration and the entrance of bacteria a spino-cellular tumour may heal completely or it may heal in the centre and continue to grow at the edges. The malignant cell, however, would appear sometimes to adopt a special procedure in order to ensure survival—viz., it ceases to keratinise. When dealing with spindle-cell tumours one is struck by the absence of deep sepsis and necrosis of tissue, the dense wall of interlacing cells seemingly forming an impermeable barrier to the surface infective micro-organisms. Thus one is led to believe that the change to the spindle cell is a necessary consequence of the inability of the prickle cell to withstand sepsis; if metaplasia does not take place then that particular focus of malignant cells is liable to be totally destroyed. It is also probable that sepsis is the primary factor in causing the tumour to change from a keratinising to any of the varieties of medullary tumours, the relatively healthy undifferentiated cell offering a more effective resistance to bacteria than the keratinising (degenerating) highly differentiated cell. Consequently, central healing of an ulcerated medullary tumour is not commonly seen.

We have come to the conclusion that the change in morphology of the cells is often due to the influence of neighbouring cells, a fundamental biological phenomenon. Thus it would appear that when a spino-cellular tumour under the influence of sepsis changes its method of growth to that of spindle cells, the latter as they spread from the central ulcer beneath the intact surface epithelium cause this epithelium also to proliferate directly as spindle cells and not as squamous cells (Fig. 7). Also, we have seen that the malignant spindle cells as they infiltrate the connective tissue may gradually lose their morphological characteristics and become microscopically indistinguishable from fibrous tissue cells, but the significance of this phenomenon we are not at present prepared to discuss.

It has been mentioned that our tumours are rarely pure and on the contrary often possess several of the features described. For instance, we classify a tumour as a pure spino-cellular or a pure spindle-celled, while we have mixed spindle-spino-cellular and intermixed spindle-spino-cellular (Fig. 9), &c. An intermixed tumour of the kind referred to is really a spindle-celled tumour with definite areas of keratinisation, or if one prefers to look at the subject from another angle it is a spino-cellular tumour which, under the influence of some physico-chemical stimulation (sepsis), grows as a spindle-celled tumour.

It is to be noted that metastases which we have found in lymphatic glands, lungs, and once only in the kidney, have all been of the ordinary spino-cellular type. A tiny metastasis in the kidney is shown in Fig. 10, but there were also several larger ones in the same organ.

Of some interest was the simultaneous occurrence in an animal of an experimental mixed spindle-spino-cellular epithelioma and a breast spontaneous cystic adenocarcinoma. We consider it fairly safe to assume that the latter was a spontaneous tumour, although we have observed that female mice suffering from experimental epitheliomatous disease may on occasions show definite evidence of mastitis.

In Fig. 11 the spindle cell portion of the epithelioma is seen to be invading the cystic breast, which latter was elsewhere definitely carcinomatous. It was difficult to estimate which of the two tumours would ultimately have survived had the animal lived, although on the whole the

microscopic evidence was in favour of the epithelioma-tous spindle cells being in the process of destroying the breast carcinoma.

C. Tumours of the Sebaceous Glands.

Benign tumours only have been encountered. They are divided into: (1) sebaceous cysts, and (2) sebaceous adenomata. It is unusual for a tumour to be pure in type, a tumour of the sebaceous cells being generally a cystic adenoma. A cystic adenoma and a pure adenoma are shown in Figs. 12 and 13. As gas tars and synthetic tars tend to cause sebaceous cell atrophy tumours of this group are rarely seen in animals painted with such materials. Certain other agents appear to induce a sebaceous cell hyperplasia and occasionally definite tumours may subsequently arise. Medicinal liquid paraffin and oleic acid are examples of such agents, their action being apparently increased by the addition of certain insoluble aromatic hydrocarbons. As we do not consider that the development of a sebaceous adenoma is induced by the carcinogenic principle in our agents these tumours are excluded from our calculation of carcinogenic potency. However, we have only met with about 20 specimens up to the present time.

D. Tumours of Connective Tissue Origin.

No benign and only one malignant tumour of this group occurred among our animals. In this particular case there was no evidence that the tumour concerned was of epithelial origin, although it may have so originated. Microscopically it resembled a round-celled sarcoma. The history of the case was as follows:

Mouse 17719 was painted twice a week with a synthetic tar which had been treated by bubbling through oxygen at a temperature of 160–165° C. A wart developed during the 14th week of the experiment which later fell off and left an ulcerated surface. During the 28th week a small hard lump was palpable which was diagnosed as an epithelioma, and the animal died during the following week. A microphotograph of the tumour is shown in Fig. 14.

E. Tumours Composed of Mast Cells.

The invasion of the subcutaneous tissues and the corium by mast cells is a notable feature in the skin of animals painted with carcinogenic agents, but more so in the case of tars than in the case of oils. The extent of the invasion is usually roughly proportional to the amount of subepithelial inflammation present. Aggregation of these cells may give rise to definite tumours which may be visible to the naked eye and simulate small flat warts (Fig. 15). There is often a tendency for the cells to lose their basophile granules and to become smaller in size with a clearly defined nucleus, and when such changes are exaggerated they take on the appearance somewhat resembling a nevus cell. As in nevi the tumours may be situated directly beneath the epithelium (Fig. 16). All such tumours appeared to be benign, but it is interesting to note that a diffuse infiltrative condition of the internal organs seemed to have been the cause of death of one of our animals:

Mouse 21070 was treated with bi-weekly applications of a 10 per cent. solution of synthetic tar B/10 in oleic acid and during the 14th week of the experiment developed a wart which showed evidence of malignancy within four days. The animal died eight days later, the malignant tumour having ulcerated. On post-mortem examination the spleen was found to be large and swollen with the normal tissue replaced by nodules of growth of a greyish appearance. The liver was slightly large and anæmic but showed no definite nodular new growth formation.

Microscopically the skin showed a small epithelioma which was evidently being rapidly destroyed by sepsis. In the subcutaneous tissues was a small mast cell tumour. The spleen showed a central mass of tumour with two lateral areas of blood which contained lysed patches of tumour cells. In the margin were remnants of comparatively normal splenic tissue. The tumour edge was, on the whole, sharply defined from the hemorrhagic tissue. The individual tumour cells, where isolated, were round cells about 20 μ in diameter, and with a well-defined roundish nucleus 5–8 μ in diameter. Stained with hematoxylin the cells were packed with the granules and were identical

in appearance to the modified mast cells so frequently found as a tumour in the subcutaneous tissues of mice painted with tar (Fig. 17). A noteworthy feature of the splenic tumour cells was that many of them were full of red blood corpuscles. The cells were crowded together were more irregular in shape and size. No definite mitoses were observed in the tumour cells. In the liver microscopic nodules of tumour cells were present and there were isolated cells infiltrating the liver parenchyma (Fig. 18). The cells were similar in appearance to those found in the spleen, but no intracellular blood-cells were seen.

Transmission of the condition to other mice was not attempted. Had such transmissions been tried we do not think for several reasons that we should have had any positive results.

THE EFFECT OF RIVANOL IN THE TREATMENT OF AMEBIC DYSENTERY.

By A. G. BIGGAM, M.D. EDIN., M.R.C.P. LOND.,

PROFESSOR OF CLINICAL MEDICINE, EGYPTIAN UNIVERSITY;
DIRECTOR OF THE WHOLE-TIME MEDICAL UNIT,
KASR-EL-AINI HOSPITAL, CAIRO;

AND

DR. M. A. ARAFA,

MEDICAL REGISTRAR OF THE HOSPITAL.

RIVANOL (ethoxy-diamino-acridine-lactate) is a yellow dye-stuff with a powerful antiseptic action. It has been used as a local antiseptic in various septic skin conditions and in genito-urinary and other infections. More recently its employment in dysenteries and allied conditions of the lower gut has been advocated. Urchs¹ obtained good results in the treatment of tropical colitis by the use of rivanol solution injected rectally, and considered the benefit derived to be due largely to its antiseptic action on the superadded secondary infection. Peter² carried out further investigations with the drug, using the rectal route of medication in cases of colitis definitely proved to be due to infection with *Entamoeba histolytica*. He observed rapid improvement in the general condition of these patients in two or three days, and the bowel symptoms also rapidly subsided, tenesmus being the first to disappear, usually by the second day. The frequency of the stools was not, he found, much influenced until after the second day, but after an average of five days' treatment usually only two or three formed stools were passed daily. Blood began to diminish by the second day and had entirely disappeared two days later; mucus was found to persist a day or two longer than the blood. A further beneficial effect was observed by him during treatment—namely, the disappearance of the tenderness and contraction of the large gut; this was usually completely relieved by the sixth or eighth day—the usual duration of the ordinary course of treatment. The microscopic findings confirmed the clinical observations, the vegetative forms of *E. histolytica* vanishing after the five days of treatment; they were never found when mucus had disappeared from the stools, and cysts behaved in a similar fashion. Provocative medicines were administered before the patients were discharged and repeated stool examinations carried out with negative results. No special diet was found necessary during the treatment, and at the beginning milk was usually given, the diet being increased as symptoms subsided. The average stay in hospital from the commencement of treatment was ten days. The concentration of the rivanol solution recommended was 1:10,000, this being found the most efficacious and the least irritating to the intestines.

The technique of rivanol administration is described by Urchs.³ A preliminary cleansing enema being first given, 500–800 c.cm. of rivanol solution are run in slowly at body temperature and retained as long as possible, for at least 15 minutes. Peter considered the rectal method unsuitable in certain

cases with high bowel infection, and therefore commenced the oral method of medication, and gives a description of 34 cases so treated.⁴ He found that on an average the patients so treated were amœbæ-free after four days, or at least no amœbæ could be found in the stools after this period, even with provocative medication followed by repeated daily examinations of the stools. The usual total amount necessary for cure in adults was found to be 0.843 g. of rivanol. Apart from the lethal action on the entamœbæ, a marked antispasmodic and anæsthetic property was observed, even more so than when the drug had been administered per rectum. Tenesmus soon disappeared, stools returned to normal, and all abdominal and colon tenderness subsided. The course of treatment recommended was to commence as soon as the diagnosis had been confirmed by giving a dose of Carlsbad salts; this was to be followed by 0.03-0.05 g. of rivanol every two hours until the second day, after which this dose was given three times a day for six to eight days. If, clinically and microscopically, marked improvement set in early this dose could be reduced; on the other hand, where diarrhoea and tenesmus persisted to the second or third day of treatment extra dosage was recommended. The highest dose used by Peter was 0.2 g., no ill-effect being observed. In chronic obstinate cases a second course for the sake of certainty was advised after an interval of a week. In a further communication⁵ Peter describes the results of treatment in cases of enteritis and enterocolitis in which no definite causative agent could be discovered, the result in these cases being usually satisfactory, even in various diarrhoeas of infants.

Experimental work on rivanol was undertaken by Wagner⁶ in order to ascertain whether the drug attacked and destroyed *E. histolytica* or whether it merely exercised a restraining influence on the secondary infections caused by the accompanying micro-organisms. Observations were accordingly made both in vitro and in living animals. In vitro, rivanol proved to be the strongest direct amœbicide, a solution of 1:100 causing death of the amœbæ in 24 hours; in dilutions of 1:2000 the action began to fail. Yatren and emetine had to be used in strengths ten times that of rivanol in order to destroy the amœbæ in culture. In living animals (infected cats where the infection follows a very acute and serious course) the results agreed with those in vitro, a solution of 1:1000-1:1250 alleviating the course of the disease and in some cases completely healing the bowel infection. He considered the action to be a direct lethal one on the amœbæ.

Schaumann⁷ demonstrated experimentally the spasmolytic action of rivanol, the colon of the living rat being found most suitable for this purpose. In order to observe the mode of action of the drug, pilocarpine (a nerve stimulant) and barium (chiefly a muscle stimulant) were used, the resultant spasm being relieved by rivanol and papaverine, and the results compared. Finally, experiments were carried out on the hypertonic bowel of rabbits suffering from advanced tuberculosis. He found the action of rivanol to be quite as strong as that of papaverine, the most effective dilution being 1:100,000. Rivanol in dilute solution was found to have a neutralising effect in the spastic hyperexcitability of the bowel, this action being due to an inhibitory effect on the sympathetic nerves. In large doses rivanol was shown to have, in addition to this action through the sympathetic nerves, a direct paralysing action on the bowel muscle, similar to the action of papaverine. He administered the drug to cats in doses of 5 mg. per kg. of body-weight per day during a period of four weeks without any ill-effect, thus showing that the oral route is apparently a safe method of administration.

Recently Weitzmann⁸ has reported the use of the drug in four cases of amebic dysentery, oral administration being employed in doses of 0.05 g. four times in the 24 hours for a period of six days. At the end of the six days' treatment the number of stools was found not to have diminished and the vegetative

forms were still present and actively motile. He concludes from his series of cases that the brilliant results obtained by Wagner, Schaumann, and Peter in the treatment of dysenteries had not been confirmed.

Manson-Bahr⁹ considers that rivanol injected per rectum in a strength of 1:2000 may produce results similar to those obtained by yatren, and recommends that ten or more such injections should be made in order to obtain satisfactory results.

Results Controlled by Sigmoidoscopy.

Investigations have been carried out by us in a series of cases of amebic dysentery of different degrees of severity, the diagnosis in each case being confirmed by the finding of actively motile *E. histolytica* either in the discharge from the intestine examined fresh in the ward and in the laboratory or through the sigmoidoscope by means of Volkmann's spoon. Scrapings being thus obtained direct from the base of the amebic ulcers. In two of the cases (Nos. 1 and 12) where repeated examination of the fresh stool had failed to demonstrate the entamœbæ, typical ulcers were seen through the sigmoidoscope, and scrapings produced numerous actively motile entamœbæ, emphasising the importance of this method of investigation in arriving at a correct diagnosis in cases complaining of symptoms of dysentery. Careful note was also made of the appearance of the ulcers through the sigmoidoscope before treatment was commenced, and weekly or more frequent examinations by this method were carried out during the course of treatment, so as to observe visually the effect of rivanol on the bowel lesions. The stools were also inspected daily in the bed-pan, the time of disappearance of the mucus and blood being noted, and the length of time taken for the diarrhoea and tenesmus to subside observed. During treatment the patients were kept on milk diet until symptoms had subsided, after which the diet was gradually increased. The patients were all male.

Résumé of Cases.

CASE 1, a man from Kaliub, aged 23, complained of diarrhoea four times daily with blood, mucus, and tenesmus of three years' duration with sudden onset. The stools were negative for amœbæ by microscopic examination, but found positive in material obtained by spoon-scraps through the sigmoidoscope, which demonstrated small depressed amebic ulcerations. This patient was put on rivanol, one capsule (0.025 g.), three times daily for 17 days, but although the stools became normal in appearance after a few days on rivanol, yet on the thirteenth day of treatment the sigmoidoscopic picture showed the same amebic ulcers and a spoon-scraps was still able to demonstrate the presence of living amœbæ. Three days after stopping rivanol the sigmoidoscopic picture of the gut had improved, the ulcers gradually diminishing in size, so that after three weeks they could no longer be seen. Entamœbæ could not now be demonstrated either by the scrapings through the sigmoidoscope or by microscopic examination of the stools, but we were not satisfied that the case was cured, as there were still areas of hyperæmia in the gut, and also much sticky mucus. The patient was discharged, but on reporting again after two months he was found to be suffering from symptoms of dysentery. The sigmoidoscope now showed typical amebic ulcers and the stools contained living amœbæ. He was put on a course of yatren treatment.

CASE 2, aged 60, was admitted to hospital complaining of diarrhoea, tenesmus, and loose yellowish stools with blood and mucus of four days' duration, the disease starting suddenly. Living *E. histolytica* were detected in the stools. The sigmoidoscope showed much mucus sticking to the bowel wall; underneath it were patches of normal mucous membrane, separating large depressed ulcerated areas. Scrapings contained living amœbæ. The patient was put on rivanol, one capsule (0.025 g.), three times daily, for a week. On the fourth day of treatment tenesmus disappeared and blood and mucus became scanty from the third day. The sigmoidoscopic picture after a week's treatment showed a slightly cleaner appearance of the ulcers. Rivanol was then increased to two capsules three times daily for a week, after which further slight improvement had occurred in the sigmoidoscopic appearance. Amœbæ disappeared from the stools on the tenth day of treatment; blood and mucus had disappeared by the end of the second week. Rivanol was given for a third week in increased dose—i.e., three capsules thrice daily—and during this week the stools continued to be

quite normal in appearance with no amœbæ, even on scraping through the sigmoidoscope. On the completion of this intensive three weeks' course of rivanol the sigmoidoscope showed the ulcers still there, but even a scraping failed to discover living amœbæ, only dead amœba-like bodies being seen. Rivanol was then discontinued for one week, after which the picture of the ulcers had improved, but a spoon-scraper now demonstrated the presence of living entamœbæ. The patient was then put on a course of emetine and stovarsol.

CASE 3, aged 35, was admitted to hospital complaining of diarrhoea 20 times daily, and tenesmus, with blood and mucus in the stools. The history of the onset was sudden, and the duration of the complaint was 45 days. The stools contained living *E. histolytica*, trichomonas, and pus cells. The blood showed a leucocytosis of 13,800. The sigmoidoscope revealed two or three elevated patches of mucous

put on yatrien enemata and stovarsol, but he died a week later from right lobar pneumonia.

CASE 5, aged 45, was admitted complaining of diarrhoea, 20 times daily with blood, mucus, and tenesmus. These symptoms had lasted five months, the onset being sudden, but he stated that he had had frequent previous attacks. His liver was tender and he had chronic nephritis with general weakness, œdema of the legs, puffiness of the lids, dyspnoea, and cough. Living *E. histolytica* were found in the stools. On sigmoidoscopy, the large gut was found very patulous, while the mucous membrane showed many depressed hæmorrhagic areas and small punched-out ulcers. The mucous membrane in between was coated with mucus which could easily be swabbed away, exposing healthy mucous membrane underneath. Rivanol, one capsule (0.025 g.) by mouth, was given thrice daily. After two weeks' treatment much the same sigmoidoscopic picture

TABLE SHOWING RESULT OF TREATMENT BY RIVANOL IN AMEBIC DYSENTERY.

No.	Amebic ulcers seen by sigmoidoscopy.	Entamœbæ present in sigmoidoscopic scrape.	Entamœbæ in stools (lab. or ward).	Treatment (rivanol in grammes).	Result of treatment.
1	+	+	-	0.025 t.d.s. 17 days.	Relapse after 2 months entamœbæ + ulcer present.
2	+	+	+	0.025 .. 1st week.	After a week's rest entamœbæ present in stools.
3	+	+	+, also trichomonas.	0.025 .. 2nd ..	
4	+	+	+, also trichomonas.	0.025 .. 3rd ..	After a week's rest entamœbæ +.
5	+	+	+, also Lambliæ.	0.025 .. 1st ..	Stools showed entamœbæ.
6	Very small ulcer.	+	+	0.025 .. 2nd ..	Stools still + for entamœbæ.
7	Small ulcer +.	+	+	0.025 .. 3rd ..	Do.
8	+	+	+	0.025 .. 10 days.	Stools + for entamœbæ.
9	One small ulcer.	+	+, also Lambliæ.	0.025 t.d.s., enema 1:10,000 (1 week, then enema stopped) continued per os	Entamœbæ- and ulcers healed.
10	Normal membrane, only sticky mucus.	-	+	0.025 t.d.s. 1st week.	Relapse 2 months later with large ulcers and many amœbæ.
11	Very small ulcer. +	+	+, also Morgan.	0.025 .. 2nd ..	Ulcer healed. No symptoms for 6 months.
12	+	+	-	0.025 .. 20 days.	Negative entamœbæ still negative 2 months later.
13	Punched out ulcers + diffuse inflammation.	+	+, also Flexner.	0.025 .. 10 ..	Do.
				Enema 1:2000, stopped after 1 week local irritation. Rivanol 0.025 t.d.s. 9 days' wash 1:10,000 m.c. 5 days.	Local irritation compelled stoppage of treatment. Same appearance of ulcers as on admission. Entamœbæ still present.

AVERAGE DURATION OF SYMPTOMS AND SIGNS AFTER STARTING RIVANOL TREATMENT.

	Blood.	Mucus.	Diarrhoea.	Tenesmus.
Days	3.3	3.3	5	3

hæmorrhagic material which, on being swabbed away, revealed small amœbic ulcers underneath. Rivanol, one capsule (0.025 g.), was given thrice daily, the latter disappearing entirely on the fifth day. After a week of this treatment the sigmoidoscopic picture remained the same. Rivanol was then increased to two capsules three times daily by mouth for another week, after which the ulcers were seen to be somewhat smaller, but the scrapings still contained *E. histolytica*. Rivanol was further increased to three capsules (0.075 g.) thrice daily. Next day the blood and mucus had disappeared, and no amœbæ were found in the stools. At the end of the third week, after the completion of this intensive rivanol course, the sigmoidoscope still showed ulcers, but scrapings from these only demonstrated immobile amœba-like bodies. Rivanol was then stopped for one week, at the end of which time the same ulcers were seen on sigmoidoscopy and material obtained by scrapings now contained living *E. histolytica*. A course of emetine and stovarsol was then given.

CASE 4, aged 40, was admitted to hospital complaining of diarrhoea, five to seven times daily, with blood, mucus, and tenesmus of two months' duration. The onset of the disease was gradual. The stools contained blood and mucus, and the microscope revealed *E. histolytica* and Lambliæ. Sigmoidoscopy showed depressed square-shaped hæmorrhagic ulcers, with healthy mucous membrane in between. Rivanol one capsule (0.025 g.), thrice daily, was given for ten days by mouth, after which time the stools still contained *E. histolytica*. Rivanol was stopped and the patient was

was seen, the mucous membrane being studded with small punched-out ulcers having yellowish bases in some and hæmorrhagic spots in others. The rivanol treatment was continued for 18 days, after which the sigmoidoscopic picture had improved somewhat. The stools looked normal in appearance, but living amœbæ were still present. Stovarsol was therefore started, and 12 days later sigmoidoscopy showed a normal mucosa, and scraping was negative for amœbæ.

CASE 6, aged 42, complained on admission to hospital of diarrhoea 10 to 12 times daily with blood, mucus, and tenesmus. These symptoms had commenced gradually ten days previously. The stools were liquid, containing blood, mucus, and living *E. histolytica*. Through the sigmoidoscope, tiny elevations with central pits were observed, and with the aid of the magnifying glass they were seen to be very early amœbic erosions, very little ulceration having yet taken place. Rivanol, one capsule (0.025 g.), three times daily, was given by mouth for ten days, on the fourth day of which treatment blood, mucus, and tenesmus had disappeared. The stools became solid on the seventh day. Amœbæ had disappeared from stools by ordinary microscopic examination without scrapings by the ninth day of treatment. On the tenth day tenesmus disappeared, and the sigmoidoscope revealed small areas indicating amœbic infection of the bowel wall. Material by scraping was positive for *E. histolytica*. The patient was then put on stovarsol.

CASE 7, aged 27, complained on admission to hospital of diarrhoea seven times daily with blood, mucus, tenesmus,

and colicky pains. The onset had been gradual and the condition had persisted for two years. The stools, in addition, to mucus and blood, contained living *E. histolytica*, and the mucous membrane on sigmoidoscopy showed small circular hemorrhages and tiny punched-out ulcers, with here and there some blood-stained mucus adhering in the bowel wall. Scrapings under the microscope showed living amebæ. The patient was put on rivanol, one capsule (0.025 g.), thrice daily by mouth, and rivanol rectal enema 1:10,000 retained as long as possible. One week later, through the sigmoidoscope, the same picture was seen with some super-added inflammation and sticky mucus low down in the gut, probably the result of irritation from the rivanol enema which were then stopped. After 12 days of rivanol per os the mucous membrane still looked unhealthy with sticky mucus. Rivanol was stopped and an emetine course given, and under this treatment the ulcerations disappeared.

CASE 8, aged 45, was treated as an out-patient, and attended in the ward every week for observation. He complained of attacks of diarrhoea with tenesmus, mucus, and blood in the stools, these symptoms coming and going irregularly throughout a period of six months. The first attack came on suddenly, the average daily number of motions being seven or eight. The stools contained mucus and blood. Microscopical examination revealed the presence of living *E. histolytica*. The sigmoidoscope showed scattered, depressed amebic ulcerations with healthy mucous membrane in between; spoon-scrapings contained living entamebæ. The patient was given one capsule of rivanol (0.025 g.) thrice daily for the first week and two capsules thrice daily for the next two weeks. Tenesmus disappeared on the second day of treatment, and on the third day the stools had regained their normal appearance and consistency, and blood and mucus had disappeared. After the first week of rivanol treatment the sigmoidoscope showed much improvement in the ulcers, and entamebæ were not found by a spoon-scraps. A week later the mucous membrane appeared quite healthy, and continued so through the following weeks. When the patient was seen a month later, after stopping the rivanol, he did not complain of anything, and the sigmoidoscope showed a normal mucosa. The patient reported, two months after completion of the rivanol treatment, with a return of his dysenteric symptoms; the sigmoidoscope then revealed extensive amebic ulcerations, and active *E. histolytica* were seen under the microscope. He was put on yatren treatment.

CASE 9, aged 28, was admitted to hospital with severe anemia and diarrhoea of one month's duration without blood or mucus, but with tenesmus. The onset of the diarrhoea was gradual and the number of the stools varied from seven to ten a day. The stools were loose and pale in colour. No naked-eye mucus or blood was seen, but the immediate examination in the ward and later in the laboratory revealed the presence of living *E. histolytica*. The sigmoidoscope showed a healthy mucous membrane except for the presence of a little depressed hemorrhagic ulcer 20 cm. up. The patient was put on rivanol capsules by the mouth (each 0.025 g.), one capsule thrice daily for 20 days. On the twelfth day of treatment the diarrhoea had disappeared. On the last day of rivanol treatment the patient showed by sigmoidoscope a normal mucosa. He was put on ferrum reductum for his anemia, and when seen six and a half months later he did not complain of any symptom. The sigmoidoscope then showed a few hemorrhagic spots low down in the gut, but the material obtained by the spoon did not show any *E. histolytica*.

CASE 10, aged 40, was admitted to hospital complaining of colicky pains in the abdomen, tenesmus, and diarrhoea with mucus and blood, lasting for five months. The onset of the disease was gradual, the number of stools being 12 to 15 a day. The naked-eye examination of the stools showed the presence of blood and mucus. Immediate examination in the ward and later in the laboratory revealed the presence of *E. histolytica*. No amebic ulcers were seen by the sigmoidoscope, the mucous membrane appearing normal except for some mucus sticking to it; bleeding was readily produced during the passage of the sigmoidoscope. The patient was given rivanol by the mouth, one capsule (0.025 g.) thrice daily for ten days. On the second day of treatment the diarrhoea dropped from 12 times to an average of three times daily. On the fourth day the appearance of the stools was almost normal, and on the fifth day tenesmus had ceased and blood and mucus were absent; by the tenth day the stools were quite solid and normal in appearance. Examination of material obtained by spoon-scraps before the patient was discharged did not show any living *E. histolytica*. Re-examined two and a half months later, he complained of no symptoms, and the sigmoidoscopic picture showed only a moderately congested mucosa, scrapings being still negative for *E. histolytica*.

CASE 11, aged 45, was admitted to hospital complaining of diarrhoea, colicky pains in the abdomen, tenesmus, and blood and mucus in the stools. The onset was gradual and the duration of the symptoms only five days. The patient passed three to four motions daily. The stools were liquid and contained blood and mucus and living *E. histolytica*. Morgan's bacillus was also isolated on culture. The sigmoidoscope showed abrasions in the mucosa and also small depressed pits with slightly elevated inflamed rims. The patient was given rivanol, one capsule (0.025 g.) thrice daily for nine days. Diarrhoea, tenesmus, blood, and mucus disappeared on the third day of treatment, and by the fifth day the stools had regained their normal appearance. After the course was completed the picture of the gut did not reveal any abnormality to the sigmoidoscope on several occasions. The patient was seen two and a half months later, complaining of no symptoms. The sigmoidoscope showed no ulcerations, and the spoon-scrapings were negative for *E. histolytica*.

CASE 12, aged 18, was admitted to hospital complaining of diarrhoea, with blood, mucus, and tenesmus for 40 days. The onset of the disease was sudden, the number of motions varying from two to eight a day. The patient gave a history of relapses during the preceding five years. Small, scattered, punched-out yellow ulcers and hemorrhagic depressed areas were seen through the sigmoidoscope, with healthy mucous membrane in between. The patient was put on rivanol wash by rectum in a strength of 1:2000 daily, but this was stopped after a few days owing to his complaint of local irritation, intense inflammation being seen by the sigmoidoscope. The patient was then put on stovarsol treatment.

CASE 13, aged 10, was admitted markedly emaciated, complaining of diarrhoea with blood, mucus, and severe tenesmus. The onset of the disease was sudden, commencing 16 days previously. The daily number of motions was four. The stools were mixed with blood, mucus, and pus. Living *E. histolytica* were detected in the stools in the ward and laboratory, and *B. dysenteriae* Flexner was also isolated on culture. The sigmoidoscopic picture showed numerous punched-out ulcers typical of amebic dysentery. The mucosa between these amebic ulcers was moderately congested, bleeding readily, and covered with blood-stained mucus, an appearance typical of bacillary dysentery. The patient was put on rivanol capsules (0.025 g.) thrice daily for nine days and rivanol enema 1:10,000 twice daily for the same period; at the end of it the same punched-out ulcers were still seen in the gut, and amebæ were seen microscopically.

In only three cases (Nos. 9, 10, and 11) have we been able to obtain results that may be looked upon as satisfactory; the period of observation in these three cases, however, is much too short for anything like a cure to be claimed. No. 9 has been free from symptoms and has shown no pathological sigmoidoscopic changes during a period of six and a half months, while Nos. 10 and 11 have only been observed free from symptoms for two and a half months. The bowel lesions in these three cases were very slight from the first, No. 10 appearing normal sigmoidoscopically. In all the other cases in our series, except No. 12 where treatment had to be discontinued owing to local irritation, adequate doses of rivanol were administered over a sufficiently long period, but within a short time of the termination of the treatment actively motile *E. histolytica* were readily demonstrated in the material obtained from the intestines. In one case (No. 8) the ulcers were observed to heal during rivanol treatment and symptoms to disappear, but a relapse occurred two months later, when large amebic ulcers were again seen in the lower bowel and actively motile entamebæ were demonstrated microscopically. In three cases (7, 12, and 13) rivanol enema were employed. A strength of 1:2000 was found to produce marked local irritation both subjectively and as seen through the sigmoidoscope. A strength of 1:10,000 was used in Cases 7 and 13 in addition to rivanol orally (0.025 g. thrice daily) given at the same time. Even this combination did not effect a cure. Very large oral doses were given in Cases 2 and 3, rivanol 0.025 g. thrice daily being given for the first week, 0.05 g. thrice daily for the second week, and 0.075 g. thrice daily for the third week. No toxic symptoms resulted from these large doses but entamebæ still persisted after the completion of the course.

Relief of Symptoms by Rivanol.

The symptoms of diarrhoea, tenesmus, and passage of blood and mucus were very greatly relieved during the rivanol treatment and, as a result, these patients experienced very considerable comfort. The first symptom to be relieved was tenesmus, which was found to disappear in an average of three days from the commencement of the treatment. Naked-eye blood and mucus next disappeared from the stools, this taking place in an average of 3-3 days; the stools, however, did not regain their normal consistency until, on an average, five days after the commencement of the rivanol treatment.

The relief of symptoms in these cases is doubtless due to the anæsthetic and antispasmodic properties of the drug. The cleansing and healing effect observed on the ulcers is probably due to the antiseptic action of the drug on the superadded infection. There seems unfortunately to be only a very mild specific lethal action on the entamoebæ themselves, as in most cases, after a short period of rest from the treatment, actively motile entamoebæ can again be readily demonstrated.

The drug has been employed by us for its sedative action in cases of rectal bilharziasis where tenesmus has been a marked and troublesome symptom.

Conclusions.

Rivanol administered as a local application rectally has been found to be irritating to the mucosa in a concentration of 1:2000, marked hyperæmia of the rectal mucous membrane as viewed through the sigmoidoscope having resulted. In a dilution of 1:10,000 no lethal effect on the entamoebæ has been noted.

Rivanol administered orally, even in doses as high as 0.075 g. thrice daily, has not been found to produce any toxic effects on the individual nor has it been observed to have any markedly lethal action on the entamoebæ. In only three very mild amœbic infections were we able to get rid of the dysenteric symptoms and free the bowel from *E. histolytica* for any considerable period. All our other cases soon showed a return of the symptoms and their intestines were found still to harbour active vegetative forms of *E. histolytica*, either immediately or shortly after discontinuing the drug. Marked relief from symptoms was, however, experienced in most cases during the course of treatment, tenesmus, blood, mucus, and diarrhoea soon disappearing, usually to return shortly after stopping the rivanol.

We consider that the antispasmodic and antiseptic action of the drug may with advantage be utilised for the relief of colic and tenesmus, and for assisting in cleansing the bowel of some of the superadded infection in various dysenteric conditions where lower bowel symptoms are a marked feature of the disease.

We wish to express our thanks to the following house physicians for their assistance in carrying out the investigations on these cases: Dr. Nishokaty, Dr. Shukry, and Dr. Fikry.

MOTOR ACCIDENTS AT ALTRINCHAM.—The General Hospital at Altrincham, in mid-Cheshire, stands upon a road much used by motor traffic, and consequently receives many accident cases. In 1929 it took in 150 sufferers from road accidents, who stayed for a total of 3039 days; one of them occupied a bed for 11 months, and others remained for eight and nine months.

THE ORAL INJECTION OF LIPIODOL

AS AN AID TO THE DIFFERENTIAL DIAGNOSIS OF UPPER LOBE BRONCHIECTASIS AND PULMONARY TUBERCULOSIS.

By W. BURTON WOOD, M.D. CAMB.,
M.R.C.P. LOND.,

PHYSICIAN TO OUT-PATIENTS, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK.

The clinical picture in a case of well-marked basal bronchiectasis is usually clearly defined. The characteristic odour of the breath, the copious purulent sputum, the clubbed fingers, and the physical signs of consolidation and excavation make diagnosis easy. When, however, an upper lobe is the seat of the trouble the resemblance to the chronic fibroid type of pulmonary tuberculosis may be close, even when the disease has reached an advanced stage. In such a case the erect position ensures continuous drainage which is more effective than that obtained by occasional posturisation such as is practised by sufferers from basal disease. The sputum is less copious and may be inoffensive. There is less constitutional disturbance and there may be no clubbing of the fingers. The added sounds may have a dry quality compared with the bubbling râles due to accumulated secretion. Apart from the absence of tubercle bacilli in the sputum a diagnosis of pulmonary tuberculosis would seem justified. Difficulties in diagnosis are overcome by the use of lipiodol, and its administration by the oral route in suitable

FIG. 1.

Bronchiectasis of the right upper lobe before the injection of lipiodol.

cases provides the easiest means of arriving at a correct solution.

A woman aged 28, a clerk, first visited the out-patient department at Victoria Park Hospital in 1921, complaining of cough. She attended for some months. There was a history of pneumonia in infancy and the case was regarded as one of pulmonary fibrosis. No tubercle bacilli were found in the sputa. In 1924 she attended the tuberculosis dispensary attached to the hospital on account of chronic cough and blood-stained expectoration. The physical signs were consistent with a diagnosis of chronic phthisis; there was impairment of the percussion note over half of the right side of the chest, in the same area. But the

tubercle bacilli, and though the case had been notified as tuberculous, Dr. H. T. Howell was not prepared to accept this diagnosis. She continued to attend the dispensary at intervals during the next six years owing to frequent re-notifications elsewhere. (T.B. O, 1924 (4), 1925 (1), 1927 (1), 1930 (2)). Cough persisted but there was no deterioration in the patient's general condition, and the weight remained constant.

In February, 1930, the patient's panel doctor noted an apparent extension of the signs of disease in the right lung. On account of this she was sent to a general hospital where a skiagram was taken. The radiologist reported that there was evidence of chronic phthisis of both lungs and the patient was again referred to the dispensary. It was at this stage that Dr. Howell, who was not satisfied with this explanation of the condition, asked me to see the patient. The physical signs in the chest, noted above, had persisted while harsh breathing heard below the right clavicle indicated that there was probably cavitation in this region. A skiagram taken at Victoria Park showed numerous linear shadows radiating upwards to the level of the clavicle and outwards to the periphery. The appearances were those associated with extensive fibrosis of the right upper lobe. The lower half of the lung field showed no abnormality. In view of the history of the case, the physical signs and X rays, a tentative diagnosis of bronchiectasis of the right upper lobe was made (Fig. 1). After a preliminary test for iodine intolerance an injection of lipiodol was administered by the oral route on March 20th. A skiagram taken immediately after the injection showed that the whole of the right upper lobe was riddled with cavities, the bronchi of the lower lobe being normal (Fig. 2). A further skiagram taken in the erect position showing clearly defined fluid levels indicated the presence of some forty cavities. The picture was quite unlike that seen in fibroid phthisis and the diagnosis of bronchiectasis was thus confirmed (Fig. 3).

The injection of lipiodol by the oral route is seldom practised in this country, but in selected cases it is

FIG. 2.

After the injection: patient in the prone position.

a method suitable for out-patient work, since it dispenses with the need for tracheal puncture and the injection of cocaine. A brief note on the technique of this method may therefore be of service.

The method is unlikely to succeed and should not be attempted when the patient is a child. A measure of intelligence and a willingness to coöperate on the part of the patient are also essential. Further, unless a clear view of the pharynx is obtained when the mouth is widely opened and the tongue extruded it is useless to inject by the oral route. In the absence of these contra-indications success may be expected in a considerable proportion of cases. If the method fails injection by the cricothyroid

route is indicated, and for this admission to hospital, though not essential, is desirable.

The confidence of the patient having been gained, he is instructed to take hold of the tongue with a dental napkin and to draw it well forwards and slightly downwards, keeping the mouth as widely open as possible. In this posture deep breathing through the mouth must be practised several times a day for a few days preceding the injection. With

FIG. 3.

After the injection: patient erect.

a little practice the patient will overcome the initial discomfort of the position.

For the injection the patient lies upon an operating table, supporting the head upon the right or left arm in such a way that the side of the chest to be injected is inferior, and leans upon the corresponding elbow. The attitude thus resembles that of a guest at a Roman banquet, and has been described by Dr. J. J. Singer as "the Cleopatra position." The foot of the table is now slightly lowered. A 20 c.cm. syringe fitted with a straight cannula 10 cm. in length and 2 mm. in diameter is filled with warm lipiodol. The proximal end of the cannula is steadied against the upper jaw of the patient, and the distal end projected into space between the tonsil and the uvula. It is obviously important to avoid touching the palate, pharyngeal wall, or tongue if retching is to be avoided. Injection of a few drops of oil is made during each inhalation with pauses during expiration. If this precaution is neglected oil will be blown into the mouth by the force of the expired air. Two or three minutes should suffice for the injection of 20 c.cm. If the injection is proceeding satisfactorily a slight gurgling sound will indicate that the oil is passing down the trachea. (A completely silent injection is evidence that the patient is swallowing the oil, a fact which may be verified later by X ray examination of the stomach.) Directly this has been accomplished the table is tilted head downwards to the full extent to ensure the flow of oil to the summit of the lung. The patient is then taken on a stretcher to the X ray department, remaining in a horizontal position till the first skiagram has been taken.

My acknowledgments are due to Dr. H. T. Howell, senior tuberculosis officer for Bethnal Green and Hackney, who kindly brought to my notice the patient whose case is described, and supplied notes on the past history.

A NEW TECHNIQUE COMBINING THE USE OF SURGERY AND RADIUM IN THE TREATMENT OF CANCER OF THE BREAST.

By W. TURNER WARWICK, F.R.C.S. ENG.,
SURGEON TO OUT-PATIENTS, MIDDLESEX HOSPITAL.

THE objective aimed at in the radical treatment of cancer of the breast is the complete removal or destruction of the growth, however far it may have extended. The success of any procedure depends on its capacity for dealing with all-important paths of spread. These are grouped as follows:—

1. *Local growth*, spread along the tissue spaces and through the alveoli and ducts themselves.
2. *Lymphatic dissemination*. (a) Growth along lymphatic plexuses lying on fascial planes; (b) growth along lymphatic channels lying along vessels; (c) embolus along lymphatic ducts.
3. *Blood spread*. (a) After advanced lymphatic invasion; (b) early, after embolus following direct invasion of venous channels.

Complete cure can only be hoped for in those cases where lymphatic dissemination is limited. If blood spread has occurred, whether clinically recognisable or not, the growth is beyond cure by local treatment.

The procedures at present in use in dealing with carcinoma of the breast may be grouped as follows:—

- (1) Surgery alone—extensive radical amputation.
- (2) Radium (or radon) alone, with needles, using Keynes's technique.
- (3) Radium and surgery.
- (4) Radium bomb.

The comparative claims of the first two procedures are those on which general attention is at present focused. In a well-planned surgical operation the local infiltration is removed and an attempt is made by wide excision of fascia to eradicate the growth that has spread by permeation. Lymphatic spread, however, can only be dealt with to the limited extent that a careful clearance of the axilla affords. With radium alone destruction of the local growth is not so certain, but a more definite attack is made on the line of spread into the supraclavicular triangle and into the anterior extremities of the upper intercostal spaces.

The results obtained by Sampson Handley in his recent cases¹ show an improvement on those of his previous series which, he suggests, may be due to the addition to his technique of inserting radium in the supraclavicular fossa and in the anterior extremity of the intercostal spaces.

The possible limits of the application of radium to the lymphatic spread have not yet been explored. Observations in the post-mortem room of advanced cases of cancer of the breast show that, where lymphatic spread has been slowly progressive, the upper intercostal spaces on the affected side, looked at from the pleural aspect, are frequently outlined by growth throughout their whole extent and the supraclavicular region is infiltrated by it. The growth could reach these intercostal spaces either through the anterior extremities or laterally, as in both these situations vessels and accompanying lymphatics perforate the external intercostal muscle. It is not as yet certain whether we are justified in regarding the spread along the intercostal spaces as occurring chiefly forwards or backwards, although it has been generally assumed that it occurs chiefly towards the spine.

Certain experiments made in the Bland-Sutton Institute with the Brown-Pearce tumour, which has both lymphatic and blood spread, may have some bearing on this question of direction of spread in the intercostal spaces. Inoculations of an emulsion of this tumour into the intercostal muscles of two rabbits have on each occasion shown little spread backwards but have produced growth in the anterior mediastinum massive enough to cause marked pressure effects. Further investigations are being made.

In view of our limited knowledge of spread along this path the only safe course is to assume spread from both directions. The intercostal spread, therefore, has been dealt with by the insertion of radium needles between the intercostal muscles of the upper five or six spaces from the anterior extremity to a point posterior to the egress of lateral nerves. Only when a radical breast operation has been performed can radium be placed accurately between the intercostal muscles and in the desired situations in the axillary and supraclavicular spaces.

Investigations as to the immediate results of such a combined technique have been made, and this report is based on the results of a short series of unselected cases under my care during the six months from the middle of December, 1928, to the middle of June, 1929. Since that time, owing

FIG. 1.

Diagram showing position of needles.

to the shortage of radium in the Middlesex Hospital through rearrangement of tubes, the work has been interrupted, but the cases have been reviewed within the last month for the purpose of this preliminary report.

Technique of the Operation.

Operation, apart from the preliminary skin incision and dissection of the axilla, has been carried out with the diathermy knife. (It is essential that charring on the inner surface of the reflected skin flap be minimal, and if the diathermy is not working well it is better to resort to the scalpel.) In cases associated with ulceration and fungation the affected area is cauterised by diathermy before the reflection of skin flaps. If this cauterisation is carried out efficiently and the spread is not too extensive, the ordinary radical operation is performed but, if efficient cauterisation is impossible, if the growth is obviously too far advanced, or if marked sepsis is present, an extensive operation is contra-indicated and the operation and radium insertion are both modified.

A skin incision widely encircles the growth and skin flaps are reflected to the clavicle, the opposite side of the sternum, the epigastric angle, and posteriorly beyond the anterior border of the latissimus dorsi.

¹ Handley, W. S.: Surg., Gynecol., and Obst., 1927, xlv., 721.

This is followed by removal of a wide area of fascia, including that covering the upper portion of the rectus and the clavicular part of the pectoralis major, the sternal head of the pectoralis major, and the pectoralis minor. Finally, the axillary glands are dissected out. The lateral thoracic nerve branches are left long at first as a guide to the insertion of the long posterior intercostal needles.

Radium is then inserted along the possible directions of spread beyond the limits of operation.

The following is the general distribution (Fig. 1), minor modifications being made according to the site of the tumour.

A. One 1.5 mg. (2 cm. long) needle above the first rib anterior to and below the axillary vein after clearing out the minute pocket in this situation.

B. Two 3 mg. (4 cm. long) needles above the clavicle. These are inserted through the skin of the supraclavicular triangle with a guiding finger in the axilla protecting the plexus and vessels.

C. Four or five 2.5 mg. (3 cm. long) needles on each side into the anterior extremity of the upper four or five intercostal spaces. On the side of the operation they are placed between the intercostal muscles, and on the opposite side they are inserted through the skin after closure of the wound.

D. Ten or twelve 3 mg. (4 or 6 cm. long) needles between the intercostal muscles of the upper spaces, covering the chest wall between the sternal needles and the points of exit of the lateral thoracic nerves.

E. Four or five 3 mg. (4 or 6 cm. long) needles directed posteriorly between the intercostal muscles in the upper spaces from the points of exit of the lateral cutaneous nerves. In the first space a shorter needle may be used.

F. Four 3 mg. (4 cm. long) needles in the axilla, two anterior to the plexus, stitched to the posterior surface of the clavicular head of the pectoralis major with fine plain catgut and two behind the plexus, stitched to fascia over the subscapularis.

G. Two or three 3 mg. (4 cm. long) needles are stitched in the epigastric angle.

With C, D, and E the needle point must be seen to be raising the thin external intercostal muscle while it is being inserted beneath it.

The threads attached to the needle are drawn through the line of skin suture or through special stab holes made with a tenotomy knife. This insertion of radium adds 15 to 20 minutes to the time of a radical operation. The needles are removed a week later under gas and oxygen anaesthesia. Obviously care must be taken that the exit holes through the skin are so placed that the taut thread from the needle to them continues the direction of the needle.

FIG. 2.

Diagram of section of chest wall to show position of radium needles. S. = skin. E.I. and I.I. = internal and external intercostal muscles. P. = pleura.

Thread direction as in A will ensure easy removal and allow for slight displacement. With thread direction as in B the needle will be tilted during withdrawal with risk of damage to the underlying pleura. No force should be used in withdrawing the needle. If the slightest resistance is experienced a small stab through the skin on to the butt-end of the needle ensures safe removal.

The Case Reports.

The series consists of two groups: *Group A* comprises seven cases with full technique—i.e., complete radical amputation and full use of radium. Most of them showed very little reaction. Two or three developed diffuse erythema with an oedematous condition of the skin over the area of treatment. Three cases developed pain over the distribution of the inner cord of the brachial plexus. This pain remained for some months. These cases are at present all well and apparently free from recurrence at the end of a period

of from 7 to 13 months. *Group B* comprises three cases treated with modified technique, limited amputation, and modified use of radium. Two of these were advanced and ulcerated cases. One died as a result of sepsis following operation and one from distant metastases six months later with no signs of growth near the operation site.

The following are brief notes of the cases in the two groups:—

Group A.—1. Aged 60. Duration nine months. Rounded growth, $1\frac{1}{2}$ in. in diameter in region of nipple with some puckering of skin. Firm lymph glands $<\frac{1}{2}$ in. Moderate malignancy. Breast showed cancer histologically but glands nil. Operation December, 1928. Present condition (February, 1930): no symptoms and no evidence of recurrence.

2. Aged 69. Duration over a year. Rounded growth $1\frac{1}{2}$ in. in diameter in region of nipple. Attached to skin (much puckering) and to underlying muscle. Lymph glands firm $>\frac{1}{2}$ in. Low malignancy. Breast+, glands+. Operation, December, 1928. Present condition: no symptoms, no evidence of recurrence.

3. Aged 45. Abscess in breast 1914. Lumpy near site of old abscess for six weeks. Rounded growth $1\frac{1}{2}$ in. in diameter, situated near nipple, upper and inner quadrant. Attached to skin and causing elevation of nipple. Glands $>\frac{1}{2}$ in. High malignancy. Breast+, glands+. Operation February, 1929. Present condition: no symptoms, no evidence of recurrence.

4. Aged 41. Duration over 12 months. Complained of pain in arm and shoulder. Growth axillary tail $1\frac{1}{2}$ in. in diameter adherent to skin. Glands $>\frac{1}{2}$ in. firm. Moderate malignancy. Breast+, glands+. Operation April, 1929. Present condition: occasional slight pains in side and shoulder. No evidence of recurrence.

5. Aged 41. Duration: lump four months. Large growth 2 in. in diameter, axillary quadrant attached to skin and underlying fascia. Glands $>\frac{1}{2}$ in. Moderate malignancy. Breast+, glands+. Operation May, 1929. Present condition: no symptoms, no evidence of recurrence.

6. Aged 37. Duration: lump three years, rapid growth three months. Large mass in axillary quadrant, $2\frac{1}{2}$ in. in diameter. Wide skin involvement. Glands >1 in. Moderate malignancy. Breast+, glands+. Operation June, 1929. Present condition: no symptoms, no evidence of recurrence.

7. Aged 37. Large lump in outer and lower quadrant, attached to skin. Glands felt in axilla. Typical cancer on incision after operation. No pathological report on this specimen. Operation June, 1929. Present condition: occasional pain in wound and down inner side of arm. No evidence of recurrence.

Group B.—1. Aged 66. Duration 6 years. Nine months ulceration and discharge. Large irregular growth $3\frac{1}{2}$ in. in diameter, replacing breast and extending through muscle. Glands $>\frac{1}{2}$ in. High histological malignancy. Breast+, glands+. Operation December, 1928. Breast and pectorals removed, largest glands dissected from axilla. Edges of skin stitched to deep structures. Limited use of radium. Death from general toxæmia 21 days after operation.

2. Aged 46. Duration 3 months, 1 month ulceration and fungation. Enormous fungating mass replacing the left breast, 4 in. in diameter, fixed to muscle with hard glands >1 in. in axilla. Low malignancy. Breast+, glands+. Modified operation April, 1929. Edges of skin stitched to fascia, limited use of radium (16 needles). Returned in September, 1929, complaining of pain in back, right hip, and leg. Secondary deposits in vertebra and pelvis shown by X rays. No local recurrence. Death in October following paraplegia associated with pain in dorsal region.

3. Aged 49. Duration 18 months. Lump $\frac{1}{2}$ in. in diameter in lower and inner quadrant near periphery. Attached to skin and deep fascia. No glandular involvement. Moderate malignancy. Breast+, glands not found. Operation June, 1929, limited because of collapse of patient while skin flaps were being reflected. Thirty needles of radium. Present condition: no symptoms, no evidence of recurrence.

Note.—The figures indicating size refer to measurements of actual growth and of glands by the pathological department after incision.

Conclusion.

The series is small and the survival interval too short to allow any comparison of the efficiency of this with that of any other method of treatment of cancer of the breast. The results are presented for consideration because they appear to establish the possibility of a more extensive attack on local and lymphatic spread by the combined use of surgery and radium than can be achieved by either alone.

IMMUNISATION OF THE MALTESE GOAT BY MEANS OF CUTANEOUS VACCINATION.

By SIR THEMISTOKLES ZAMMIT, C.M.G., M.D.,

AND

J. E. DEBONO, M.D.

(From the Public Health Department, Valletta.)

IN December, 1928, an informal report was presented to the head of the Government by one of us (T. Z.) upon the continued and prevalent use of unboiled milk in Malta. In face of the widespread *Micrococcus melitensis* infection amongst the milch animals and the absence of administrative measures aimed at preventing the distribution of unsterilised milk, this report suggested that further methods must be sought for preventing the infection of milch animals, since none of the customary means of prophylactic vaccination had yielded practical results. It further pointed out that *M. melitensis* infection was readily produced through the damaged skin, and there was much evidence to show that milch animals, particularly goats, were commonly infected by this route, especially through the tender skin of the udders. Owing to their immoderate size, these organs are especially liable to become scratched and to come in contact with the urine of the infected animals. Hard fodder, accidentally impregnated with infective material, is probably another source of infection by wounding the mucous membrane of the mouth. Indeed, it is probable that when infected milk is consumed the actual site of infection is the buccal cavity itself and not the intestinal tract.

In view of these facts, Besredka's method of local cuti-immunisation might logically be expected to prove of value, and it was suggested that investigations in this direction would be useful. The suggestion was approved by the Government, and the Legislative Assembly voted the sum of £250 to defray the cost of preliminary experiments. The following is a summary of the work already carried out.

In planning our experiments our first object was to ascertain what measure of protection could be conferred on goats by simple dermal vaccination, and incidentally to ascertain whether *B. abortus* Bang could be substituted for *M. melitensis* in the preparation of the antigen, for the cultures of the latter organism are more dangerous to handle.

First Series of Experiments.

The antigen first used was prepared as follows:—

Nutrient broth (+8 Eyre's scale) was inoculated with a newly isolated culture of *M. melitensis* obtained from the Public Health Department and incubated at 37° C. for twenty-four days. At the end of this time the reaction of the broth had undergone a change to +2, and it became turbid owing to the luxuriant growth of the organism. It was then filtered through a Chamberland filter candle and the sterility of the filtrate proved by the absence of growth on agar subcultures. The same *melitensis* strain, when reinoculated into the filtrate, failed to develop. The antigen was completed by the addition of tricesol in a concentration of 0.6 per cent. Goats were exclusively employed in our experiments. They were kept in a cool, clean, and airy place; they were well fed and the rectal temperature was taken daily at 6 p.m.

Seven goats were employed in this series. On preliminary examination three of the animals gave a positive serum reaction. This was unfortunate, for it showed that the goats had been drawn from a tainted herd, and possibly the other goats, despite a negative serum reaction, might be in an initial stage of the infection. These three infected goats were at once replaced, but owing to pressure of time the new goats could not be kept under observation for more than a week, and later events made it probable that one of the fresh animals was incubating the disease during the experimental period.

Of the seven goats, one was retained as a control; the remaining six were each treated as follows:—

The belly was washed with soap and water and the base of the udder shaved with a safety razor. About 10 c.cm. of the filtrate were sprayed over the mammary area and into the mouth by means of an atomiser. One c.cm. was also injected intradermally in four places at the base of the udder. The treatment was repeated five times on alternate days. The blood-serum of all the goats was repeatedly examined for specific agglutinins, but none was observed except in one of the new goats, No. 6, referred to above, which gave a reaction of 1 in 100. It is improbable that this reaction was due to the treatment, since it was absent in the other goats, and we have every reason to suspect that it was due to an infection acquired before the goat came into our possession.

Two days after the last treatment all the goats, including the control, were inoculated subcutaneously with 1 c.cm. of an emulsion of living (virulent) *M. melitensis* (approximately 3000 millions). The milk of all the animals was plated every four days, and a specimen of blood was taken for hæmoculture every week. No untoward symptoms were noticed until the fourth day, when there was a sharp rise of temperature to 105° F. in the control. This persisted for three days, and then came down gradually. Eight days after inoculation the serum reaction of all goats became positive in dilutions varying between 1/80 and 1/100, but in the control it went up to 1/320. On the eighth day the organism was recovered in great abundance from the milk of the control, and persisted until the milk dried up completely four weeks after infection. In spite of repeated attempts, *M. melitensis* could not be obtained from the milk of the other goats, except once from No. 6, which, as already explained, was under considerable suspicion. Hæmocultures were negative except in the case of goat No. 3, which proved positive four weeks after infection.

Six weeks after infection all the goats were killed and a complete post-mortem examination was carried out. No gross pathological changes were observed. Portions of the spleen, kidney, and liver, and of the mammary, inguinal, and mesenteric glands were removed and plated on liver-infusion-gentian-violet agar. The plates were kept under observation for 15 days and suspicious colonies were subcultured and examined both microscopically and by the agglutination test. The results are shown in Table I.

TABLE I.

Goat.	Liver.	Mes. gland.	Spleen.	Kidney.	Mamma.	Ing. gland.
1	—	—	—	—	—	—
2	—	—	—	—	—	4 cols.
3	—	—	—	—	—	3 cols.
4	—	—	—	—	—	—
5	—	—	—	2 cols.	—	—
6	—	—	—	—	+	—
Control	—	—	+	—	+++	+++

Result.—Two animals successfully resisted infection; in three others the infection was light.

Note.—The numbers refer to the number of colonies identified; +, means infection. Goat No. 6 we consider was already infected when bought.

Second Series.

The same technique was followed but a different antigen was employed.

The broth culture was not filtered, but devitalised by the addition of tricesol and used without further preparation. This series comprised five goats, one being reserved as a control. After the five treatments, the blood-sera of each of the vaccinated goats gave a positive reaction thus: No. 8, 1 in 320; No. 9, 1 in 640; No. 10, 1 in 640; No. 11, 1 in 1280; control, nil. The reactions in this case were obviously due to the intradermal injection of the bodies of the dead or devitalised microbes.

Two days after the last treatment (twelve days after the first) all five goats were infected by rubbing an emulsion of living *melitensis* over a slightly scarified area of skin measuring about a square inch. Again no signs of infection were noticed, even in the control.

As the goats were not milking, the milk could not be tested. The serum reaction remained unaltered in titre in the vaccinated animals, but the control invariably gave a negative result. Hæmocultures were attempted every week, but with negative results. Owing to the non-appearance of the serum reaction in the control we waited eight weeks before destroying the animals. Eventually they were killed and the usual organs were plated as in the previous experiment, with the result given in Table II.

TABLE II.

Goat.	Liver.	Mes. gland.	Spleen.	Kidney.	Mamma.	Ing. gland.
8	—	—	—	—	—	+
9	—	—	—	—	—	+
10	—	—	—	—	—	—
11	—	+	+	—	—	—
Control ..	—	++	—	+	+++	+++

Result.—One animal successfully resisted infection.

Third Series.

The antigen was again varied and this time a sterilised unfiltered broth culture of *B. abortus* was employed. This strain was kindly furnished by Dr. Weigmann, of Copenhagen, through the good offices of Prof. Maurizio Ascoli, of Catania. The third series comprised only three goats, of which one was retained as a control. The treatment was the same as in the second experiment, and the *melitensis* infection was induced by scarification. After the treatment no symptoms of any sort were noticed, and the temperature remained normal throughout. The agglutination reactions stood at 1 in 540 and 1 in 1280 respectively. Hæmoculture was negative in all the cases and the control showed a negative serum reaction up to six weeks after infection. Six weeks after infection the goats were killed and the results shown in Table III. were noted on post-mortem examination.

TABLE III.

Goat.	Liver.	Mes. gland.	Spleen.	Kidney.	Mamma.	Ing. gland.
1	—	—	+	—	+	+
2	—	—	—	—	—	—
Control ..	—	—	+	—	+	+++

Result.—One goat successfully resisted infection.

Results.

Subsidiary to the main question but of fundamental importance is the observation that the serum reaction remained persistently negative in two of the controls, in spite of a very heavy infection revealed post mortem. Hitherto the existence of the serum reaction has been considered as an index of infection and its absence the proof of normality, but our observations throw considerable doubt on its reliability when used as a test for the detection of infected animals. This point is sufficiently important to demand fuller investigation.

Reviewing our results as a whole, it is clear that we have not achieved complete and effective immunity, and at the same time it is evident that we conferred a certain measure of protection in what is normally a very susceptible animal. If we disregard goat No. 6, on the grounds of natural infection before purchase, we can say that: (1) *B. melitensis* was not found in the mammae or in the milk of any of the treated goats, while it was present in the milk of the first control and in the mammae of the other two. (2) In four out of twelve treated goats there was no sign of infection. (3) In the remaining eight the infection was mild as compared with that of the controls, in that only a few colonies of *melitensis* were obtained, whereas most of the plates made from the controls were crowded.

(4) *B. abortus* employed as antigen appears to be as effective as *B. melitensis*.

We believe that, with certain modifications in technique, cutaneous vaccination can be rendered more effective and that we have obtained enough *prima facie* evidence to justify a continuation of our experiments, which are only preliminary.

Clinical and Laboratory Notes.

TWO YEARS' EXPERIENCE OF THE KAHN REACTION.

By D. S. MURRAY, B.Sc., M.B. GLASG.,
PATHOLOGIST, LAMBETH HOSPITAL, LONDON.

WHEN in 1927 it became obvious, from the increasing number of reports appearing, that the Kahn reaction for the diagnosis of syphilis was gaining ground, it was decided to try the method at this hospital. For a few months a preliminary test was done, and as the results were favourable it was decided to employ the reaction as a routine on all sera sent for Wassermann. Kahn's technique has been followed as closely as possible, while the Wassermans have been done by C. H. Browning's method which has given very consistent results when checked against the results obtained at another laboratory using a method recognised by the Ministry of Health, where most of our Wassermann tests are duplicated. The results given here do not include tests done in the preliminary trial of the method.

In the period covered, 3823 sera have been tested by both methods, and Table I. shows the degree of agreement reached.

TABLE I.

—	Absolute agreement.	Relative agreement.	Absolute disagreement.
Total and percentage	3534 (92.42)	146 (3.83)	143 (3.74)

Table II. shows what has been taken as absolute and relative agreement.

TABLE II.

—	Absolute agreement.				Relative agreement.				Absolute disagreement.			
Wassermann {	+	+	+	—	+	+	+	—	+	+	+	—
Kahn .. {	+	+	+	—	+	+	+	—	+	or —	+	+

The figure for absolute disagreement is very close to that reported by other workers, but further considerations allow of improvement even on this. Among the 143 sera showing absolute disagreement are 51 "repeats." Removing these from the Table—i.e., considering only results of single tests on single

TABLE III.

—	—	Absolute agreement.	Relative agreement.	Absolute disagreement.
Antenatal cases.	Total and percentage {	780 (96.3)	16 (2.0)	14 (1.7)
New-born infants.	Total and percentage {	591 (98.5)	3 (0.5)	6 (1.0)

patients—the absolute disagreement is only 2.43 per cent. Removal of the treated cases would still further lower this figure. It is our experience that

the Kahn test remains positive after the Wassermann has become negative in a large number of cases. The actual degree of disagreement between the two methods is probably best shown by Table III., which gives the figures for the antenatal clinic and newborn infants.

Here we are dealing with 1400 sera taken as a routine, without selection and without any clinical suggestion of syphilis.

When the agreement between the tests is relative, we have found the Kahn to be stronger in 60 per cent. of cases, but in those entirely disagreeing the Kahn is stronger in 95 per cent. of tests. This agrees with the finding that in treated cases the Kahn remains positive longer than the Wassermann. It is difficult to make a complete analysis of all the tests which disagreed and to correlate them with the clinical findings, but we have definitely found the Kahn of great value in such cases as the following:—

CASE 1.—A male, aged 21 years, was seen with a primary sore. *Spirochaeta pallida* was identified in the smears. The Wassermann was negative, but the Kahn strong positive. The Wassermann has never been positive; the Kahn is now negative after treatment.

CASE 2.—A new-born infant. Blood from the cord gave a negative Wassermann and a strongly positive Kahn. The mother's blood gave a positive Wassermann and a strongly positive Kahn.

CASE 3.—A female, aged 53, was admitted with a diagnosis of tabes dorsalis. The blood—Wassermann was suspicious and the Kahn a strong positive. The cerebro-spinal fluid gave a strongly positive Wassermann.

The Kahn test has now taken its place among our routine examinations and is done on all sera sent for Wassermann. It does not take long to do, and, though it requires care and practice in reading the results, its value has been proved. There is no intention of replacing the Wassermann, but the Kahn is definitely considered a useful addition to the older test.

A FATAL CASE OF DIPHTHERIA WITH CEREBRAL THROMBOSIS.

By J. B. ELLISON, M.B. CAMB., D.P.H.,

ASSISTANT MEDICAL OFFICER, GROVE HOSPITAL, TOOTING.

ALTHOUGH toxin is damaging to the whole vascular system, intracerebral catastrophes appear to be very rare during the course of clinical diphtheria. J. D. Rolleston (1916) has published 96 cases from the world's literature, with an account of 18 post-mortem examinations, but I am unable to discover any record of such a case since 1916. The 18 recorded necropsies revealed cerebral embolism 13 times, cerebral thrombosis three times, hemorrhage once, and "sclerotic atrophy" once. Owing to the unusual character of the clinical and pathological findings, the following case appears worthy of record, although a satisfactory explanation of the disaster is wanting.

On Nov. 23rd, 1929, a boy aged 6½ was admitted to the Grove Hospital suffering from severe faucial diphtheria. There was a previous history of measles, whooping-cough, and chicken-pox. On admission a thick membrane was observed covering the tonsils and the pillars of the fauces, with a slight extension on to the soft palate, and there was some oedema of the neck. The first sound of the heart was softened at the apex and the pulse-rate was 132. The child had apparently been ailing for about two days before admission. An intramuscular injection of 32,000 units of antitoxin was given. Next day the membrane showed signs of separating, but a further injection of 24,000 units of antitoxin was given subcutaneously. The heart was not dilated and the pulse was of good volume, with a steady rate of 110. Two days later the membrane had completely separated and the patient appeared to be making very good progress.

On Dec. 1st he vomited and the pulse became irregular (ninth day since admission). Adec pain in the four-hourly was ordered, and the foot of the bed was raised. Next day the pulse had improved in volume and steadiness, the heart sounds were normal, and there was no further vomiting, but on the following day, although the pulse showed further improvement, early paralysis of the palate was detected.

The first sound of the heart was softened and slightly prolonged at the apex. At 8 P.M. on Dec. 5th the nurse in charge reported that the patient had suffered a "convulsion," with moaning and grinding of the teeth, lasting about five minutes, after which he appeared to be paralysed on the right side. When seen at 8.10 P.M. flaccid paralysis of the right arm, leg, and right side of the face was noted. The patient was conscious; he could swallow and protrude the tongue, but was unable to speak. The limb jerks and abdominal reflexes were absent on the right side, and a right extensor plantar response was elicited. The inability to speak was apparently the result of total motor aphasia which made it difficult to decide whether there was any loss of sensation on the affected side. The pupils were equal and reacted to light and accommodation. There was no nuchal rigidity. The pulse remained steady at a rate of 80 and was regular.

On Dec. 6th spasticity of the right arm was present and the knee-jerk had returned on the right side. Complete aphasia was still present. A diagnostic lumbar puncture was performed, revealing a fluid of normal composition with one cell per cubic millimetre. The pulse remained steady and of good volume. On Dec. 8th increasing spasticity of the right arm and leg was observed, while the facial weakness

Section of myocardium.

was much less obvious. The patient appeared to be in pain but was unable to articulate any word. At 9 P.M. he was reported to have had another "convulsion" lasting a few minutes, accompanied by moaning and grinding of the teeth. When seen a few minutes later he was unconscious with conjugate deviation of head and eyes to the right. The pupils were equal and widely dilated, but reacted to light. Cheyne-Stokes respiration was noted. Physical examination revealed spasticity of the left arm and leg with brisk knee and ankle-jerks, and patellar clonus. There was now a double extensor response. The optic discs were injected and the retinal vessels appeared to be dilated. The patient became gradually weaker and died at 12.20 A.M., without regaining consciousness. The pulse remained of good volume until near the end.

Post-mortem Examination.

The body was that of a normally developed boy of about 6 years. The brain was uniformly softened (examined four days after death). The convulsions were not flattened, and there was no excess of cerebro-spinal fluid. Examination of the circle of Willis revealed thrombi completely occluding the main trunks of both middle cerebral arteries. On each side the thrombosis appeared to have begun at the first bifurcation and to have extended peripherally into all the smaller branches. The thrombus on the left side appeared older than that on the right and showed early organisation. Macroscopically the cerebral arteries appeared quite healthy and were well developed.

A microscopic section of the thrombosed vessels showed, on the left side, a thrombus about two days old in which polymorphonuclear leucocytes could be seen breaking down haemoglobin. The right artery showed thrombosis of very recent origin, probably only a few hours. There was no evidence of any disease or malformation of the vessel walls. The brain showed softening of the white matter, atrophy of nerve-cells, and numerous capillary thromboses. The meninges were healthy.

Heart.—The heart was flabby and dilated, but the valves and mural endocardium appeared perfectly healthy. The condition of the myocardium was especially interesting because there seems little doubt that, but for the vascular crises, the patient would have recovered completely.

Clinically his heart appeared to be improving steadily from the tenth to the fifteenth day. Microscopic section revealed marked toxic changes in the muscle-fibres; they were separated from one another and irregular in outline. The protoplasm was granular and vacuolated, while in many fibres the nuclei had completely disappeared and in others they stained but faintly and were in course of disintegration, in others again being considerably diminished in size. There was no increase in connective tissue. (See Figure.) The aorta and pulmonary arteries were quite healthy.

The remaining organs showed the usual toxic changes associated with acute diphtheria.

No cause for the thrombosis can be suggested; the condition was definitely not produced by emboli. The patient had no reaction after the injections of antitoxin, but thrombosis can scarcely be regarded as an anaphylactic phenomenon. Perhaps it is worth while to mention that two of the patient's grand-parents were stated to have died of "apoplexy." The parents are living and healthy.

As in all other recorded cases, there was a severe infection of the myocardium and a large amount of membrane on the fauces.

I am indebted to Dr. J. H. Whitaker, medical superintendent of the Grove Hospital, for permission to publish the notes on this case.

A CASE OF

ACUTE SYPHILITIC MENINGITIS.

BY N. KRAMER, M.R.C.S. ENG.,

HOUSE PHYSICIAN, ST. JOHN'S HOSPITAL, LEWISHAM.

A MAN, aged 24, presented himself at St. John's Hospital on July 6th, 1929, with a chancre on the prepuce, stated to have been there 14 days. The *Treponema pallidum* was demonstrated by the dark field.

Treatment was begun at once, beginning with a course of mercury pills followed by neoharsivan. After the fifth injection on Sept. 13th the patient gave up attending. Five weeks later he developed severe headache and giddiness and this continued for a fortnight.

On Oct. 29th he was admitted to St. Thomas's Hospital. The following account is taken from the notes kindly forwarded from there. On examination there was slight bilateral papilloedema and paralysis of the left seventh and eighth nerves. The blood Wassermann was positive (+ +). The cerebro-spinal fluid contained 1500 cells per c.mm., and 98 per cent. of them were lymphocytes. There was a gross excess of globulin. The cerebro-spinal Wassermann was very strongly positive (+ + + +). Treatment was by a course of 12 mercury inunctions, six injections of 0.3 g. of novarsenobenzol, and one injection of stabilarsin. He was discharged on Nov. 21st, 1929, feeling quite well, and showing no abnormal physical signs.

On Nov. 26th he attended the clinic at St. John's Hospital. He was treated by a course of mercury pills and potassium iodide. The blood Wassermann on Nov. 26th was + +, and the Vernes 79. On Jan. 14th the blood Wassermann was + + and the Vernes 80. Very soon after this he developed severe headache, giddiness, and diplopia. On Jan. 30th he was admitted to St. John's Hospital. He was semi-comatose, was delirious at times, and showed marked hyperaesthesia. All reflexes were very brisk, and the plantar responses were flexor. The pupils showed no abnormality and the discs were normal. Of the cranial nerves only the right facial was affected. The cerebro-spinal fluid was under pressure and slightly turbid and contained 790 cells per c.mm.; the majority were lymphocytes. There was a gross excess of globulin. The cerebro-spinal fluid Vernes was 94.5. The patient was treated by one injection of 0.3 g. of neoharsivan, followed by a course of intramuscular injections of mercury cyanide 1 c.cm. (1 g.) twice weekly for eight injections. This was followed by three injections of bismogenol: 0.5 c.cm., 1 c.cm., 1.5 c.cm., at intervals of four days.

Shortly after admission the patient's condition greatly improved and four days later he was quite well and showed no abnormal physical signs. He was discharged five weeks later on March 11th. The cerebro-spinal fluid then was clear and contained 80 cells per c.mm., most of them being lymphocytes. The cerebro-spinal fluid and blood Wassermann was + +.

The case presents some very unusual features. In spite of the fact that treatment was started as

soon as the chancre was found, meningitis developed after four months, and again, although treatment was continued uninterruptedly, a second attack of meningitis occurred within three months of the first one. At the time of writing the patient is quite well and carrying on his occupation.

I am indebted to Dr. H. M. M. Woodward for permission to publish these notes.

Medical Societies.

POOR-LAW MEDICAL OFFICERS' ASSOCIATION.

THE annual general meeting of this Association, the last meeting under its old name, was held at the Holborn Restaurant on June 12th, with Sir ARTHUR NEWSHOLME, the President, in the chair. Prof. MAJOR GREENWOOD opened a discussion on

POST-GRADUATE EDUCATION FOR THE LOCAL GOVERNMENT MEDICAL SERVICE.

Medical education, he said, was of two totally different kinds. The first was education in the pure sense, such as Macaulay had in mind when he said that if Cherokee were taught instead of Greek in our universities the students who wrote the best Cherokee verses and understood the use of Cherokee particles best would be the best men. The second was education in the sense of technical instruction, to secure that the tyro should learn how to perform certain skilled manipulations in the best possible way. A century ago medical education in the hospitals had been almost entirely technical. The idea of general scientific education had been in its early stages about 50 years ago, and 30 years ago the transition had become complete, physiology and anatomy being taught by pure specialists. Post-graduate education had been represented by the Diploma of Public Health, which conferred a definite legal status, and the Fellowship of the Royal College of Surgeons and the Membership of the Royal College of Physicians, which in practice had the same effect. These two latter qualifications showed clearly the mixture of the two notions of education. For the Membership of the Royal College of Physicians candidates were examined in the classical languages; the examination had been somewhat perfunctory, and it had been discontinued as a compulsory test six years ago; the conception nevertheless had been that a certain breadth of culture was desirable in a physician. The Royal College of Surgeons had maintained that point of view even more strongly; the teaching and examination in physiology, for example, were supposed to have had a definite cultural value, lectures having been given on parts of the physiology of the special sense organs and similar subjects of remote technical but considerable cultural value.

It was interesting, said Prof. Greenwood, to examine the attitude of the authorities to the youngest of these special diplomas, the Diploma of Public Health. The first rules issued by the General Medical Council in 1896 had begun by stating that the possession of a distinctly high proficiency, scientific and practical, in all the branches of study which concerned the public health should be a requisite of any diploma that the Council would register. According to the German proverb, however, "*Es wird nicht so heiss gegessen als es gekocht ist*," and the practical embodiment of that high principle of the General Medical Council was the requirement of six months' practical instruction in a laboratory or laboratories in which were taught chemistry, bacteriology, and the pathology of the diseases of animals transmissible to man. The requirements for instruction in the duties of a

medical officer of health left very considerable latitude to the examining and teaching bodies; it was mainly valuable on the technical side. The general scientific value of the teaching in bacteriology and chemistry was altogether subordinate, and the public health students were often not regarded with very serious interest by the teachers of these subjects. Thirty years ago, therefore, the course prescribed by the Council had been largely a matter of indifference, and the men who had entered the public health services had been men who had seen a vision, who had wished to pursue a certain ideal; men like Power, Shirley Murphy, and the President of this Association. The material rewards had been so trivial that only a real enthusiast would enter the service. It was no stigma on the younger generation to say that its average level was lower than that of 30 years ago. Owing to the splendid success of the work of those men the public health service had been enormously extended, and now offered a career for a large number of young medical men.

Increase in Technical Training.

In 1922 the General Medical Council had promulgated a new series of rules which had had roughly the effect of making the attainment of a diploma in public health considerably more difficult. The rules of 1896 had merely required that 12 months should elapse since qualification. The new requirements laid down that:—

“A period of not less than two years shall elapse between the attainment by a candidate of a registrable qualification in Medicine, Surgery, and Midwifery and his admission to the Final Examination for a Diploma or Degree in Sanitary Science, Public Health or State Medicine.

The Council had explained its reasons—perhaps a fault in legislators—for this legislation:—

“The purpose . . . is to provide opportunity for candidates for the Diploma or Degree in Sanitary Science, Public Health, or State Medicine to pass from the state of pupillage to that of responsible practitioners, to give mature consideration to the obligations and duties involved in the work of the public health service, and to acquire direct experience of medical work in a responsible capacity either in practice or in hospital or laboratory appointments. The Council believe that, in the public interest, the time has arrived to adapt the diploma or degree to candidates who are seriously intending to take up public health work as a career.”

The Council had next set down in much greater detail than before the subjects which they considered should be studied by candidates for the Diploma in Public Health. In the old days a complete ignorance of, for example, vital statistics would never have deprived a candidate in this country of a single mark. The latest orders of the Council, besides repeating the old requirements in bacteriology, chemistry and physics, laid down the minimum number of hours which should be devoted to these subjects. It required a minimum of 180 hours' study of bacteriology and parasitology, not less than 150 hours being occupied in practical laboratory work; it prescribed a minimum of 90 hours' work in chemistry and physics, and of 10 hours in meteorology and climatology in relation to public health. Epidemiology and vital statistics must be allotted at least 20 hours, and sanitary law and administration another 20 hours. Provision had been made in London for the teaching of students in the new School of Hygiene and Tropical Medicine, which had been equipped at great expense and had a full-time staff.

Practical Difficulties.

The problem was how far it was possible to turn out students who were really better trained than their fathers or grandfathers had been. The first difficulty was the mixture in medical education of technical and general training. A specialist criticising this schema would say that it was utterly impossible to turn out highly trained technicians in the time allotted to each technical subject. The time was too long for a more popular introduction to the subject and too short to produce real technical skill. The practical

difficulty encountered by the teacher of public health students was that the whole point of view of undergraduate medical training was necessarily and rightly utterly different from the point of view of an epidemiologist. The clinician was concerned with relieving and curing the sickness of individuals; the epidemiologist with disease as a mass phenomenon. It was enormously difficult in dealing with young medical graduates to prevent them from either adopting dogma or from passing over into a state of ignorant scepticism. The young medical graduate had had a large amount of technical education, but when presented with a general argument was often as helpless as a child. In public health work the most certainly ascertained results were based on a balance of probability. A conclusion with respect to the importance of contamination of water-supplies in the history of typhoid that anybody considering the evidence as a whole would accept, was never based on a conclusive proof in the sense of a crucial experiment. Sometimes the balance hung still more doubtfully, and it was of the utmost importance that the young graduate who was going in for public health work should acquire some skill in the weighing of probabilities. The amount of time at the disposal of teachers was so short and the technical requirements so great that there was a real danger that a university school might degenerate into a mere institution for cramming students with selected wads of technical information. There was one safeguard: that the student was examined by his own teachers on the teaching actually given in the school, but the teaching had to conform to the rules of the General Medical Council. Some parts of the curriculum were given much more time than the minimum. So long, however, as students were stretched out on this procrustean bed there was a danger of producing young men with merely a certain smattering of technical knowledge. Prof. Greenwood submitted that there was a certain amount of English hypocrisy about the system—a pretence that things were different from what they really were—and he suggested that the pretence that it was possible to turn out highly trained technicians after even a year's course was a little dangerous. He asked whether it might not be better to admit frankly that parts of the course, so far as they had a value, were valuable in the general educational sense. The students who could acquire the scientific spirit from a course of epidemiology and vital statistics were probably going to be mere breakers of apparatus in a bacteriological laboratory. On the other hand, some men to whom statistics and the doctrine of Hippocrates were mere sound and fury might obtain a glimpse of the spirit of science in a laboratory. It would probably be better, he suggested, to pitch a very low general minimum of technical requirement; and then give students a choice of the subjects on which they must spend extra time, and to require a higher standard of those subjects.

The tendency to increase technical instruction in post-graduate and undergraduate medical education might be a necessary evil, but it was a great one. Prof. Greenwood suggested that the physiology taught 30 years ago had had greater educational value than that taught to-day; the increase of knowledge and the complication of method was so great that it would be impossible, even if the teacher had far more time, to make the student understand the general principles of the investigations which now led to results. He suggested, first, that young graduates were less educated than their predecessors of 30 years ago, although they had more knowledge, and, secondly, that the higher level of general culture on which the Royal Colleges had insisted was really required in men who were going to give their lives to the public health service. The prizes of the public health service could not compare with those of the clinical side of the profession, and the type of students likely to be attracted was composed of men who, if they had been laymen, would have tried to enter the Civil Service—who wanted something

safe. A great many men of the highest type with a real vocation would undoubtedly join the service, but it would not attract the pick of the ambitious undergraduates. Teachers had to try to repair the deficiencies in their students' education, and the very overburdened technical course might make this task somewhat difficult.

Discussion.

The PRESIDENT thought that Prof. Greenwood was unduly sceptical about the average capacity of aspirants for the public health service. He agreed that the requirements of the General Medical Council erred somewhat on the side of standardisation, but admitted the arguments in favour of a minimum standard, even if the minimum were not an adequate one. Many of Prof. Greenwood's criticisms, he said, would apply equally well to the ordinary medical course. The medical student could not hope to be equally proficient in all the subjects he was taught, but if he had no knowledge of them at all he would be correspondingly inadequate and unsatisfactory. The future medical officer of health must have a fairly complete syllabus. He was the general practitioner in preventive medicine. Sir Arthur looked forward to the day when the public and the private health services would be identical, when the general practitioner would be the medical officer of health for the families of whom he had charge, and the medical officer of health would play a minor part. He wished that the General Medical Council had included in its syllabus the practical training which every would-be medical officer of health ought to receive; which corresponded to the hospital work of the medical student. He had nearly always, when he was a medical officer of health, had a young man attached to him without a salary, who had sat at his elbow, gone on his visits with him, and assisted him with his office work and reports. Men who had had this experience were better trained than those who had not. The difficulty was that, although general culture was desirable, the public health practitioner had to be trained all round as a preliminary to his specialised training. He regretted that general practitioners and public health men alike knew so little of the science of social relations—of the questions of public morality and pauperism in relation to public health. This knowledge had a science attached to it, and was perhaps more important in the present complicated condition of social affairs than even vital statistics.

Dr. A. E. COPE said that the present-day "technicalitis" was only part of a much wider movement. The system of allowing candidates to choose their subjects had many advantages, but had the danger of increasing the formation of ruts in the minds of young people and developing technical at the expense of general education. The problem of post-graduate education was a hard one for the general practitioner, who found it difficult to leave his work and who sometimes, when he had left it, encountered restrictions and conditions which were very difficult to comply with. He often did not wish to take the full course, but to follow a limited bent. The London School of Hygiene and Tropical Medicine should make some provision on the lines of the University extension lectures, so that the general practitioner could refresh his knowledge where he needed it, and become familiar with the subjects which were most important.

Dr. C. E. MCDADE pleaded that teachers should be entrusted with examining boards and allowed to allot a certain number of marks for proficiency before the student went up for examination at all. The ideal was that each man should develop along the lines that suited him best.

Mr. ZACHARY COPE was thankful that there were no internal examinations on the medical side. The system was not only wasteful, but candidates were apt to do badly when examined by their own teachers. Public health should not be discussed apart from private health; the two were identical. He foresaw the time when all branches of medicine

would be coördinated into a single service—not a State medical service but one which offered plenty of scope for private enterprise. The medical school and the public health school could do no more than cast the student into a certain mould, upon which his specialisation would depend. There must be a modicum of instruction. Dr. Johnson had said that the average man could always get a living at medicine. As the average man was pretty dull, the modicum must be fairly low. There was a great opportunity in the future for the municipal hospitals, with adequate organisation and coördination, to give practical instruction to the newly qualified. He hoped that the examination for the Fellowship of the Royal College of Surgeons would in future require that the candidate should have had practical experience.

Dr. WILLIAM SHACKLETON suggested that a man who had made a personal study of certain individual trees and their habits and growth might take a very good view of forestry. Perhaps a vision of the whole subject of medicine followed on the study of individuals.

Dr. JAMES BUCHANAN welcomed the new Diploma of Gynaecology and Obstetrics; this subject was the basis of general practice. Post-graduate courses on ophthalmology and diseases of the ear, nose, and throat would also be of great use. Moreover, the average general practitioner knew very little about skin diseases.

Dr. T. B. HAIG mentioned that general practitioners sometimes complained that the welfare officer took away their babies from their charge; the President suggested that they should learn more about welfare work.

Reply.

Prof. GREENWOOD assured the meeting that the students who sought instruction were not by any means to be despised, but were average men. The average men were those whom a competent teacher should seek to instruct, he should not concentrate upon the best students. Minor sicknesses, especially minor mental disorders, were much more important than cancer and tuberculosis; the London School of Hygiene was acting with great foresight in giving courses on the minor psychoses. The School was also trying to provide special courses to meet the individual needs of graduates. He thought the student was as likely to be tongue-tied before external examiners as before his own teachers. It was possible that the public had been encouraged overmuch to demand a long array of diplomas; the profession should set its face against this multiplication.

At the meeting the name of the Association was changed by resolution to the "Association of Local Government Medical Officers of England and Wales."

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

At a meeting of this Section on June 13th, with Mr. CYRIL H. WALKER, the President, in the chair, a paper entitled

AN EXPERIMENT IN KERATOPLASTY

was read by Mr. J. W. TUDOR THOMAS. He said that at the end of four years of experimental work in efforts to carry out transplantation on rabbits' cornea the results he had achieved were so poor that it seemed hopeless to expect to obtain transparent grafts, such as in fact he later secured. These latter he had demonstrated at the annual congress of the Ophthalmological Society. The purpose of the experiment now described was to ascertain whether the retention of a very minute pedicle of corneal tissue would suffice to enable the graft to maintain its transparency. He made a rectangular incision into the cornea of a rabbit, penetrating the whole corneal thickness but retaining a pedicle, 2 mm. thick, at the postero-superior cornea. The rectangle

measured 7.5×4 mm., and the incision was across the centre of the cornea. Four stitches secured the flap in position. There was good union of the flap, and, with the exception of a marginal scar, the flap later became transparent. It was in this way shown that the keeping of a small pedicle enabled the graft to maintain its transparency. Though there was only 2 mm. width of pedicle, it sufficed to retain life in the graft and without loss of transparency. The graft was cloudy for a week after the operation, and at the end of a fortnight was still slightly cloudy. After three weeks it had become sensitive to touch over an area embraced from the 2 mm. pedicle to the posterior 2.5 mm. of the inferior margin. At this time the graft was clear in the sensitive area and somewhat beyond it, the rest being only slightly cloudy. At the end of a month it was clear except in the case of the marginal scar. In 13 weeks from the date of the operation sensation was normal all over the scar, except for about one square millimetre near the middle of the anterior end. Twenty-eight months after the operation the animal was killed, and microscopical examination of the sections showed that in general the graft was a little thicker than the remainder of the cornea, and that Descemet's membrane was at least as thick as the normal membrane; also it stained a little deeper. In the main graft there was no appreciable increase in the number of nuclei, but at the opaque margins of the graft the following changes were evident:—

The epithelium was thickened; there were six layers of cells, the basal ones being elongated. In this region the stroma contained twice as many nuclei, and there were numerous spindle-shaped spaces between the fibres. Between the free end of Descemet's membrane in the substance of the cornea and the posterior membrane the tissue fibres were coarser and more numerous; some iris pigment could be seen at the site of the anterior synchia, and the pigmented cells were covered by a layer of endothelial cells with a new Descemet's membrane. But a minute split was discovered between the two layers of Descemet's membrane; in places this split could be seen to extend throughout the whole breadth of the graft. A small detached portion of Descemet's membrane could be seen curled up in the region of the scar near the posterior surface, but covered posteriorly by the new membrane. This showed that detached portions of Descemet's membrane were but little altered in the course of years.

The appearances of Descemet's membrane in this case, said Mr. Thomas, agreed with the observations of others as to the healing of corneal wounds—namely, that the cut ends of the membrane did not unite, but were joined by the new membrane which was formed, either to unite the cut ends or to fuse with the posterior surface. In this case a new membrane had been formed, which passed quite across the graft and fused almost completely with the graft's original Descemet's membrane. It seemed clear that the marginal portion of the new membrane must have been formed by the endothelial cells of the surrounding cornea. The specimen showed that a new membrane could be formed under such conditions as obtained in this experiment, and over quite a large area, and that it actually covered and fused with the membrane of the graft. It did not accord with the view expressed by Weinstein that the new membrane was composed of differentiated corneal lamellae. The experiment showed that retention of even a small pedicle of corneal tissue was a material help in revitalising the graft. His experimental experience had been that if a small pedicle had not been retained, even the same method of stitching as in the present case would have produced an opaque graft, and if the present graft had been left without stitches to secure it, the eye would probably have been useless, or at best there would have been a staphylomatous cornea.

With a clean perforating wound of the human cornea it was possible that corneal suturing might again give the patient a useful eye when a pad-and-bandage application might result in adhesion of the iris with a gaping wound, so that the eye must be removed. Such an accident as a penetrating wound of the cornea might occur in a man's only good eye,

and if this grafting could be done without the risk of sympathetic trouble supervening, it seemed very desirable to try it. A large corneal wound tended to gape, the anterior chamber did not re-form, the iris became extensively adherent to the wound, and there was real risk of infection.

Discussion.

The President said he thought the eventual result of this fine and laborious piece of work would be great.

Mr. HUMPHREY NEAME pointed out that a section shown by Mr. Thomas in which a portion of Descemet's membrane was reduplicated was reminiscent of the sections seen in old interstitial keratitis. He had had such specimens to examine, either because of the supervention of glaucoma or because a blind eye had ruptured. Sections of such eyes showed a very thick new formation of fibrous tissue behind the remains of the old cornea, and the obviously ruptured Descemet's membrane was curled up in the same manner, and lying at the middle depth of the existing cornea. The new fibrous tissue was fixed and was most obvious in the lower part of the cornea, but in a much inflamed eye there was considerable formation of cellular material in the anterior chamber which accumulated in the lower part.

Mr. J. H. FISHER said it did not strike him that in the case described by Mr. Tudor Thomas the endothelium had spread in from the periphery to cover the posterior surface of the graft and secrete a new deposit of hyaline material. Apparently all the other tissues of the graft had survived well, and he saw no reason why the endothelial cells, in such an experiment, should not also retain their vitality. It was not, he thought, an ingrowing of epithelial cells from the periphery, but a survival of the cells on the deep surface of the graft, which, under the conditions of excessive activity, had produced a second layer.

Mr. MAURICE WHITING thought the value of Mr. Tudor Thomas's experiment lay in the possibility of usefully repairing wounds of the cornea. But when a cornea was wounded in actual life, the conditions differed from those in a laboratory experiment; the wound was caused by a relatively blunt instrument and so a good deal of injury was sustained by the cornea, and infection was very likely to supervene. During the late war he had several times tried to preserve a wounded cornea by means of a flap, but the attempted suture under those conditions in order to secure the wound edges usually resulted in even greater damage; therefore he fell back on the simpler pad and bandage to keep the flap in position. Conjunctival flaps he judged to be unsuitable under war conditions.

Mr. F. JULER commented on the fact that Mr. Tudor Thomas seemed to use a suture for each lip of the wound.

Lieut.-Colonel A. E. J. LISTER spoke of two cases of corneal wound in which conjunctival flaps were successful.

Mr. TUDOR THOMAS, in reply, said he did not know whether endothelium survived in the cornea, but probably it did. He agreed that wounds of the cornea in actual life were usually caused by a blunt instrument and were liable to infection, but even so, for a plain incised wound, suturing might be useful. In a clean wound, an edge-to-edge corneal suture was best. Animals, he found, tolerated corneal stitches very well provided they were not inserted right through the cornea.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

CYCLOTHYMIA IN GENERAL PRACTICE.

At a meeting held on June 5th, Dr. W. BARRINGTON PROWSE, the President, being in the chair, Dr. HELEN BOYLE read a paper on the Milder Forms of Manic-

depressive insanity and cyclothymia in General Practice. The term manic-depressive, she said, was of Kraepelin's classification and embraced, according to its author, a vast variety of conditions from acute mania to marked alteration of mood in the sane. She made a plea for several subdivisions under the heading manic-depressive, and called attention to the association between some manic-depressive states and thyroid disturbances (hyper-, hypo-, and possibly dysthyroidism), and also to a group associated with hyperpirosis, arterio-sclerosis, morbid intestinal states, and kidney trouble. Real progress could only be assured in the treatment of these cases by close coöperation between the general practitioners (who saw and treated all the early cases) on the one hand, and those specially interested in neuro-psychiatry on the other. This aim was now being pursued, and mental medicine, which had for long been crying in a wilderness inhabited by witches, spiritualists, criminals, and others, was being welcomed back into the fold of general medicine. This was especially desirable in connexion with manic-depressive insanity in which the patients often have long periods of normality and of capacity for carrying out valuable work. In Kraepelin's classification manic-depressive insanity covered a wide field—including the whole domain of so-called periodic and circular insanity, simple mania, the greater part of the morbid states termed melancholia, a not inconsiderable number of cases of amnesia (confusional or delirious insanity), and certain very slight colourings of mood. People liable to marked variations of mood were familiar to all, and all had suffered at times and at times rejoiced and benefited by the feverish energy, optimism, joy of life, and determination to put things through of cyclothymics. They were, in moderation, invaluable to the community. In their euphoric stages, short of insanity, they were sublimely self-confident, and superbly devoid of self-criticism and inhibitions, and by that temper which could feel no difficulties fine feats could be achieved. Cyclothymia, which signified a nervous or mental illness, which showed a cyclic tendency, was a useful term to apply to the occurrence of mild manic-depressive states in patients who were not insane and very possibly never became so. Few would object to being called cyclothymic while many objected to manic-depressive as a description of their condition. After quotations from various authors showing the similarity between the hyper- and hypo-thyroidic illness and manic-depressive states, Dr. Boyle pointed out that in some of the latter there was a history of enlargement of the thyroid during adolescence, sometimes accompanied by cyclothymic tendencies. It would be of great value if practitioners would take note of this condition in schools or private practice and confirm or disprove the observation that it was a forerunner of cyclothymia in adult life. The treatment or neglect of adolescent thyroid enlargement would have to be modified, for it could hardly be doubted that the young persons suffering from this enlargement should be removed from competitive work or play of all kinds with its accompanying strain of anxiety.

The other group of manic-depressives, associated with a hyperpirosis which might show itself in early adult life, had one clear indication for treatment. The blood pressure, even when considerable, should only be reduced with great care; steam baths, colon douches, and other eliminative measures could be used. The high pressure was required for efficient excretion, and unless this was secured by other means an attack of insanity supervenes. In these patients 185 to 190 was usually the lowest limit of safety. One patient, after several severe attacks of insanity at fairly regular intervals for which she had to be certified, subsequently went through the rest of her life (some 10 to 15 years) without another attack. These patients in later life showed confusion and disorientation in their attacks. Even these attacks, if the blood pressure went up and elimination was successful, might clear up in 24 hours.

Reviews and Notices of Books.

RADIUM IN GENERAL PRACTICE.

By A. JAMES LARKIN, B.Sc., M.D., D.N.B., Radium Consultant on Staff of Wesley Memorial and other Hospitals; Instructor in Dermatology (Radium), Northwestern University Medical College. New York: Paul B. Hoeber; London: Humphrey Milford, Oxford University Press. 1929. Pp. 304. 27s.

This book is written for the practitioner and is commendably simple. It is, moreover, well adapted to its purpose, for it indicates clearly the cases in which he will and will not find radium therapy of service. It does not pretend to give the knowledge that will make him an expert in the technique, but it fulfils the author's intention of giving a quick reference to the therapeutic possibilities of radium in any particular type of case. The essentials of the mechanics and physics of radium are condensed into the first 16 pages, and the whole of the rest of the book is devoted to a detailed consideration of the treatment and probable reaction of the various pathological conditions that are influenced by radiation therapy. These are considered under four headings: (1) general diseases, which include the blood and ductless gland conditions; (2) gynaecological diseases; (3) miscellaneous tumours; (4) miscellaneous skin lesions. A list of about 70 simple and malignant types of disease are given separate consideration. An outline of the pathology, radium indications, prognosis, a typical condensed case-history, and a bibliography are given for each lesion. In this way the author places at the disposal of the practitioner a summary of the most important information available on the particular disease in which he happens to be interested. The method calls for repetition under each heading, but this does not matter since the author only touches lightly the salient features and avoids detail. In Dr. Larkin's practice and experience it is evident that the combined effect of X rays and radium has not received much consideration, in spite of the fact that in European clinics they are largely used together in the treatment of malignant disease. We could find only one reference to X rays in the book, and this is to the effect that X rays will only be employed where a sufficient quantity of radium is not available.

The book is, however, an admirable guide for the practitioner who wants to learn which of his cases are likely to be benefited by radium treatment.

DIABETES.

A Diabetic Manual for the Mutual Use of Doctor and Patient. Fourth edition. By ELLIOTT P. JOSLIN, M.D., Clinical Professor of Medicine, Harvard University, Boston, Massachusetts. Philadelphia: Lea and Febiger. Pp. 248. \$2.

This manual is designed to teach both doctors and patients the elements of the principles which govern the treatment of diabetes mellitus. It is well adapted for this purpose, since the racy descriptions and clear sketches and photographs amply compensate for the author's rather diffuse style of writing. The dangers of the disease are explained with the errors which have caused them, and their treatment is clearly outlined. The directions for dieting are good, the diet tables, although very elaborate, are still drawn up in percentages, leaving the patient to do the calculating. Admittedly the patients or their attendants ought to be able to work out sums by the rule of three, but in practice many prove incapable of so doing. In parts of the book which have been revised, Dr. Joslin has begun to speak of 5 g. equivalents, and it is to be hoped that the next edition will see this change in the diet tables. The new carbohydrate values worked out by McCance and

Lawrence have not been adopted. A great change has been made in the carbohydrate ration. Instead of limiting the carbohydrate to 50 or 60 g., Dr. Joslin has increased it to 100 or even 150 g. This increase, of course, demands an increase in the insulin dosage, in order to maintain the blood-sugar at a normal level. This increase, however, is less than might have been expected. The additional amount of insulin necessary for an increase of carbohydrate of 100 g. is not 50 units, but only 30 or even 25 units. The general condition of the patients is improved on this diet, and the necessity for special diabetic foods disappears. Dr. Joslin adds a warning that it is more difficult for a patient to refrain from taking too much carbohydrate when he is already allowed so much, and draws attention to the well-known difficulty of the alcoholic in limiting himself to moderate amounts of alcohol. However, provided the additions are made cautiously, under medical supervision, with adequate amounts of insulin, this difficulty should not be insuperable. The sections on minor ailments, and especially that on the care of the feet of elderly patients, are especially good. The section on treatment of coma, though adequate for the patient, is hardly full enough for his medical attendant who will have to refer to a bigger manual.

Unbekanntes von Insulin. Von W. FORNET, Oberstabsarzt a.D. München: Verlag der Aerztlichen Rundschau. 1929. Pp. 41.

ALTHOUGH it is true that a great deal still remains to be discovered about insulin, Dr. Fornet has hardly advanced our knowledge. The natural desire, which is shared by all physicians, to be able to recommend as effective the oral administration of insulin has led Dr. Fornet to examine the evidence in favour of the view that insulin is absorbed from the alimentary tract. Unfortunately, this evidence is presented in a very one-sided manner, and the experiments against the view are mostly ignored. Thus the experiments showing that raw pancreas given by mouth is effective are quoted, but the results of others who refute the claim are not mentioned. Dr. Fornet has endeavoured to prevent the action of pepsin and trypsin on insulin by protecting it with bile. The preparation made on this principle is given in pill form, and good results are claimed for it. The evidence produced, however, does not carry conviction.

SURGERY OF THE GALL-BLADDER.

Das Für und Wider der Chirurgischen Behandlung des Gallenleidens. By Prof. Dr. PAUL ZANDER, Chirurg des Elisabethenstifts in Darmstadt. Leipzig: Georg Thieme. 1930. M.8.50.

THIS is a review of the immediate and later results of 800 operations for disease of the gall-bladder and bile-ducts. The operations included 708 cholecystectomies and only three cholecystostomies. In 138 cases the bile-ducts were also opened, and in 81 some operation upon the stomach was performed as well. The analysis of the cases has been careful, and a number of lessons are to be learnt from the records. Perhaps the most interesting is the fact that among those patients who suffer from colic without stones and without pronounced naked-eye changes in the gall-bladder, only 42 per cent. are cured of their complaint when the gall-bladder is removed. There has been a tendency of late, especially amongst Scottish surgeons, to remove the gall-bladder from patients who have no gross lesion of the organ. Even where evidence of disease can be obtained by microscopic examination or culture of the wall, it seems that adaptation to loss of the gall-bladder when its function has not been gradually destroyed is difficult. There is a 90 per cent. complete recovery-rate in hydrops of the bladder, and a 70 per cent. rate when stones or suppuration confined to this organ are present. The results get worse when infection has spread to the ducts. Obviously, then, early

operation is desirable in the presence of infection, but the fact that intervention in conditions where stones are absent and inflammatory changes at a minimum is not very successful must be remembered. It would be interesting to test the effect of cholecystostomy in these patients, and to ascertain whether or not the dye test would enable the surgeon to select those cases likely to benefit from operation. This book gives a fair survey of the surgical treatment of gall-bladder disease, and deserves attention.

ESSENTIALS OF MEDICINE.

Ninth edition, revised. By CHARLES PHILLIPS EMERSON, M.D., Professor of Medicine, Indiana University. London: J. P. Lippincott Company. Pp. xx. + 588. 12s. 6d.

THE ninth edition of this well-known text-book, designed essentially for junior students and nurses, has been thoroughly revised with the assistance of Miss N. G. Brown, R.N., assistant director of the Indiana University Training School for Nurses. The easily read, narrative style, the general clear presentation of the subject, the well-chosen illustrations, and the detailed table of contents combine to make a useful volume which lay people interested in medicine might also read with advantage.

OXIDATION-REDUCTION POTENTIALS.

By L. MICHAELIS, M.D. Translated by LOUIS B. FLEXNER. London: J. B. Lippincott Company. 1930. Pp. 197. 12s. 6d.

THE measurement of oxidation-reduction potentials has proved in the hands of Mansfield Clark and his co-workers in Washington so useful in the study of purely chemical oxidation-reduction systems that the results so far obtained by application of the same methods to biological systems are disappointing. The reasons for this are made clear by Prof. Michaelis's admirable analysis of the problem, in which his own fundamental work on the electrode potential of cysteine is presented in a new light. Although his conclusions tend to throw doubt on the value of much of the work, his criticisms are sound and will place the whole subject on a firmer basis. One of his most important contributions concerns the nature of the potential established at an indifferent electrode by sulphhydryl bodies which are present in all tissues. He shows that in the presence of oxygen the electrode is not indifferent—it is attacked—so that the potential is not a true oxidation-reduction potential. This fact alone obviously places grave restriction on the use of electrodes in the study of living systems. He also points out the fallacy of speaking of the oxidation-reduction potential of a living aerobic system, since the existence of a definite potential implies a true equilibrium which is incompatible with life; we may speak of the potential of the tissue fluid of the culture medium, but not of the potential of the cell or the bacteria. The book has been translated by Louis Flexner, who is well-known for his work in this field. It opens with a complete theoretical discussion, the second part being devoted to physiological applications. Dr. Michaelis's exposition of the limitations as well as the possibilities of the study of oxidation-reduction potentials as applied to biological problems will clear the ground and deserves careful study.

MECHANO-THERAPY.

A Text-book for Students. By MARY REES MULLINER, M.D., formerly Instructor in Mechano-Therapy in the Summer School of Harvard University, and in the Sargent School for Physical Education. Philadelphia: Lea and Febiger. Pp. 265. \$2.75.

THIS is an interesting and well-constructed book. The general advice offered to the student of massage is excellent, and well worthy of close attention not

only by the practising masseuse but by the practitioner who employs her. A few curious slips are noticeable—such, for instance, as the statement that callus consists of cartilage, but they are few and far between. The nomenclature given to the movements of massage is confusing, but this is a point which need not be stressed, since no standard nomenclature is available. The short notes on "contra-indications for massage" are inadequate.

Throughout the book the right impression is left that the cure of the conditions treated by physical treatment does not depend entirely upon the operator, but much on the help of the patient. Particularly good are the chapters on the prescription of exercises and on relaxation; and, had the very high standard of the first seven chapters been maintained in the latter part of the work, this little book would deserve nothing but praise. At this point, however, there is a curious falling-off; indeed, the book leaves the same sort of impression as the paper of an examination candidate who, having devoted all his energies to answering the first few questions, becomes too tired to maintain a high standard. The early treatment of injuries is advocated, but not described, and far too much stress is laid on massage as distinct from treatment by movement. Few injuries are dealt with separately, and those who require help in this matter must seek it elsewhere. The accurate writing in the first pages gives place to such grotesque statements as that "massage may grind away these bony growths" (p. 174). The standard of the book improves again towards the end with occasional lapses, and little fault can be found with the chapters on digestion, the heart, and the central nervous system. It is curious that a subject like neuritis should be disposed of in half a page, and that peripheral neuritis should not be mentioned.

The book is concise and well written. The bibliography adds materially to the value. It might very easily be made the best of the short books on this subject of which the importance is becoming more generally recognised. If this end is to be attained considerable additions must be made, and some at least of the subject matter will have to be rewritten.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXVII., April-June.—Dr. N. Gray Hill contributes a paper entitled Notes on the Treatment of Juvenile Rheumatism based on the study of over 500 cases treated at Queen Mary's Hospital, Carshalton, since 1927. He discusses the various therapeutic methods, such as rest, heliotherapy, tonsillectomy, drugs, vaccines, and serums, and states that the basis of the treatment at Carshalton is rest under good hygienic conditions with a very gradual return to the normal activities of life. Although no specific treatment has been found up to the present, there are indications that calcium therapy may prove of value.—In a paper on Indications and Contra-indications for Removal of Tonsils in Children, Dr. P. D. Davidoff, of Taganrog (Russia), reviews the literature and records six personal cases in which tonsillectomy or tonsillectomy was performed with beneficial results for various conditions besides chronic tonsillitis.—Dr. D. Sage Sutherland contributes a paper on Gangrene Associated with Scarlet Fever, in which he emphasises the rarity of the condition, and records two personal cases. The first was that of a Jewish boy, aged 4½ years, who on the eighteenth day of a mild attack of scarlet fever developed gangrene of the left leg. A definite line of demarcation appeared just above the knee in the fourth week. A diagnosis of embolic gangrene was made and amputation was performed a fortnight later. No evidence, however, of thrombosis or embolism was found in the amputated limb. Recovery took place. The second case of gangrene occurred in a boy, aged 4 years, suffering from post-scarlatinal nephritis and otitis media, who developed purpura fulminans on the thirty-sixth day

of disease and died on the forty-second.—Dr. Meta Mackenzie reports a case of Acute Haemorrhagic Pancreatitis in a Congenital Idiot. The patient was a girl, aged 3 years, who developed acute abdominal symptoms after an attack of septic sore-throat and died suddenly. The autopsy showed a condition of acute haemorrhagic pancreatitis with almost complete necrosis of the organ. All the other organs appeared normal, and nothing could be found in the brain to account for the sudden death.—Dr. A. V. Neale records a fatal case of acute anaphylactic shock. The patient was a girl, aged 6 years, who had never had any previous injections of serum or protein, but had been subject to attacks of shortness of breath since infancy. Thirty minutes after injection of hæmostatic serum to check hæmorrhage caused by tonsillectomy death occurred from respiratory and circulatory failure. A conspicuous feature post mortem was complete absence of coagulation of the blood. The thymus was normal.—The abstracts from current literature are devoted to acute infectious diseases.

New Inventions.

A NEW RADON SEED DEPOSITOR.

THE intention of the instrument here illustrated is to overcome the rather slow and tiresome operation of loading the gun each time with one seed; only one rod (P) is used and need not be taken out of the instrument at all, as is done in other models. (M) is the magazine lined with 2 mm. of lead which will hold about 15 0.5 cm. or eight 1 cm. radon seeds. The magazine is loaded by ramming home piston rod (P), which closes the opening of (M) into the open

breach (H) and introducing seeds at the lower end of the magazine. The ejector rod (E) is then screwed in until it meets the last seed. Having introduced the barrel (B) (ruled at 1 cm. intervals up to 10 cm.) into the tissues, the rod (P) is pulled back until it is clear of the breach (H)—a slight turn of the rod (E) which is a spiral, pushes up the column of seeds and under direct vision one seed is seen to appear and lie in the breach; rod (P) then pushes it on and out of the barrel (B). This process can be repeated in quick succession and the magazine emptied. The ring, finger and thumb grips (R R R) facilitate the use and steadying of the whole instrument. (S) is a sliding sleeve which may be fixed at any point along the ruled barrel (B). The rod (P) is bevelled slightly at its distal end and acts both as a needle and a pusher quite effectively. The instrument is heavy, simple, effective, and saves time. I would draw attention to two points; the breach is left open above deliberately to enable the operator to see one seed properly and safely introduced. It is absolutely necessary to allow one seed only to lie in the breach—the oncoming seed, if pushed too far by the fine adjustment rod (E) will foul the rod (P) when it is pushed home. The knack is easily acquired.

The makers are Messrs. Allen and Hanburys, Ltd. of Wigmore-street, London, W.

W. ETHERINGTON WILSON, F.R.C.S. Eng.
Torquay.

NATIONAL HOSPITAL, QUEEN-SQUARE.—From July 2nd the out-patient department of this hospital will be open from 1 P.M. on Wednesdays. Under this new arrangement out-patients will be seen each afternoon except Saturday.

THE LANCET.

LONDON: SATURDAY, JUNE 21, 1930.

REMOVAL OF THE PROSTATE.

In his Lettsomian lectures on enlarged prostate and prostatectomy, publication of which was completed in our last issue, Sir JOHN THOMSON-WALKER has given us a shining example of the way in which progress is made in medicine and surgery. To every scientific advance innumerable workers contribute their quota, and whilst some may have given more than others to no single individual can be accredited all the merit of the final victory. Moreover, as the history of prostatectomy shows, progress is not necessarily continuous. Periods of stagnation and even of retrograde movement alternate with periods of progress. Unfortunately, in dealing with the enlarged prostate surgeons have not always recognised so clearly as has Sir JOHN THOMSON-WALKER this fundamental truth, and in the past an unwholesome rivalry has centred round the question who was the true discoverer of the modern operation of suprapubic prostatectomy. For this reason Sir JOHN THOMSON-WALKER's excellent historical survey is to be welcomed, holding as it does a just balance between the rival claims of different pioneers and of different schools of urology.

Although the French surgeon AMUSSAT had removed an enlarged middle lobe with scissors by the suprapubic route in the year 1836, the story of prostatectomy really commences with McGill's operation in 1887. But from his own writings it is clear that McGill, however valuable we may deem his contribution to prostatic surgery, was content with the removal only of that portion of the prostate that projected within the bladder. Whilst this was a step forward in proving that enlargement was amenable to surgical intervention, the operation itself gave inconstant results. Dissatisfaction with McGill's operation of partial prostatectomy was soon voiced by BELFIELD of Chicago and KÜMMEL of Hamburg. Since normal micturition was not invariably restored by the removal only of the intravesical projection it was obviously necessary to deal with the remaining portion of the gland. As this was difficult by the suprapubic route, attention was directed to a new approach—namely, through the perineum. GOULEY of New York, HENRY MORRIS at the Middlesex Hospital, and ZUCKERKANDL of Vienna, all made attempts to remove the gland by the perineal method but with variable success. That the encouragement to push this line of attack was slight is indicated by the appearance at this moment of a new method of treatment which for a time stopped further progress. Working on the analogy existing between uterine fibromyoma and prostatic overgrowth, J. W. WHITE of Philadelphia suggested that a shrinkage of the enlarged gland might be obtained by the removal of the gonads. Castration therefore for a time was adopted as the easiest method of dealing with enlargement, but this mutilation gave

results that were no more constant than those obtained from partial prostatectomy. Moreover, severe mental disturbance often followed castration in those patients who already displayed a degree of mental instability. Resort was had to vasectomy in an attempt to avoid this difficulty, but, although HARRISON and ROVESING recorded cases of cure from this procedure, it became increasingly clear that indirect methods offered little promise of victory over prostatic enlargement. The year 1900-01, as Sir JOHN THOMSON-WALKER aptly puts it, showed the renaissance of prostatic surgery. Those who had wandered from the path and sought a way round the difficulty retraced their steps. Partial prostatectomy both by the perineal and the suprapubic route found new advocates and again became the routine method of treatment of prostatic obstruction. At this moment FREYER made his appearance on the stage and by his publication of four cases treated by a "new and at first sight formidable operation" called the attention of the world to the possibility of completely removing the enlarged gland. Not that FREYER's advocacy of total prostatectomy was received with universal favour after the publication of his successful cases; MAYO ROBINSON, for example, had no hesitation in describing the complete extirpation of the prostate in its capsule as impracticable from an anatomical point of view. The confusion that then existed concerning the pathological anatomy of enlargement and the surgical anatomy of enucleation has continued in a minor degree until the present time. But FREYER's success stimulated surgeons all over the world to attack the prostate directly and the death-blow was given to the idea of indirect surgery.

In his later lectures Sir JOHN THOMSON-WALKER discusses the refinements of the operation. Of these the most important are the methods of controlling hemorrhage and the means of assessing the functional activity of the kidneys before operation. Whilst hemorrhage was the more dramatic complication it was slowly realised that renal failure after the operation was a more frequent cause of death. Laboratory methods of estimating renal function were introduced to supplement clinical observations, and for those whose renal function tests worked out below a certain level a two-stage operation was instituted. Finally, the lecturer himself became a strong advocate of a new technique, the object of which was to bring prostatectomy into line with other operations and to substitute for blind enucleation an open operation carried out under full ocular control. As the recent discussion in the Urological Section of the Royal Society of Medicine has shown, this operation is now in general use amongst British prostatectomists, although there are still some who consider that it is unnecessary and that the additional time entailed in carrying it out counterbalances any advantage it has to offer. At this point Sir JOHN THOMSON-WALKER's interesting historical summary of prostatectomy ends, for it is here that we stand at the present moment. In spite of the knowledge we have gained, in spite of the improvements we have introduced into our operative technique, prostatectomy is still an operation that carries with it an unnecessarily big mortality. Speaking generally, it may be said that the nearer a technique approaches to the ideal the less are the variations introduced into its practice by different operators. That we are far from having reached uniformity in the carrying out of prostatectomy was amply demonstrated at the Royal Society of Medicine. We still have far to travel.

THE CAUSES OF FOOD POISONING.

WHILE the tendency during the last two decades has been more and more to regard the salmonella group of bacteria as the most important cause of food poisoning, it is clear that this organism cannot be held responsible for every poisoning outbreak outside the rare cases of botulism. W. G. SAVAGE and P. BRUCE WHITE have shown that certain dysentery strains produce food poisoning. Again, the *Bacillus proteus* group has often been brought forward, but here the supporting evidence has been slender, and a very clear case would have to be made out before any particular outbreak could be accepted as having such an origin. The same is true of the *B. coli* group, where the evidence has been even less cogent. On the other hand, there have been many outbreaks of gastro-intestinal disturbance in which bacteriological investigation has drawn a blank, and the responsible organism has been undetected. This has happened especially in mild outbreaks associated with consumption of cheese and milk, and in some of them the possibility of salmonella infection can be ruled out.

Recently in Chicago two sets of observations have suggested a new possibility. DACK and co-workers¹ have described an outbreak of food poisoning affecting 11 persons after eating three-layer sponge cakes filled with cream. Nine were acutely ill with vomiting, mild cramp, and severe diarrhoea, with an incubation period of one and a half to four hours; all recovered. The separate different components of the cake were without ill-effect when fed to monkeys and to human volunteers, but a volunteer who ate 50 g. of the sponge cake substance itself developed symptoms closely resembling those of the original sufferers. Bacteriological examination of the cake substance showed a yellow hæmolytic staphylococcus as the most prevalent organism. A human volunteer who drank 25 c.cm. of a sterile filtrate from a broth culture was ill exactly three hours later with extreme prostration, diarrhoea with blood and mucus in the stools, and apparently some vomiting. Two other volunteers who drank 10 and 5 c.cm. respectively had minor symptoms. Following up this experience Prof. E. O. JORDAN,² the head of the same laboratory, tested the effect of other staphylococci, and isolated five strains which yielded filtrates, toxic when taken by the mouth. Three were obtained from normal human throats, one from a case of human septicæmia, and the other from cheese suspected of causing an outbreak of food poisoning in a village in Porto Rico. These five strains, and also the cake strain, differed from one another culturally, so they do not represent a homologous type. The method of testing employed was to filter 48 hours' old broth cultures through Berkefeld filters and, after testing for sterility, to feed to human volunteers in doses of 5 to 10 c.cm. given in pasteurised milk. About 80 feeding tests were made on 48 male volunteers, and in most of them symptoms of mild food poisoning developed several hours afterwards. These symptoms included dizziness, loss of appetite, weakness of the legs, headache, abdominal pain, nausea, vomiting, and diarrhoea. They were transient, and usually by next morning the patients were quite well. Boiling, and even heating for 30 minutes to 60° C. or 65° C., destroyed the potency of the toxins.

Prof. JORDAN concludes that various strains of staphylococci of diverse origin and different cultural

characters are capable of generating in broth a substance which, when taken by the mouth, produces gastro-intestinal disturbance, and he suggests it is not unlikely that bacteria of other groups may produce similar substances that are irritating to the human alimentary canal. If these observations are confirmed and found applicable to this country, it may be possible to explain more of our minor food poisoning outbreaks. Animal experiments are, however, almost useless for this type of investigation, and the Chicago investigators seem to have been particularly fortunate in having at hand an unlimited supply of "subjects" willing to offer themselves for experimental purposes.

EXPERIMENTAL CARCINOGENESIS.

THE production of cancer in laboratory animals was a most important advance in modern medicine, and the possibilities of the method are now being exploited along different lines by a great many workers. One advantage of working with such a short-lived animal as the mouse is that cancer can be produced in a relatively short time under experimental conditions. A large amount of pathological material can be collected by a single group of workers for the investigation of any one of the numerous problems of cancer in the time it would require to collect a few isolated cases in man. The paper published in our columns by Dr. C. C. TWORT and Mr. J. M. TWORT is based on 4000 tumours of the skin produced by exposing over 29,000 mice to the action of various carcinogenic agents. Of these tumours 1743 were malignant, and the paper is an attempt to classify the different types of growth which have been observed. It is remarkable how great is the variety of forms in which the process of malignancy can express itself in one and the same tissue; under the influence of a carcinogenic agent the cells of the epidermis, or of the hair follicles, or of the sebaceous glands may become malignant. Morphologically the malignant cells themselves may show wide variations, even taking on the shape of spindle cells so as to resemble a sarcoma. Most of these appearances have been described before, but not on such an extensive scale. What is new, however, is the suggestion that the change to the spindle form is due to septic infection of the growth. The prickly cell, being unable to withstand sepsis, would be destroyed by infection, unless it underwent metaplasia into the spindle-cell type which is supposed to be more resistant. Change in morphology of the cells is attributed by the authors to the influence of neighbouring cells; they refer to this change as "a fundamental biological phenomenon." It is a very interesting suggestion, but before it can be accepted more conclusive evidence is required. The experimental methods of transplantation and of tissue culture might help to throw light on the point.

A very different line of investigation has been pursued by Dr. E. L. KENNAWAY and his associates. Since the normal carcinogenic agents, such as tar or shale oil, are crude mixtures containing a large number of different substances, Dr. KENNAWAY has been working on the assumption that these mixtures owe their carcinogenic action to the presence of a chemical substance which has the specific property of producing cancer. Although it is not clearly stated, he seems to consider it possible that when cancer arises spontaneously this may be due to such a substance being produced by the cells of an organ when they are submitted to chronic irritation—a working hypothesis applied with much experimental

¹ Dack, G. M., Cary, W. E., Woolpert, O., and Wiggers, H.: Jour. Prev. Med., 1930, iv., 167.

² Jour. Amer. Med. Assoc., 1930, xciv., 1648.

skill and resource. In a series of extensive investigations¹ Dr. KENNAWAY and his co-workers have prepared and tested a large number of organic substances, some of them fairly pure, while others have been mixtures obtained by the action of heat or of aluminium chloride on relatively simple organic compounds. The object of using the reaction with aluminium chloride was to seek for carcinogenic compounds formed at lower temperatures. It was found, however, that while the undistilled material was inactive, distillation under reduced pressure produced a fraction, boiling at 260°-320° C., which was actively carcinogenic. It appears, therefore, that the carcinogenic substance was produced by the heat of distillation, and that the original object of producing carcinogenic substances at body temperature was not attained. Of the number of simple substances tested 1:2:7:8-dibenzanthracene was the only one which was clearly carcinogenic. Contrary to expectation the carcinogenic power of this simple substance was weak, the period of induction being very long. So far the results do not support the idea of a specific carcinogenic agent, and Dr. KENNAWAY's further researches on this point will be awaited with great interest.

In the course of these observations Dr. I. HIEGER,² working with Dr. KENNAWAY, observed that many of the substances having a carcinogenic action possess the property of fluorescing intensely when exposed to ultra-violet light. In studying with a spectroscope the fluorescence of a number of substances which were also tested for their carcinogenic property, he found that many substances producing cancer had a characteristic spectrum. It may be possible, therefore, to use the spectrum of a substance as an indicator of its probable carcinogenic activity; for final proof a test on mice would remain necessary. Since certain heavy petroleum oils have been shown to be carcinogenic the fear has been expressed that the refined petroleum oils, taken internally for medicinal purposes or applied externally to the skin or nasal mucous membranes, might produce cancer. A priori the suggestion is improbable, for these materials have been used extensively over a number of years without producing any ill-effect. Prof. F. CARTER WOOD, of New York, has submitted³ the question to exhaustive test both by external application to mice and by internal application to rats and mice. As was to be expected, these refined products were found to be entirely non-carcinogenic.

PROPOSED EXTENSION OF ST. MARY'S HOSPITAL, LONDON.—The annual report gives details of the extensive enlargements which it is proposed to make at this hospital. The scheme of immediate development comprises a pay-bed unit of 30 beds obtained by the conversion of a floor of the existing nurses' home, the provision of increased maternity accommodation, made possible by the rehousing of the inoculation department, which will set free some 50 beds, and the erection of the first block of the new nurses' home which will house 224 nurses. The general scheme provides also for the rebuilding of the medical school and the erection of a new inoculation department and institute of pathology and research. For these purposes an appeal for £250,000 will be made. Last year in-patients numbered 4995, their average stay was 22 days, and the average annual cost per occupied bed (average 302) was £181 3s., £21 below the average of the London teaching hospitals. It is pointed out as a financial weakness that 22 per cent. of last year's income was derived from legacies and grants from residuary estates which are necessarily uncertain and fluctuating.

Annotations.

"Ne quid nimis."

THE PÆDIATRIC CONGRESS AT STOCKHOLM.

It is to be hoped that this country will be strongly represented at the International Paediatric Congress¹ to be held at Stockholm from August 18th to 21st. The attendance from abroad is likely to be large and influential, but it is felt in Sweden that the Congress cannot be a complete success without active British coöperation. On such occasions the main advantage usually comes from personal contact between people interested in the same specialty, but the official discussions will be noteworthy if we may judge from the names of the contributors. The first subject, introduced by A. F. Hess, of New York, will be the Biological Effect of Direct and Indirect Ultra-violet Irradiation, and the speakers will include P. F. Armand Delille (Paris), K. Huldscinsky (Berlin), P. Medowikoff (Leningrad), and I. Jundell (Stockholm), who is chairman of the Swedish organisation committee. The second big discussion will be on the physiological and pathological significance of the thymolymphatic system, and the principal speakers will be J. A. Mammam (Uppsala), C. Cattaneo (Milan), E. Moro (Heidelberg), and G. Mouriquand (Lyon). On the fourth day R. D. Gillespie (London), together with F. Hamburger (Graz), N. Krasnogorski (Leningrad), and V. Pechère (Brussels), will bring before the Congress the significance of the psychology and pathopsychology of childhood in its relation to paediatrics and medico-social work. Outside these meetings there will be many lectures and individual communications, and after the Congress excursions may be made both near and far. Further information about the programme and arrangements may be had from Dr. J. C. Spence, 3, Elington-terrace, Newcastle-on-Tyne, who is the secretary of the British committee of the Congress. The other members of this committee are Dr. Robert Hutchison, Dr. H. Morley Fletcher, and Dr. Donald Paterson.

THE CLINICAL FORMS OF OBSESSION.

OUR French colleagues have always paid great attention to the minor mental disorders, and in their "Obsessions et la Psychasthénie" (1903) Raymond and Janet describe what appears to some English readers as an unknown world of symptomatology. Dr. C. Vurpas, a physician of the Salpêtrière, takes up the subject in the *Presse Médicale* of June 4th, and points out how the sufferers hide their troubles from their friends and carry on with the affairs of life even though the symptoms lead to serious disturbances of conduct. The bookkeeper who must continually verify his accounts and his cash cannot carry out his work satisfactorily, nor can the waiter who must ceaselessly count his money till he loses himself in his calculations. How many unhappy homes, Vurpas asks, are to be explained by the obsessions and phobias of one of the spouses? Over-scrupulous self-questioning may progress to haunting doubts of every action, till the sufferer's only refuge is a breakdown, during which he is spared the need of adjustment to the demands of ordinary life. The clinical descriptions given by Vurpas create an uneasy feeling that in this country the facile acceptance of "neurasthenia" or "nervous breakdown" as a diagnosis may hinder full understanding of the conditions we are treating, and those who are accustomed to seek for such symptoms as Janet described are not surprised to discover them concealed under such diagnoses. The concealment can be understood when we remember that the essence of an obsession—when the word is used in its proper sense—is that

¹ See THE LANCET, March 22nd, p. 639.

the symptom is recognised by the patient as absurd and irrational and is therefore to be hidden from the world. The frequent association of the disorder with high intellectual ability and devotion to work suggests that some puzzling cases of suicide, in which the victim is described as having possessed those qualities, may have their explanation in an unsuspected obsessional state, or, as Vurpas would express it, in a constitutional psychasthenia. He believes that in the true psychasthenic there are minor indications which, apart from the obsessions, reveal the psychical constitution; when these indications are absent the case belongs to some other group, commonly the manic-depressive, and this observation may help in the recognition of certain cases which, beginning apparently as obsessional states, falsify the resultant prognosis and become certifiable as frank melancholia. Obsessions may also, he thinks, mark an early stage of dementia præcox or general paralysis, may appear as fugitive symptoms in senile or arterio-sclerotic psychoses, or evolve parallel with another psychosis. Thus the obsessional symptom occurs in a larval form compatible with ordinary social life, being then controlled or even dissimulated; it often leads to a temporary breakdown or permanent incapacity; it is sometimes a part of a psychosis belonging to a well-defined clinical group. Although Vurpas follows Janet in regarding psychasthenia as a constitutional disorder for which only palliation is possible, yet more hopeful views are held as to the accessibility of these patients to analysis. His discussion of clinical possibilities is, therefore, of interest to the general practitioner who might overlook an important group of troubles, to the psychotherapist who must carefully select his cases for treatment, and to the psychiatrist who has the opportunity of watching the evolution of the psychoses.

DISCIPLINE IN MUNICIPAL HOSPITALS.

IN the army, the navy, the police force and other public services it is well understood that a clearly defined channel must be provided for the making of complaints. It is certain that there will always be grumblers, but it is equally certain that some grumbles will be justified. The sense of unfairness and injustice is not so bitter if the supposed grievance can be reported, investigated and dealt with by a known superior officer under some open and well-recognised system. The same principle applies to service in the nursing staff of a hospital. Prevention being better than cure, disciplinary difficulties may often be averted if the persons concerned are clearly instructed in their rights and duties. The public assistance committee of the Birkenhead Corporation recently had occasion to consider this question in connexion with the administration of a poor-law infirmary which the corporation had taken over under the Local Government Act of last year. The incidents which led to the inquiry are of no public concern; the recommendations which resulted are of more than local interest. Those who have any share in the organisation of a municipal hospital may usefully examine their own disciplinary conditions; if they have made no provision for the ventilation of grievances they should study the admirable report drawn up by Dr. D. Morley Mathieson for the public assistance committee at Birkenhead as the result of the recent inquiry and published in the *Medical Officer* for June 7th (p. 257). Discipline, as he observes, must be maintained. Discipline does not mean oppression; it means efficiency, precision, balance, fairness, self-control and harmony; the alternative to discipline is disorder. The hospital committee must support the medical superintendent and matron; the matron must support the sisters, who are her lieutenants. A matron cannot discuss a sister with a probationer; a member of the committee cannot discuss a matron with a sister, or a sister with a probationer. The nursing staff cannot approach individual members of the committee to voice grievances or discuss their conditions of work. Members of the nursing staff must be instructed that

they are never to discuss hospital matters outside the hospital. Gossip about the patients or the staff is unprofessional and a serious breach of hospital discipline.

Dr. Mathieson's recommendations for the improvement of hospital discipline may be briefly summarised. He suggests that a log-book be provided for each sister wherein all reprimands and complaints are to be recorded. Minor corrections and admonitions such as normally occur in a probationer's training are not to be reckoned as reprimands for this purpose. But if a sister has occasion to reprimand a probationer for neglect of duty, disobedience, insolence, breach of rules or gross breach of nursing practice or for any other reason of like gravity, the sister will enter the full facts in her log-book. A complaint by a probationer is similarly to be entered. In either case both sister and probationer will sign the entry. If the probationer declines to sign on the ground that the entry incorrectly records the matter, there is to be an immediate reference to the matron, who will investigate forthwith and, if necessary, consult the medical superintendent. In certain events there is to be an appeal to the sub-committee. Where the reprimand concerns a sister, or where a sister makes a complaint, similar records will be made by the matron. The purpose of this machinery is to ensure the prompt and regular disposal of matters of complaint, and thus to prevent the nursing of grievances and the demoralising effects of cavilling and other forms of disloyalty. The machinery should be as simple as possible. Recourse to it will not be frequent if those in charge of subordinate staff avoid ill-temper, undue severity and unfairness. "A good disciplinarian," says Dr. Mathieson, "has no need to employ despotic or spectacular methods, and is kindly, impartial and even-tempered when dealing with subordinates; this is especially so when any reproof or correction is called for."

SO-CALLED SCIATICA.

THAT man's assumption of the erect attitude has much to do with many cases of sciatica is becoming increasingly evident, and A. P. MacKinnon¹ says that he regards most cases of sciatic pain as due to some disturbance in the fundamentally unstable sacro-iliac or lombo-sacral joints: Goldthwait, Smith-Petersen, and Danford and Wilson in America, and Sicard and Putti in Europe, have drawn attention to the part which strains, injuries, and disease of the lower part of the spine may play in producing pain along the course of the sciatic nerve. C. W. Buckley² in this country found that in 108 patients complaining of sciatic pain the main underlying conditions were osteo-arthritis of the hip (30 cases), lumbar and sacro-iliac strain (26), neuritis of the sciatic nerve (20), and sacralisation of the last lumbar vertebra (9)—or, to put it another way, only 20 of his cases had a neuritis of the sciatic nerve. MacKinnon looks on lumbo-sacral arthritis as the main cause, and thinks that other pathological conditions, especially sacro-iliac disease, are of minor importance. It is true that the anterior ramus of the fifth lumbar root, which plays such an important part in the formation of the sciatic nerve, is the largest of the emerging nerves, passes through the smallest intervertebral foramen, and has the longest bony canal to traverse before it reaches the cavity of the pelvis. On the other hand, our methods of differentiating lumbar arthritis and strains, sacro-iliac and lumbo-sacral disease are still so unsatisfactory that it is hard to accept his claim that the large group of cases previously classed as idiopathic sciatica should be regarded as symptomatic sciatica due to lumbo-sacral arthritis. If this were true the good results reported from local treatment of the nerve trunk itself would be difficult to explain. The nomenclature of sciatica will remain somewhat

¹ Canad. Med. Assoc. Jour., April, 1930, p. 492.

² Buckley: Practitioner, June, 1930, p. 653.

chaotic till more is known of the cause or causes. It is fairly certain that patients will stick to the familiar word, and practitioners will know exactly what they mean, especially if they too have suffered. There are few terms in medicine which are so definitive in the mouth of a patient, and at the same time so apt to mislead writers and readers of medical literature. There is much to be said for Siciard's classification of sciatic pain into high, middle, and low, according as to whether the mischief arises in spine, pelvis, or buttock and thigh. As Buckley points out, this is a useful differentiation for purposes of diagnosis.

HOSPITAL LIBRARIES.

THE address given by Dr. C. Hagberg Wright at St. James's Palace during the recent British Empire Red Cross Conference was a timely reminder of an undertaking which has a great future as well as a very creditable past. The hospital library scheme, started by Mrs. Gaskell early in the war, was run on a vast scale by the British Red Cross and the Order of St. John. The war over, the marvellous stream of books to hospitals began to wane, but so urgent was the demand for books, and more books, by those who had known their stimulus and cheer that the Joint Red Cross Council gave a fund for the continuation of the scheme; and to-day the library is housed at Lancaster Gate, and carried on, in over 2000 hospitals, by a very small staff. Appeal is constantly being made to the public for books and magazines, which are distributed to hospitals that ask for them; when required and whenever possible, special technical books in addition are bought and supplied. But although the work has been unobtrusive, the realisation that libraries in hospitals should mean something more fundamental than a mere collection of books has begun to take root and to grow towards not only a national but an international ideal. America has an extensive and highly developed system of hospital libraries; Germany is giving close study to it, and efforts are being made in other countries. Public opinion is awakening to the necessity of a well-stocked library as part of the curative equipment of every hospital. But the well selected library is only the first stage of the work. It is of little value unless the books are distributed according to the tastes and the physical condition of individual patients. This means a system of librarians with knowledge of psychology as well as of literature. Sometimes a member of the hospital staff combines these duties, but more often a volunteer from outside has to be found. Methods vary in certain countries and their comparative merits await further study. In the stage that has been reached certain facts stand out clearly. First, hospital libraries depend for their success on wide study and above all on public opinion. The Hospital Officers' Association is taking a keen interest in the movement, and the February issue of the *Hospital* outlines a scheme for running a library in a large London hospital. In the Manchester Royal Infirmary a rota of 200 H members in conjunction with their league of women helpers distribute books to patients five nights in the week. Such libraries need the backing of the great body of doctors, nurses, hospital authorities, and welfare workers. It is easy enough to send a parcel of books to a hospital; it is less easy to fit the reading to the state of the patients, and to select books so that they may alleviate, amuse, or stimulate, as the need may be. In countless instances the mind of a patient can be relieved by the right book at the right moment; this is especially the case with interrupted studies. There are many incidentals of the work, such as unpacking, rebinding, cleaning, mending, listing, and packing, all important to the successful working of the scheme. Those who are doing this hospital library work would welcome inquiries and constructive criticism. Correspondence may be addressed to the secretary at 48, Queen's-gardens, Lancaster Gate, W. 2.

REDUCTION OF FRACTURES.

THE first essential in the treatment of a fracture is its reduction, and this will often test the skill of the most experienced. Some form of traction is necessary, and during the last few years many surgeons have been considering what is the best way of applying it. Lorenz Böhler, of Vienna, has drawn attention to the value of pin-traction as a means of reducing, and maintaining the reduction of, fractures of a long bone. In fractured femur, for instance, a steel pin is passed in and out of the limb, through two skin punctures, and transfixes either the shaft of the femur below the fracture or the tibia below the anterior tuberosity; to the ends of the pin a steel stirrup is attached, and from this last a traction cord passes to a pulley and weight. The use of Kirschner's wire is lending this method a remarkable simplicity and precision. Recently a valuable contribution to the technique of fracture reduction has been made to the *Journal of the American Medical Association* (May 17th, p. 1517) by Robert Soutter, of Boston. The method is to increase traction gradually, under an anæsthetic, to an amount that will in 15-30 minutes relax the muscles enough to make reduction fairly easy. The traction is facilitated by an apparatus consisting of a rod 80 inches long bent at right angles at one end. The figure which we reproduce from the *Journal* shows the method of reducing fractures of the humerus and elbow.

"At the end of this right angle is a hook and at the other end of the rod is a hook. The rod is made up of several pieces, so that it may be taken apart and put in a small case. Each section is about 20 inches long. It is made of tubular steel and not of iron piping, as the latter does not stand the strain. Each tube is fastened to the next by a steel rod which is inserted in the tube. The steel rod should not bend and should be very strong. There are two webbing straps 40 inches long and 3½ inches wide with a heavy steel ring in each end. The webbing should be strong and double, and the ring should be stitched solidly so that the stitching will not rip. There is a spring balance that will measure 100 pounds, and there are two double block pulleys

with heavy cord. These block pulleys are 3 inches long and 1½ inches broad, and there are rings for hooks at each end."

Unbleached calico is used for making a Delbet knot for traction at the wrist or ankle in fractures of the upper or lower limb respectively; or at the ankle, instead of this knot, loops may be employed of heavy webbing 1 inch broad and 5 feet long made of three thicknesses stitched firmly together. The ankle and foot are encased in thick felt and the webbing is applied over it in the form of a figure of eight.

On the average traction begins with 10 lb., increasing at three-minute intervals to 20 or 25 lb., at which it remains for 15 to 30 minutes. The maximal traction in some cases is 15 lb., while in others, especially fractures of the femur, it may be 50 lb. or more; the amount is measured by a spring balance. At the end of the indicated time there is muscle relaxation lasting five to seven minutes, and during this period the fragments are manipulated into position with or without the maintenance of traction. If reduction is unsuccessful, then the maximal traction is applied again for five or ten minutes more and another attempt made. When reduction is effected full traction is applied until the controlling splint is fixed; after this the traction is diminished—for example, when Thomas and sheet metal splints

have been securely applied to the leg the traction need not be much more than 10 lb. In summarising his views on this mode of treating fractures Soutter says that the difficulty lies not so much in the reduction as in the ability to wait patiently for the proper length of time before manipulating the fracture. He holds that many fractures which cannot be reduced by the usual methods will respond to this technique.

TUBERCULOSIS IN AMERICAN CHILDREN.

A GROUP of four articles reprinted in book form¹ from the *American Review of Tuberculosis* for October, 1929, deserves attention. The first is by E. L. Opie, H. R. M. Landis, F. M. McPhedran, and H. W. Hetherington, who describe the widespread incidence of tuberculosis in childhood and discuss the difference between children who may profitably receive treatment to prevent further development of tuberculosis and those, who, though infected, require no treatment. In the second article the same authors describe a survey undertaken in the attempt to determine the prevalence of tuberculous infection in school-children. It gives a full account of tuberculin results and X ray findings in children of different races and ages. The incidence of the tuberculin reaction increases from birth till adult life. The third article, by H. W. Hetherington, describes the organisation of open-air schools for the treatment of tuberculous children, and the fourth article, by F. M. McPhedran, deals with the diagnosis and classification of pulmonary tuberculosis in childhood and adolescence, and concludes with 44 excellent plates showing X ray appearances reproduced by an adaptation of the aquatone process. The usual clinical examination is not sufficient to discover what children need protection against tuberculosis, and the authors show the importance of other methods, such as tuberculin and especially X rays, without which no examination is complete. The work is one of considerable importance and will be much appreciated by those interested in the diagnosis, treatment, and public health aspects of tuberculosis.

INSTRUCTION ABOUT DIET.

THE fundamental truth that man's body is built up largely of his food has always been easily apprehended, and the notion that its quality and quantity can influence his development and maintenance has been pondered over and taught about by philosophers, prophets, and law-givers as far back as history records. Mr. Walter de la Mare has pointed out that "It's a very strange thing, as strange as can be, that whatever Miss T. eats, turns into Miss T." But what interests her parents, guardians, or medical advisers is the effect it has on her in the process. This is not at all easy to ascertain. The adaptability of living matter to obvious changes in the food-supply, its failure of adjustment to quite obscure changes, and its individual variation in responding to changes of any given kind, make it very hard to discover a definite relation between the character of the food eaten and the health of any particular person. It is true that much has been done of late years to shed light on the complicated problems involved. Careful experiments on animals have taught us to appreciate the value of certain foods and food constituents and, in a few instances, controlled observations on large groups of human beings have yielded definite results leading to similar conclusions. It is easy to be impatient of this tedious method of arriving at the truth and, impressed perhaps by a few casual observations, one may feel called upon to expound principles of nutrition which not only have no scientific backing but may even have been proved contrary to demonstrable facts. If any useful purpose is to be served by whole-

sale propaganda in favour of food reform it is essential that any definite recommendations made should be supported by clear evidence that they are fundamentally desirable. A pamphlet on children's diet, recently published by the Food Education Society, illustrates the difficulties of broadcasting practical advice concerning the choice of food for children. Some of the advice contained in the leaflet is without question of real importance, as for example the warning against too exclusive a use of sugars and starches, the encouragement of a more liberal consumption of vegetables, salads, and fruit, and training in good habits of mastication. But in many respects the advice given must prove puzzling to those who are acquainted with the established principles of nutrition. The impression is given, for instance, though perhaps not intentionally, that milk is not merely unnecessary for young children but positively harmful. Meat is considered almost a poison, and meat soups, gravies, and extracts are even more dangerous, because they are said to contain the concentrated poisons of animals. It is suggested that children should rely on cheese, eggs, and nuts for their necessary protein though even eggs are to be used only in moderation. Bananas are stated to be responsible for a great deal of digestive disturbance and milk puddings should be barred from every table. That children may apparently thrive under such régimes no one need doubt, for it is known that men can be reared on diets of extraordinary diversity. The education of the public to realise that the nature of the food given to a child may determine the perfection of his physical development and his reactions in after life to disease-producing agencies is an estimable object. It cannot be too strongly emphasised, however, that for such propaganda to have any enduring success it must be based on facts which can be scientifically proved and must be as free as is humanly possible from any taint of prejudice.

PUBLIC HEALTH IN SHANGHAI.

THE report of Dr. C. Noel Davis, commissioner of public health of Shanghai for the year 1929, has just appeared, and is a document of real interest. Indeed the Shanghai Medical Society, upon its publication, has placed on record its high appreciation of the activities of the public health department of the Shanghai municipal council. But the honorary secretary of the Society, Dr. H. Cooper Patrick, in sending the findings of a sub-committee of the Society presented to the annual meeting some two months ago, indicates that it is only the position of State medicine that is satisfactory to the Society, for otherwise the medical profession suffers in Shanghai from heavy professional drawbacks. The report of the subcommittee of the Society emphasises the mischief done through the licence enjoyed for medical practice by persons who are not registered as qualified practitioners in their own country. At the present their practice and professional status seems unaffected by the absence of proof that they are doctors. The Society therefore suggests that a board of medical registration should be formed with the duty to issue licences to those properly qualified to practise in the Settlement, and that similar registration restrictions should also be required for pharmacists. It is almost a direct sequel to such resolutions that the Society should also insist on the standardisation of teaching schools, especially those attached to hospitals. These resolutions are in accord with recognised developments of medicine in civilised countries, and the suggested reforms would follow along the indicated lines. The Shanghai Medical Society enjoys a good professional position and membership is open to all properly qualified medical practitioners recognised as such in their own country. It has existed nine years, its presidential chair has been occupied by members of American, British, Chinese, and French nationalities, and its proceedings should assist the undertakings of the League of Nations in international

¹ Tuberculosis in Public School Children. By Various Authors. From the Henry Phipps Institute of the University of Pennsylvania under a grant from the Metropolitan Life Insurance Company. Pp. 223.

hygiene. Dr. Noel Davis's report calls particular attention to the epidemics during the year of cerebrospinal fever, which was reported in Shanghai in March, and cholera which appeared in September in a severe form, though with a lower mortality than had characterised previous outbreaks. In this connexion he makes reference to the visit paid at the end of the year by Dr. Rajchman, Director of the Health Section of the League of Nations, finding it "impossible to estimate too highly the achievements of the League in the cause of international science." Dr. Rajchman was accompanied by Dr. Boudreau, and they took part in an interesting discussion with a number of Chinese and foreign officials, having for its object the prevention of cholera and other communicable diseases in Shanghai. The statistical summary, derived from an interesting report, justifies Dr. Davis's optimistic outlook.

UNDULANT FEVER IN MALTA.

THE paper by Sir Themistokles Zammit and Dr. J. E. Debono, which we publish on another page, comes as a rude reminder of the fact that although the labours of the Mediterranean Fever Commission of 1904-05 removed, for all practical purposes, the dreaded undulant fever from the medical history sheets of the Services, the civil population of Malta, left to work out its own salvation, still suffers as heavily as ever. From the most recent report on the health of the Maltese islands we learn that in 1928 undulant fever headed the list of notifiable infectious diseases, with a total of 962 cases and 42 deaths among the total population of 230,618. As the bulk of the cases involve young adults, the problem is a serious one for industry as well as for the public health authorities. It is now generally accepted that in at least 70 per cent. of the cases the disease is conveyed by milk derived from goats infected with *Bacillus melitensis*, and it is equally clearly established that the infectivity of the milk can be readily destroyed by boiling or even by efficient pasteurisation. It is difficult, therefore, to understand why the disease has not been stamped out from the Maltese islands during the interval (now a quarter of a century) that has elapsed since the findings of the commission were made known, and why no attempt has been made to cope with the situation either by the adoption of palliative measures such as compulsory sterilisation of the milk, or measures based upon the Bang process for the eradication of the infected animal—practical proposals which were made by Dr. John Eyre in a report upon the work of himself and his colleagues in 1906. The answer to these questions undoubtedly is that local conditions, only too familiar to those who have worked in Malta, coupled with lack of financial support, have stultified the efforts of the public health department in dealing with the infected milk goat. It is true that Zammit, who has never allowed his ardour in the study of *melitensis* infection to lessen, has from time to time aroused the sympathetic attention of various authorities, but in the past lack of funds has operated adversely toward his endeavours. His present investigation, however, appears to have received material support from the Legislature of the island, and the results he records, though by no means conclusive, suggest that he has achieved a measure of success. His attempts at cuti-immunisation form a logical corollary to Besredka's claims, and if these latter are based on solid foundations, it may well be that modifications in technique will enable Zammit to confer a lasting benefit upon his fellow-countrymen. Incidentally his observations bring out a disquieting but very important point—namely, that certain animals, though proved by post-mortem examination to be heavily infected, fail during life to show what has hitherto been regarded as the cardinal sign of infection—i.e., specific agglutinins in the blood serum. This observation is one that demands further and fuller investigation, because if it holds good to any marked extent it must greatly increase the difficulties of prevention.

STREET ACCIDENTS.

THE note on street accidents in Bremen (see p. 1302) by Major P. G. Edge, of the London School of Hygiene and Tropical Medicine, raises an interesting question. Major Edge points out that the allocation of responsibility for traffic accidents made by the Bremen authorities contrasts glaringly with that established here with respect to fatal accidents, and suggests that a concentration of attention upon the latter may give us an incorrect view of the aetiology of a disease which claims thousands of victims. Some of the most fruitful work of the Industrial Health Research Board has been based on the study of trivial accidents, has established the importance of individual psychological factors, and has gone some way towards the differentiation of the temperamental types prone to accident. It is probable that these results may be generalised and that there are now in legal control of masses of steel capable of being hurled through our streets at high velocity many persons not only unfit to shoulder such a responsibility, but not capable of discipline by legal sanctions. Evidently the first step towards real knowledge is a more precise analysis of a sample of the facts than has yet been published. Major Edge makes some valuable suggestions. In addition to these we think some use might be made of car insurance data. The companies presumably now possess extensive particulars of accidents of all degrees of gravity. Is it too much to hope that this experience will be used? An analysis of such data by a scientific committee containing medical, psychological, statistical, and engineering experts should be illuminating. It may be true that a mere test of proficiency, even if administratively practicable, would be but a poor safeguard; yet the contrast between the stringent conditions imposed upon would-be amateur aeronauts and the free trade in terrestrial locomotion is curious. That the only guarantee of fitness our laws demand of a raw lad, before he is allowed to bring out upon a crowded highway a ton and a half of machinery, capable of passing from rest to a velocity of 60 miles per hour within a few seconds, is his ability to write his name and pay a sum of 5s. may seem to a future generation at least as monstrous as any of the savage customs of our ancestors.

VARIABLE RESPONSE TO INSULIN.

IT is a common observation that some diabetic patients vary from time to time in their reaction to similar doses of insulin, even in the absence of complications, such as infections, which tend to aggravate the disease. Karelitz and co-workers¹ have recently investigated the suggestion that this variability in response to insulin is due to the presence in the diabetic patient's blood of some substance which neutralises or inactivates insulin. They find that insulin, after incubation with blood plasma obtained from a diabetic patient, loses its power to produce hypoglycaemia in rabbits. Intact corpuscles give indefinite results, but laked corpuscles possess the same property of inactivating insulin to an even greater extent than plasma. Control experiments in which saline solution, agar-agar, and egg albumin are substituted for blood yield negative results, and such changes as occur in the pH of the incubated mixture are insufficient to explain the phenomenon. It is, however, a significant fact that normal blood possesses this same inhibiting action on insulin, although in much smaller degree. It is difficult to assess the importance of these results, since eight years of research following the isolation of insulin have failed to reveal either the structure of the hormone or the way in which it exerts its profound action on carbohydrate metabolism. Further control experiments seem desirable, for such a mixture of substances foreign to the rabbit as human blood

¹ Karelitz, S., Cohen, P., and Leader, S. D.; Arch. Int. Med., April, 1930, p. 546.

might well provoke reactions which would quite indirectly interfere with the action of insulin. Such a possibility could be excluded by observing the effect on the rabbit's blood-sugar of blood and insulin, incubated separately and injected simultaneously. A. A. Epstein and N. Rosenthal believe that in diabetes changes in the permeability of the vessels permit trypsin to leak into the blood stream, where it antagonises insulin. But it is difficult to believe that we are dealing with trypsin, for normal as well as diabetic blood possesses this property.

These experiments, at present, do no more than confirm the impression that the action of insulin involves a very complex type of chemical reaction.

INTERNATIONAL STANDARDISATION OF COLOUR VISION TESTS.

FOLLOWING on resolutions passed by the Scandinavian Ophthalmological Congress, the subject of international standardisation of colour vision tests has been considered by the International Labour Office at Geneva. A report on the subject, prepared by Prof. Oscar Oblath, of Trieste, has now been translated into English.¹ Of the tests in general use, Holmgren's wool test is found to be an inadequate test of fitness for the railway service, on the grounds that the large size of the test objects allow those with a central scotoma to pass, and that the saturation of the colours makes the test too easy for the detection of the slight defects. The most efficient test for examining on a large scale is declared to be Stilling's pseudo-isochromatic diagrams as revised by Hertel and published by George Thieme, of Leipzig (1926). In this test, on a background composed of colour spots of different sizes, numerals are marked out in spots of the confusion colours. Railway candidates, it is said, should be able to pass two of the most rigorous tests. The anomaloscope of Nagel is a test in which the candidate has to mix a measured amount of red and green lights until they match a constant yellow, and for scientific purposes a quantitative test of this sort is desirable. Edridge-Green's lantern—the test employed by the Board of Trade in this country—is acknowledged to be efficient in the hands of a competent examiner, but the fact that in this test the colours have to be named by the candidate is regarded as a disadvantage; it must be noted that Dr. Edridge-Green himself claims this as an advantage, since in actual life the engine-driver (for instance) has to name the colours to himself in order to distinguish them—a point of view endorsed by Sir John Parsons.² In view of the fact that a considerable number of railway accidents and disasters at sea have been proved to have been due to defects of colour vision, the importance of the subject is evident. The report recommends that every Government should establish regulations specifying which employees in the transport services, whether by land, sea, or air, ought to be subject to an examination of their colour vision, and stating precisely the methods to be used in the examination and the manner in which they ought to be applied. Uniform regulations for all countries is the ideal, but, short of that, each country should have a definite legal enactment applicable to all the services concerned.

² Diseases of the Eye, fourth edition, p. 381.

TREATMENT OF EARLY NERVOUS DISORDERS.—The Sussex County Hospital at Brighton is preparing to open in the autumn a department for the treatment of early nervous disorders, and Dr. Helen Boyle and Dr. George H. Harper-Smith have been appointed honorary medical officers. It will be a consultative out-patient department and will be worked in co-operation with the Lady Chichester Hospital, Hove.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. K. D. Bell is placed on ret'd. list with the rank of Surg. Capt.

Surg. Lt.-Comdr. (D) F. W. Watt is appointed to the *Victory*, for R.N. Barracks, Portsmouth.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. (temp. Col.) D. S. Skelton, from R.A.M.C., to be Col.

Lt.-Col. E. Bennett retires on ret'd. pay.

Lt. A. R. Cowan relinquishes his temp. commn.

ARMY DENTAL CORPS.

Capt. H. F. Byrne to be Maj.

ARMY RESERVE OF OFFICERS.

Maj. A. W. A. Irwin, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

MILITIA.

Maj. J. R. R. Trist retires on attaining the age limit and is granted the rank of Lt.-Col.

TERRITORIAL ARMY.

A. S. Henderson to be Lt.

ROYAL AIR FORCE.

H. R. Klein is granted a short service commission as a Flying Officer for three years on the active list.

Flight Lt. R. Boog-Watson is promoted to the rank of Squadron Leader.

Maj.-Gen. W. R. Blackwell, late R.A.M.C., has been appointed Hon. Surg. to the King, vice Maj.-Gen. H. P. W. Barrow, late R.A.M.C. (ret.).

ROCKEFELLER MEDICAL FELLOWSHIPS.—These Fellowships are awarded to graduates who have had some training in research work either in the primary sciences of medicine or in clinical medicine and surgery, and who are likely to profit by a period of work at a chosen centre in America or, in special cases, in Europe, before taking up positions for higher teaching or research in the British Isles. The Medical Research Council announce that on behalf of the Rockefeller Foundation they have appointed the following graduates to Travelling Fellowships for the academic year 1930-31: Russell Claude Brock, F.R.C.S., of Guy's Hospital; Frank Burnet Byrom, M.R.C.P., of the London Hospital; Desmond Curran, M.R.C.P., of the Hospital for Epilepsy and Paralysis; Alan Aird Moncrieff, M.R.C.P., of the Hospital for Sick Children, Great Ormond-street; Arthur Spencer Paterson, M.B., Assistant Physician to the Royal Glasgow Mental Hospital; and Charles Cady Ungley, M.R.C.P., of the Royal Victoria Infirmary, Newcastle-on-Tyne.

Dr. Moncrieff's Fellowship is tenable at Hamburg; the others at centres in the United States. Mr. Brock and Dr. Curran have been appointed on modified conditions while receiving emoluments from other sources.

HOSPITAL ACCOMMODATION IN DORSET.—The Duke of Somerset last week opened an extension of Shaftesbury Hospital which provides four additional wards, two public and two private, containing 12 beds. The extension, which has been necessitated by the growth of the Hospital League, which has brought more patients, and the increase in motoring accidents, has cost nearly £5000.—At a conference between the Dorset public assistance committee and representatives of the voluntary hospitals of the county, it was stated that there are ten voluntary hospitals in the area. They contain a total of 394 beds, 67 of them for children, and 22 for maternity cases. In 1929 they treated 5350 in-patients, an increase of 1146 since 1927, of which 221 were maternity cases. The Cornelia and East Dorset Hospital, at Poole, with 105 beds, is the largest in the county, and last year it treated 1369 in-patients and 105 mothers. It was suggested that the 393 sick and infirm now under the care of the public assistance committee in 11 different institutions might be concentrated in from four to six infirmaries, but no recommendations were made.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles Contributed by Invitation.

LXXVII.

INTERPRETATION OF BLOOD FILMS.

MEDICAL diagnosis is a kind of speculation that should, so far as possible, be founded on facts. The interpretation of a blood film as an aid to diagnosis is in this respect twofold. The facts are dependent upon an accurate recognition of any morbid changes which may be present; the speculation is the application of these facts to the clinical condition of the patient. It must be insisted at the outset that an accurate description of a blood film requires a long and very special training, and that the information afforded by a film alone is rarely sufficient for a diagnosis, and never equivalent to that provided by a complete blood examination. It is often possible, however, from the preliminary examination of a blood film to decide if a complete blood count is necessary or not, and, provided that the pathologist is given some clinical account of the patient, data bearing upon the diagnosis are frequently available.

PART I.—THE RED CELLS.

In the stained film preparation alone we have only to consider the three formed elements of the blood, the red cells, platelets, and white cells. The red cells may vary in number, size, shape, staining reaction, and maturity. The film gives little or no indication of the number of red cells present to the cubic millimetre. Deviation from the normal size can be estimated from a dried film, since the shrinkage of the red cells in the process of drying and fixation does not vary widely in different preparations.

Variation in Size.

Marked variation in the size of the red cells present is usually associated with alteration of shape (poikilocytosis), and may be found in any form of anaemia. Such cells may be pear-shaped or otherwise distorted, and these appearances can be distinguished from simple crenation or the effects of undue pressure in making the film. These changes are only very exceptionally present with a high red cell count, and are most extreme in pernicious anaemia, where they may occur before any serious diminution in the number of red cells has taken place. In the rare condition of aplastic anaemia alterations in size or irregularity in size (anisocytosis) occur without alteration in shape, the majority of the abnormal cells being small. In pernicious anaemia the average diameter of the red cells is above the normal, this increase of size is a valuable diagnostic feature, since in the majority of secondary anaemias the average size of the red cells tends to be below normal. The megalocytosis is usually sufficient to be recognised without direct measurement by the experienced observer, but in case of doubt actual measurement is advisable.

Depth of Staining.

The depth of staining of the red cells gives a fair indication of the amount of hemoglobin they contain; pallid cells with a large and colourless central area are suggestive of a considerable degree of anaemia. The percentage of hemoglobin cannot be even approximately estimated, but it is usually possible to tell from the film alone whether there is a grave hemoglobin loss or not.

Polychromasia.

A purple tinting of the red corpuscles with Leishman's stain, or *polychromasia*, is never general.

and the proportion of cells so affected is an indication of the number of immature cells. Wrinkled, polychromatophilic cells are frequently reticulocytes, and are numerous in certain phases of pernicious anaemia, but are seen in other states and are most abundant in the relapses of hemolytic icterus. The absolute recognition of reticulocytes requires a special staining process for the reticulum which is not effective in a dried film. Polychromasia is always present in films showing any marked degree of poikilocytosis and in all nucleated red cells. Generally speaking, it may be said that changes of shape, size, and staining reactions vary together and indicate the same process—namely, the reaction of the red marrow to red cell destruction. Complete absence of these changes negatives any severe form of anaemia (with the single exception of aplastic anaemia), their presence varies with the severity of the anaemia, being most extreme in untreated pernicious anaemia and least evident in the milder secondary anaemias.

Granular Degeneration.

Stippling of the red cells, or granular degeneration, is a condition in which the red cells are found to have a powdering of fine bluish granules through their cytoplasm. This change may occur in primary and, to a less degree, in any form of secondary anaemia; it is rare, however, to find granular degeneration in any considerable proportion of the cells or in a coarse and obvious form in any other condition than acute lead poisoning. Red cells showing this change may be present in lead workers without actual symptoms of poisoning, but they may be absent in chronic cases, even when colic or palsy have occurred, and as evidence of lead absorption are not so dependable as the presence of a blue line on the gums or lead in the urine. In acute lead poisoning stippled cells are in the degree in which they are usually found, almost diagnostic of the condition and may afford the first clue to the diagnosis.

Normoblasts and Megaloblasts.

Nucleated red cells are entirely absent from the peripheral circulation in normal adult life. In childhood nucleated red cells are present at birth, and may reappear in the circulation in response to mild stimuli. The interpretation of the blood film in children under 8 years of age must always be undertaken with the understanding that the cellular elements are far more subject to fluctuation than in later life, and that primitive cells may appear in considerable numbers in almost any trivial disorder. In the adult even the finding of a single normoblast is of significance, and the presence of megaloblasts may be of serious import. The distinction between normoblasts and megaloblasts is necessary owing to the different conditions associated with the appearance of these two cells in the peripheral circulation. The histological differences are mainly in the nuclei, less in the relative sizes of the cells. The normoblast is a dead cell with a deeply and evenly staining or "pyknotic" nucleus, the megaloblast—in its more primitive form—is a living cell with a peculiar stippled network in the nucleus. The normoblast may appear in any secondary anaemia, such as that consequent to hemorrhage, provided the blood loss is severe. The megaloblast is only found in a limited number of serious disorders. It is a diagnostic feature of pernicious anaemia, but occurs also in the severe anaemia of the puerperium, in myelophthisic anaemia, in the leukemias, and in the small group of disorders associated with a pernicious anaemia blood state, including the anaemia of sprue and poisoning by arseniuretted hydrogen. In these anaemias, as in pernicious anaemia, a tentative diagnosis may be hazarded from the blood film alone, the chief points being advanced alterations of shape and staining reaction of the red cells, an increase in the average size, the presence of megaloblasts even in very small numbers, and, in addition, an apparent leucopenia with a relative lymphocytosis. In the anaemia of cancer, associated with secondary deposits in the

red marrow—myelophthisic anæmia—there may be no noteworthy blood changes, but more frequently the changes are extreme, and the film alone may be almost diagnostic. The chief features are the presence of nucleated red cells, both normoblasts and megaloblasts, in numbers approaching that of the white cells, extreme changes in shape, size, and staining reactions, and the appearance of occasional primitive white cells. The general appearance of the film may be indicated by the confession that it is the preparation one usually demonstrates to students, as from a case of pernicious anæmia, a disorder in which these changes are all present but never to this degree. The average size of the red cells is, however, small, and the blood count reveals a low colour-index.

Parasites.

The examination of a blood film for the parasites of tropical diseases is scarcely within the scope of this article, but the identification of the malarial plasmodium may be mentioned, since it not infrequently happens that they are met with unexpectedly in an obscure case of fever. The parasites are recognised within the red cells in a Leishman-stained film by their blue staining cytoplasm, purple chromatin, and dark pigment granules. In the more usual forms in which they appear in blood films taken in this country the benign tertian parasite occupies an enlarged red cell without filling it; the quartan form usually occupies the entire area of a red cell of normal size, the malignant tertian parasites are usually very scanty, and appear as signet-rings and crescents.

Blood-platelets.

The blood-platelets are readily recognisable objects in the stained film, and the only diagnostic information which they yield results from an enumeration of them. An accurate platelet count is completely upset after the blood is shed and clumping of the platelets has taken place, but the film is a fair guide to any gross change of number. The most extreme diminution of the platelets is found in the purpura of essential thrombopenia, and there is an evident loss in aplastic anæmia. The finding of abundant platelets in films from suspected examples of either of these two conditions would negative the diagnosis. The platelets appear in the films in increased numbers and in large clumps in a variety of clinical states, including the chronic leukaemias and the acute inflammations. These increases, however, are accompanied by other and more readily diagnostic changes in the leucocytes.

Summary.

Briefly, the chief points to examine for in the red cells of a stained film are those alterations of shape, size, staining reaction, and nucleation which indicate red cell loss and its normal sequel—red cell regeneration. Anæmia, in its milder forms, can only be recognised by a red cell and hæmoglobin estimation. The red cell changes of the more severe anæmias can nearly always be detected in the stained film, and some indications can usually be made out of the nature of the anæmia. The film, at any rate, will frequently direct us to the necessity of a fuller blood examination.

P. N. PANTON, M.B., B.Chir. Camb.,
Director of the Clinical Laboratories,
the London Hospital.

MILLER GENERAL HOSPITAL.—The annual report of this hospital for South-east London records a financial crisis and describes how it was temporarily surmounted. Towards the end of last year the position became so critical that it was feared that a large part of the hospital would have to be closed. An appeal through the press was fruitless, but the crisis was averted by the grant by King Edward's Fund of £12,000 from the Thankoffering Fund. The year's expenditure exceeded £38,000 (151 beds were in use), as against £33,000 in 1928, when the average number of beds available was 136, and there was a deficit of £3781. The in-patients numbered 2200, an increase of 166; their average stay was 22.93 days. The new out-patients received in the various departments numbered 31,124, also a substantial increase.

STREET ACCIDENTS.

By P. GRANVILLE EDGE, O.B.E., F.S.S.,

ASSISTANT LECTURER, DIVISION OF EPIDEMIOLOGY AND VITAL STATISTICS, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

FOR some years the number of deaths caused by mechanically propelled vehicles has been increasing at about the same rate as the number of licensed vehicles. Between 1922-23 and 1928-29 the number of licensed vehicles increased from rather fewer than 1,000,000 to slightly more than 2,000,000. In 1923 2414 persons were killed in England and Wales; in 1928 the number was 5190. The price to be paid for the convenience and pleasure of motor transit is, it will be seen, a trifle heavy, and the industry and ingenuity of official statisticians are taxed to set out the information in the most illuminating way. Our own authorities are very energetic, but a recent report of the municipal authorities in Bremen¹ suggests some lines of inquiry which might be profitably followed here. The Bremen statisticians have gone to work with teutonic thoroughness; their records enable street accidents to be classified by hour, day, and month of occurrence and kind of vehicle or vehicles involved; they show whether the accident was due to mechanical defects in the vehicle, or to negligence, errors of judgment, or other faults on the part of the driver or pedestrian; whether the accident involved collision with roadside obstructions; degree of severity of injury received—slight, severe, or fatal, &c. (So complete are the particulars that it is curious to find neither the age nor the sex of persons killed or injured tabulated.)

The Bremen Data.

When attempting any examination of these records it is to be remembered that the Bremen data have reference to street accidents of all kinds, whether resulting in personal injury or deaths, or merely damage to vehicle or property. Such wealth of published information is not usual in our own country, where the tendency prevails of only publishing statistics of the numbers of persons killed or injured as the result of such accidents. It is a pity that some of the tabulations are not readily intelligible, still the general results are interesting.

It appears that street accidents in Bremen during 1929 showed an increase of 27 per cent. over the figures for 1928, largely due, no doubt, to the increased volume, both of vehicular and pedestrian traffic during the period, since motor vehicles of all kinds had increased by over 30 per cent. in 1929, motor-cycles by 51 per cent., pedal cyclists by 34 per cent., pedestrians by 29 per cent., while other traffic showed percentage increases varying from 8-16 per cent.

The distribution of these accidents by month of occurrence reveals that during 1928 fewer accidents occurred during January than in any other month. In February, however, the figures were almost doubled, and thereafter followed a steady and continuous rise each month, with a further considerable increase during the month of July, when the peak of the accident curve was reached. In 1929, February was the month of fewest accidents, followed by a slight rise during March, and then a rapidly rising tide to the end of May; during June and July accidents were fewer—a rise in August—the peak being reached during the month of September. These differences may be attributed in part to the fact that while the summer and autumn of 1928 were

¹ Die Strassenunfälle in der Stadt Bremen. 1928 und 1929. (Bremen Verwaltungs- und Wirtschafts-berichte. Heft 1. January, 1930.)

generally wet, cold, and discouraging to the majority of pleasure-seekers, those seasons during 1929 enjoyed high temperatures and fine weather—conditions favourable to increased use of road traffic by tourists and others. When the data are further analysed to discover the accident incidence by days of the week, Saturday produced by far the greatest number of street accidents, with small peaks on Tuesdays and Thursdays, Sunday appearing a comparatively innocent contributor. No exact comparison can be established with the figures for London, but if the numbers of ambulance calls (street accidents) each day are tabulated, it may be seen that in London (as in Bremen) Saturday is unquestionably the most dangerous day of the week. Sunday the safest; curiously enough, the smaller peaks in London are Fridays and Mondays (week-enders?) and Wednesdays, the latter probably having some close correlation with early closing in provincial areas.

Daily Incidence of Accident.

The characteristic features of the incidence of street accidents tabulated daily by hour of occurrence in London and Bremen seem to be as follows:—

- (a) In Bremen there is a steady rise between 11 P.M. and 2 A.M., though in London there is a decrease in the numbers of such accidents between 11 P.M. and 5 A.M.
- (b) At 6 A.M., in both cities, the tide of increase definitely asserts itself, and continues to mount—in Bremen until 2 P.M., in London there is a noticeable falling-off between 9 A.M. and 11 A.M., then continuing to rise to 2 P.M.
- (c) Between 2 and 3 P.M. a falling-off in both cities.
- (d) Between 3 and 5 P.M. a rise in both cities, though less marked in London.
- (e) 5 to 6 P.M. decrease in Bremen, followed by rise 6 to 7 P.M. 5 to 7 P.M. sharp rise in London.
- (f) Between 7 and 11 P.M. in Bremen and 7 and 10 P.M. in London numbers rapidly decrease; but in London between 10 and 11 P.M. accidents again show a tendency to increase.
- (g) Between 11 and 12 P.M. Bremen street accidents again show an upward trend, though in London during the same hours a falling-off is noticeable.

Not the least informative and useful tables are those wherein street accidents are tabulated (a) by district or ward of occurrence, and (b) according to cause. In the first of these it may be seen that Districts 1, 3, and 9 are the sites within whose boundaries the majority of these events occur—indeed, No. 1 District produces approximately 28 per cent. of the annual total of the city of Bremen; it is not without interest to note that Districts 1 and 3 are situated in the old town (*Altstadt*) with its narrow winding streets, while No. 9 District occupies the extensive dock and commercial areas of the city—all three districts on the right bank of the Weser; and suburban extensions surround these areas, and include Districts 10–25, which show the lowest street accident rates recorded in Bremen. In regard to (b) above, “causes” are tabulated according to whether the accident was deemed to have been due to mechanical defects in the vehicle (brakes, steering, illumination, &c.), faults or negligence on the part of the driver (fast driving, driving on wrong side, cutting-in, &c.), faults of pedestrians (carelessness, &c.), and unavoidable accidents.

In this table (b) appear striking features worthy of comment. The Bremen data assert that over 50 per cent. of all street accidents are due to faults on the part of the driver of the vehicle, and between 9–11 per cent. to faults of pedestrians. Compare these rates with those of London; for the past few years, and certainly for the years 1928–29, pedestrians have been held responsible for approximately 50 per cent. of all fatal street accidents; official figures for the first three months of the present year assert that of 320 fatal accidents in the streets of London no less than 155 (or nearly 50 per cent.) were due to the carelessness of pedestrians.

Dead Men Tell No Tales.

Since there is no obvious reason to suppose that German drivers are less efficient than English motorists—some of whom, at least, are not very

cautious—one is led to wonder whether the contrast may not be sufficiently explained by the adage that dead men tell no tales. After all, the most savage of motorists is not deliberately seeking the blood of his fellow creatures; his word is likely to be favourably received, and the victim is silent. The Bremen publication suggests a valuable statistical experiment. It is obvious that such elaborate details of the accidents in the whole metropolis could not be published; but there seems no reason why a sampling experiment should not be done, why typical streets of different types should not be chosen, and a complete enumeration on the German lines be published. There was a time when the motorist was the scapegoat of the community. He was preached at and fined with monotonous regularity. Times have changed; now it is the (surviving) pedestrian who is monotonously warned that “many of the fatal accidents could have been avoided by the exercise of a little care”—a truth of undoubted weight, of course, but neither new nor helpful. Just as in more technical medical statistics we need records of cases of disease as well as of deaths, here we need more information about non-fatal accidents in order to understand the etiology of the disease of speed.

THE SHEFFIELD HOSPITALS CENTRE.

A STUDY OF COÖPERATIVE MOVEMENT.

SCHOOLS of medicine in this country as a rule began either as the private enterprise of some individual medical man or as a joint foundation by the members of the staff of some hospital. Most of the latter still remain, and the connexion between the hospital and its medical school in many cases still remains as intimate as it was originally. This is especially so in London where the various medical schools, although part of the university, are primarily the adjunct of the hospital concerned and bear its name. In the provinces, on the other hand, wherever a medical school has survived, a local university has eventually been founded, and in each case the fusion between the old medical school and the young university has been of a more complete kind. In some places where the hospital originally connected with the medical school has for long predominated in size or remained the only large hospital in the locality, it has become the sole clinical hospital connected with the university. In others where more than one local hospital has earlier or later been recognised as a teaching institution, the university has become associated with more than one clinical institution for its medical students.

In many ways the single clinical institution is the more convenient. Arrangements for the supervision of the students are more simple; organisation of their work is more easy. On the other hand, there is something to be said in favour of multiple clinical institutions. They widen the student's outlook and take away the tendency to insularity which, though attractive in youth, may not be altogether the best for his later career. In Sheffield when the university took over the medical school, two general clinical hospitals were connected with it, and both have continued as places of instruction for its students. In speaking of single or multiple hospitals, it will be realised that with the gradual separation of various groups of cases (maternity, mental, fevers, tuberculosis, and even venereal diseases), there is a certain amount of multiplicity in clinical hospitals connected with every school.

At the present time there are four voluntary hospitals in Sheffield, two general and two special, and they are all attached to the university for teaching purposes, although there is no actual written agreement between the university and any one of them. By the terms of the University Charter, the Royal Infirmary and the Royal Hospital have a member of their staff on the council of the university, but the latter

has no official representation on the board of any of the hospitals. On the academic side the relations between the university and the hospitals are, and always have been, exceedingly close. Thus in addition to the purely clinical teachers, the professors of pathology, pharmacology, and physiology in the university are all members of the hospital staffs. In the case of pharmacology the professor is a full physician to the Royal Infirmary with his own beds and assistants, whilst the professors of pathology and physiology are respectively in immediate control of the clinical laboratories dealing with their particular subject at the various institutions. A short account of the origin of the voluntary hospitals and development will show how the present position has come about.

The Royal Infirmary.

The first public suggestion that an infirmary should be established in Sheffield came from a medical man (Dr. William Younge) in a letter dated April 19th, 1792. As a result of this a public meeting was held in the town hall on April 23rd, the foundation-stone was laid on August 29th, and the General Infirmary was opened with much pomp and ceremony on Wednesday, Oct. 4th, 1797 (Fig. 1).

The first addition to the original building was made in 1847, the jubilee year of the infirmary. The financial position caused much anxiety, the invested funds had fallen from £20,000 to £12,000, and the weekly board spoke of the institution as "this deserving but decaying charity." In 1849 the board advertised for a nurse "who could read and write, or at least could read writing." For the next 20 years the financial position still gave rise to continual anxiety. This was relieved somewhat by the institution of a Hospital Sunday in 1868, and a Hospital Saturday in 1877. Additions

out-patient building was built, equipped and opened. In 1887, in commemoration of the centenary of the infirmary, many additions were made, including a detached "home" for the nursing staff, ophthalmic wards, laundry, mortuary and post-mortem rooms. A new general theatre was also added, and the out-

FIG. 2.

Sheffield Royal Infirmary, 1930. The original building is seen in the central part of the picture.

patient department was enlarged. In 1911 the exigencies of the growing population of the city and vicinity were met by the erection of another surgical block containing 215 beds. Again in 1921 alterations were made to existing buildings to increase the bed accommodation, and on August 8th, 1925, Princess Mary opened a new "ear, nose and throat" department, and in 1926 a new residency was opened (Fig. 2).

The number of beds available at the infirmary when it was first opened in 1797 was between 100 and 110. At the present time there are 500.

FIG. 1.

General (now Royal) Infirmary, Sheffield: the original building, 1797.

to the original building from then onwards have had to be made at frequent intervals in order to cope with the increase of work.

In 1872 a detached block, consisting of four large wards and connected with the main building by a subway, was opened for "the isolation of contagious diseases and offensive surgical cases." In 1883 an

The Royal Hospital.

The present Royal Hospital began as a dispensary in 1832, occupying small premises in the centre of the town. The promoters (in this case a group of medical men) had previously approached the board of the General Infirmary suggesting that the dispensary should be attached to that institution. This, however,

was declined, chiefly through the active opposition of one of the latter's physicians. The work increased rapidly and the dispensary soon wanted larger premises. A house in West-street was bought, on and around the site of which the present building stands (Fig. 3).

It continued as a dispensary with little or no change for the next 25 years. In 1834 three physicians were

quarter (Fig. 5). It consisted of six beds and an out-patient department. Fourteen years later in 1878, owing to the generosity of Mr. Thomas Jessop, the present hospital was built, and henceforward known as the Jessop Hospital for Women.

Since then considerable additions have been made to the original building in order to cope with increasing demands (Fig. 6).

Outside accommodation has been obtained for the nursing staff. In 1920 Norton Hall, a mansion situated in a large park on the hills outside the city, was converted into an open-air annexe, partly for the treatment of cases of puerperal sepsis and partly for antenatal and gynaecological cases.

At the present time the hospital and the Norton annexe contain 145 beds for gynaecological, obstetrical, and antenatal cases. There are also extensive out-patient departments. The hospital is recognised for the instruction of medical students and midwives.

Children's Hospital.

This, the youngest of the four voluntary hospitals in Sheffield, was founded in 1876 by the activities of the late Dr. W. J. Cleaver. A few years later the present buildings in Western Bank were built, at which there is in-patient accommodation for 80 children together with an out-patient department. A new block of wards has recently been added and further additions are being made (Fig. 7). There is also an out-patient department in the east end of the city.

Medical School.

As the medical school was founded in 1828 it is thus seen that for the first 40 years of its existence there was only one clinical institution connected with it. From 1870 onwards there were two, which for the next ten years were rivals for the student's

FIG. 3.

Westfield House, the Public Dispensary, forerunner of the Royal Hospital.

appointed. This election proved the turning-point in the future development of the institution. Owing to the energy and influence of the senior of the three, Dr. John Charles Hall, the dispensary was rebuilt as a hospital with 25 beds in 1860, and ten years later this was enlarged to 100 beds. It was now officially recognised as a teaching institution, and from that time onwards became connected with the medical school.

The work of the new hospital increased rapidly, so that in 1889 it was found necessary to rebuild on a larger scale. The first blocks of the present buildings were completed and opened in 1895 (Fig. 4) by His Majesty the King, at that time Duke of York, permission being given for the institution to be called the Royal Hospital.

In 1914 the present block of buildings was completed. Since then no actual new buildings have been erected on the site, but various means have been obtained to increase the accommodation. Thus in 1908 a convalescent home or annexe in the suburbs was given. Residential quarters have been obtained in the outskirts of the city for most of the nursing staff, and lastly, in 1925, a former chapel adjoining the hospital site was converted into a new out-patient department. As the hospital grew the dispensary dwindled, until, about the beginning of the century, it ceased entirely.

The Royal Hospital now has 310 beds.

Jessop Hospital for Women.

The foundation of a women's hospital in Sheffield dates from 1861. This again was largely due to the efforts of a medical man, Dr. J. H. Aveling, who took an active part in its work for some years. It was called the Sheffield Hospital for Women. A large house in the centre of the town was adapted for the purpose, situated in what had once been a residential

favours. This was so unsatisfactory that in 1880 it was agreed by the staffs that the two should in future cooperate for purposes of clinical instruction, under the control of a committee composed of three representatives appointed from each. The student now paid

FIG. 4.

Sheffield Royal Hospital, 1930.

Photograph by Tait and Henderson.

one fee for general hospital practice, and could attend at each or both as he chose. Two clinical lectures per week were given by members of the staff during term at one or other place, and attendance on these was compulsory for all students. In spite of many early difficulties this joint arrangement continued.

About this time the Jessop Hospital for Women became recognised as a maternity centre, and the students began to attend their cases there. It was

the students' work in these subjects was made, but the general principle outlined above was retained.

The teachers of the pre-clinical subjects favour it. They say that it stimulates interest in the laboratory studies by giving the student an insight into the application of these to clinical work. Amongst the clinical teachers opinions differ.

Special Studies.

During the last few years the opportunity for acquiring a fuller knowledge of mental diseases, the importance of which is being realised everywhere, has been much increased in Sheffield by the co-operation of the South Yorkshire Mental Hospital and the two general clinical hospitals. At each of the latter there is now an out-patient clinic for mental diseases in direct association with the South Yorkshire Mental Hospital, medical officers from which assist in its work.

Although it is not immediately concerned with the teaching of students, reference must be made to the experimental field laboratory at Redmires, connected with the department of pharmacology of the university. The quality and quantity of experimental work carried out there during the last ten years by Prof. E. Mellanby, to say nothing of the well-known researches of Mrs. May Mellanby, have not only placed them both in the forefront as original investigators, but have also exerted a wide influence for good over every department of the Faculty of Medicine, and brought renown to the university as a centre of medical research.

Connected with the Faculty of Medicine there is also a flourishing dental school. Begun in 1895 in connexion with the Royal Hospital, it was actually a complete teaching department in 1900. It has fully equipped laboratories for dental mechanics in

FIG. 5.

Sheffield Hospital for Women, Figtree-lane, 1864.

managed independently by the hospital, and the clinical committee had no control over it. Indeed it was not until 1908, three years after the foundation of the university, that the Jessop Hospital joined the two general hospitals, and the original clinical committee became a committee of the council of the university. On this, in addition to representatives of the staffs, the dean of the medical faculty and various university representatives, both medical and lay, are appointed. More recently the Children's Hospital has joined the scheme.

This committee is responsible for the organisation of all clinical teaching both general and special. The student pays one inclusive fee to the university which covers all forms of hospital practice required. A definite scheme of study is laid down. Clinical appointments must be taken in certain rotation and equally distributed between the institutions concerned. On the other hand, the student is allowed a free choice as to the actual member of the staff under whom he wishes to hold each appointment. For some years the Faculty of Medicine has tried to bring the earlier laboratory subjects, anatomy and physiology and the later clinical studies more closely together. This although most desirable in theory is not easy in practice. Even after an extended trial the method adopted has not met with the universal approval of the staff, and there are those who consider that the objections outweigh the advantages.

The general plan adopted in 1919 was as follows:—

(a) To shorten the pre-clinical studies of anatomy and physiology by holding a second M.B. examination at the end of the second year.

(b) To start the clinical studies earlier—viz., at the beginning of the third year.

(c) To make further laboratory studies of anatomy and physiology run alongside the earlier clinical studies during the whole of the mid-period of the curriculum—i.e., from the beginning of the third to the end of the fourth winter, when at the third M.B. examination, anatomy, physiology, pharmacology, and pathology are all taken together.

N.B.—For this para-clinical instruction in anatomy and physiology three hours a week are assigned for each subject during the third and fourth winters, two-thirds of which is devoted to practical work in the laboratory.

In 1929 the curriculum was lengthened from five to five and a half years, and some rearrangement in

FIG. 6.

Jessop Hospital for Women, 1930.

Photograph by Pacion and Dralford.

the university buildings, and at the Royal Hospital there is a large dental clinic which was entirely refitted and equipped two years ago.

Up to the time of the late war, although the staffs of the four hospitals had been thus acting together for purposes of clinical instruction, yet the institutions themselves remained as distinct and isolated from each other as on the days they were founded. Indeed, not infrequently the joint clinical committee has had to step warily in order to avoid giving offence. During the war, however, members of the various hospital

staffs worked daily side by side with each other, and when the war was over they felt that this joint working was something worth trying to preserve.

Joint Hospital Staff Club.

With this object the members of the staffs of the four voluntary hospitals formed themselves into a joint hospital staff club, of which everyone on election to one of the honorary staffs becomes, ex-officio, a

FIG. 7.

The Children's Hospital, Sheffield.

member. The club has a business side and a social side. Thus, on the one hand it forms a body before which all matters affecting the honorary staffs as a whole, or any one of them individually, can be brought up and discussed. Since its formation it has helped to solve many problems which have from time to time arisen, and, without it, might easily have caused considerable difficulty. Its social side has also proved of great value in bringing the members of all the staffs into frequent contact with each other, promoting friendships, and removing misunderstandings.

This apparently unimportant arrangement has had far-reaching and unexpected effects. In the first place it suggested the idea that the four voluntary hospitals themselves might with advantage come closer together, indeed that they might really become one institution. As a result of a joint memorandum sent out to their various boards by the staff club, this idea was brought to a head, and the four boards and staffs did actually meet to consider the suggestion at the invitation of the then Lord Mayor.

Joint Hospital Council.

Once the ice was broken, the boards of the four hospitals began to come regularly together. The most important immediate effect was connected with the financial side, and resulted in the formation of the "penny-in-the-pound" scheme, the development of which has greatly altered local hospital conditions. Apart from the merits or demerits of the scheme as a whole, it has aroused a widespread local interest in the voluntary hospitals, and incidentally has since its formation produced a million sterling in aid of the hospitals. This scheme is controlled and organised by a body known as the joint hospital council, which in addition to having representatives of the boards and staffs of the four voluntary hospitals, has also representatives of the Edgar Allen Institute, of the contributors' association, and also various ex-officio members. Its chairman since its formation has been the Vice-Chancellor of the University (Sir Henry Hadow). Each hospital board still controls the domestic affairs of its own hospital, whilst the joint

hospital deals only in a consultative and advisory capacity with the many questions which are common to all.

Soon after this coöperative movement began, the idea was entertained of building one large joint hospital, situated on the outskirts of the city, and transferring the four existing hospitals there. The scheme got so far that a suitable site was bought for the purpose. Meanwhile a period of serious and unexpected depression in the coal and steel trades, the two staple industries of the district, made any early realisation of this costly scheme impossible. It was hoped that in a few years a revival of trade would ensue. These hopes have not as yet been realised, and it has become obvious that under even the best circumstances it will be a very long time before such a costly undertaking will be possible.

As has been mentioned above, the hall situated in the grounds of the purchased site has been rented to the Jessop Hospital for Women, and converted into an annexe for septic maternity cases. This has proved very valuable for its purpose.

Future Possibilities.

With the coming into force of the Local Government Act of 1930, the possibility of providing the required accommodation on different lines has presented itself. The larger of the two poor-law hospitals in Sheffield is conveniently situated on the outskirts of the city in a large area of ground. It has a large number of beds, some excellent wards, and space enough on which to add anything further that may be required.

It seemed therefore possible to those concerned that, if the city council were willing, joint action might be taken by the voluntary hospitals and the council, and the requisite relief to the waiting lists of the voluntary hospitals obtained by providing sufficient extensions at this municipal hospital. With this object, an advisory committee, composed of equal representatives of the municipality and the voluntary hospitals, has been appointed, and has agreed upon certain general principles under which such joint action could be carried out.

At the present time these negotiations are not yet complete, but it may be said that, so far, there has been an obvious desire on both sides to work together and that such difficulties as have arisen have been met in a spirit which promises well for the future. Should the scheme materialise there is every possibility that all the institutions for the treatment of the sick in the city will be working in close coöperation not only with each other, but also with the university.

A highly satisfactory note can be added as to the relations of the faculty of medicine and the staffs of the voluntary hospitals to the medical officers of the various city hospitals, and also to the medical practitioners of the city and district. Of the former, all those holding official posts dealing with subjects required by the curriculum have in the past successively joined the staff of the faculty and rendered invaluable services. The chair of hygiene has been filled by successive medical officers of health; the lectureship on forensic medicine is held by the city police surgeon; infectious diseases and tuberculosis are dealt with by the respective municipal medical officers at the head of each of these departments.

As regards the relations between the medical men practising in the city and district and the faculty of medicine, it is perhaps enough to say that in 1920 the panel committee of Sheffield voted a sum of £1000 to the university towards the equipment of the new field laboratory for its department of pharmacology.

FIRE AT A FEVER HOSPITAL.—On Monday last week a fire broke out at Lodge Moor Fever Hospital, Sheffield. The medical staff and the male nurses got the flames under control by the time the fire brigade arrived, and the damage was confined to the roofs of the wooden buildings.

MEDICINE AND THE LAW.

Alleged Neglect to Give Proper Medical Attendance.

At Bodmin assizes on June 14th a man named Snow was charged with the manslaughter of his wife by neglect to give her proper medical attendance. She had been ill, it appeared, for a long time. Counsel for the prosecution suggested that her need of medical attention must have been apparent to the husband. A doctor who had attended the woman gave evidence that after some time she objected to his advice, and he then put the district nurse in attendance. The nurse stated that, after she had attended the patient a little while, the husband told her that there was no need for her to come again, as everything was being done that was necessary. It was alleged that eventually, when his wife was getting worse, the husband asked the doctor to examine her. The doctor ordered her immediate removal to the infirmary and there the doctors and nurses were horrified at her condition. She died soon afterwards. Mr. Justice Swift told the jury that he was unable to understand why the doctor and the district nurse ceased to attend the woman who was consequently left in the sole charge of the husband and a feeble-minded daughter. It was for the jury to say whether such neglect as there was could be brought home to the accused. The jury then found Snow "not guilty," and he was discharged.

Earlier in the day the learned judge had expressed surprise that Snow had been singled out for prosecution. If any charge were to be proceeded with, he said, others should be in the dock with the accused. Later he asked why the daughter, the doctor, or the district nurse was not included in the charge. This was no doubt a rhetorical question. Every judge has been an advocate in his time, and he properly employs the art of the advocate to secure acquittal where he thinks that justice requires a verdict of "not guilty." There is no need to take too seriously the suggestion that the doctor and the district nurse should have been prosecuted for the poor woman's manslaughter. They did not cause the neglect to which death was due. The doctor whose advice is rejected and the district nurse whose services are refused cannot be held criminally responsible for that rejection or refusal. The doctor has no power to enforce a course of treatment. If he attempted to do so, nobody would be more ready than His Majesty's judges to point out his error.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Ambulance Work in Ireland.

THE Dublin Ambulance and Nursing Divisions of the St. John Ambulance Brigade in Ireland had their annual inspection last Saturday in Merrion-square in glorious weather. The Brigade in Ireland has shown no sign of inertia following on the war period, but having performed notable service both during the war, and subsequently during the troubled times in Ireland, has now thrown its energy into social services useful in peace time. It trains men and women in first-aid, and women in home nursing. It supplies skilled first-aid workers to attend theatres, picture houses, and other places of amusement, as well as horse and motor races and public functions in general. A year ago when some quarter of a million people assembled in the Phoenix Park for the celebration of the anniversary of Catholic emancipation, the entire ambulance arrangements were carried through without a hitch by the St. John Ambulance Brigade. In addition to this ambulance work proper the Brigade (in coöperation with the British Red Cross Society) maintains the Hospital Supply Depot

founded during the war, its gifts being now devoted to the patients of the Queen's Institute of District Nurses. During the year some 70 bales of dressings were supplied gratuitously to the district nurses throughout Ireland. Invalid requisites are also supplied to poor patients, or on very easy terms to those who cannot pay much. The welfare department gives free dinners daily to some 70 destitute expectant or nursing mothers, and when a child is born baby-clothes are given. Many of the women attending this department would be on the verge of starvation were it not for the food there given them. The department works in close association with the maternity hospitals, and encourages the women to attend the antenatal departments of the hospitals regularly. A close relation is also maintained with the maternity and child welfare schemes organised by the city health authorities. In a recent letter to the press, the Commissioner of the Irish District (Sir John Lumsden) puts forward a plea for the equipment of motor transport with first-aid appliances. He points out the increasing frequency of accidents due to motor transport, and the necessity for adequate first-aid treatment.

"The results of many crashes are grave enough, but even graver are the aggravated injuries caused by injudicious handling of victims by well-meaning but untrained bystanders. Every facility exists for the acquisition of a knowledge of first-aid, and everyone should possess it."

Sir John suggests: that all 'buses and trams should carry a first-aid box, with dressings, restoratives, iodine, &c.; (2) that all drivers and conductors should be trained to render first-aid; and (3) that all A.A. and R.I.A.C. patrols should be likewise trained, and carry first-aid material.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The New M.O.H. for Edinburgh.

THE town council of Edinburgh have appointed Dr. John Guy as medical officer of health for the city, in succession to Dr. William Robertson. A graduate of Glasgow University, he has been tuberculosis officer and assistant medical officer of health for Edinburgh for 16½ years. His clinical experience has been various, being gained especially as medical superintendent of the sanatorium, the orphanage, and epileptics' colony at Quarrier's Home, Bridge of Weir. His main experience has been in dealing with tuberculosis; but he also had an active part in the public health administration during and after Dr. Maxwell Williamson's time.

Edinburgh is now face to face with a group of the most difficult problems in administrative medicine, including not merely the readjustment of 'school health administration, and the work of the transfigured poor-law, but particularly the correlation and development of hospital services. Dr. Guy is credited with very definite views on hospital policy, but public opinion is ripe for drastic changes, and the use he makes of his opportunity will be watched with keen interest.

Measles in Edinburgh.

This summer measles has become formidable in Edinburgh. As early as January, and even in December, small numbers of cases were notified; but they began to rise rapidly towards the end of March, when 104 cases were intimated. At the same period the notifications in Glasgow, Dundee, and Greenock had risen into hundreds per week. For the five weeks in April the Edinburgh numbers were 158, 191, 282, 419, and Dr. Guy reports that the epidemic, which started in the Canongate and spread through every district in the city, is the worst that Edinburgh has known for many years. During the first two weeks of June 1401 cases were notified, and since March of this year the disease has visited over

4000 homes representing some 8000 cases. Twenty-one deaths have been attributed to measles in the last fortnight.

It is suggested that the normal two-yearly visitation was missed last year and that the susceptible material is accordingly much greater. Glasgow had its usual winter and spring epidemic, but this has now tailed off. There is nothing to indicate that this epidemic shows the peculiar virulence of the great epidemic of 1893-94 and the lesser epidemics of the years following. It was then commonly said by the doctors that, when called in, they had usually to sign the death certificate. Two, three, and four deaths in a family were relatively common.

LISTER INSTITUTE OF PREVENTIVE MEDICINE.

REPORT OF GOVERNING BODY FOR 1930. CHANGES IN THE STAFF.

THE names of Sir Charles Martin, F.R.S., and of Prof. A. Harden, F.R.S., are so closely and so honourably associated with the Lister Institute of Preventive Medicine that the news of their approaching retirement, on reaching the age limit, will be received with regret throughout the scientific world. In the annual report of the Institute which has just reached us the governing body pay tribute not only to the scientific distinction but also to the high administrative ability of Sir Charles Martin, who has been director of the Institute for 27 years. Prof. Harden, whose researches into the chemistry of alcoholic fermentation were recognised last year by the award of the Nobel prize in chemistry, has served for even longer (33 years), and as head of the department of biochemistry he has played an important part in the scientific development of the Institute. The governing body are fortunate in being able to fill the vacant appointments by men who have not only the requisite scientific standing, but who have had long experience in association with their predecessors. Prof. J. C. G. Ledingham, F.R.S., who becomes director, joined the serum department of the Institute in 1905, and when his chief, the late Dr. George Dean, was transferred to the bacteriological department, Dr. Ledingham followed, and in 1908 succeeded him as head of the department. Mr. R. Robison, D.Sc., F.R.S., who will have charge of the department of biochemistry from January of next year, has been on the staff of the department since 1912, and its first assistant for over ten years. He was made a Fellow of the Royal Society this year for his researches on ossification, which revealed the enzyme (phosphatase) as an active agent in this complicated process.

Other changes of staff include the resignation of Dr. T. W. Lumsden, Mr. E. Boyland, and Miss M. H. Roscoe, on receiving other posts, and the attachment of Mr. R. R. McLaughlin, M.Sc., Ph.D., and Miss A. M. Copping, M.Sc., to the departments respectively of biochemistry and experimental pathology.

The governing body record appreciation of the continued co-operation which the Institute has enjoyed with other scientific bodies whose financial support, by the provision of the salaries of skilled investigators working in different departments, has greatly increased its scientific activities.

DEPARTMENT OF BACTERIOLOGY.

The researches carried on in this department include the experimental production by Dr. G. F. Petrie of potent serum derived from the successful immunisation of a horse with vaccinia virus. Potency tests with the concentrated serum are being carried out by Prof. Ledingham, and its content of antiviral substance proves to be large. In view of statements to the effect that some cases of post-vaccinal encephalitis have benefited by the administration of serum

from convalescent vaccinees it is proposed to offer the serum for trial in such cases. Its value in the treatment of small-pox also requires investigation.

Dr. G. H. Eagles is studying the properties of a strain of cow-pox recovered from a vesicular lesion on the arm of a milker. On rabbits and monkeys it produces, after scarification, lesions which differ somewhat from those following scarification with calf-propagated lymph, in the intensity of the associated dermal inflammation and hemorrhagic tendency. Monkeys vaccinated with this strain fail to respond to small-pox virus recovered from cases of the mild form now prevailing in England. It may be recalled that in 1925 Prof. Ledingham reported the fact that small-pox virus when inoculated intradermally in rabbits produced a characteristic lesion which is neutralised by antivaccinal serum. McKinnon and Desfrés of Toronto, and Sobernheim of Berne, have recorded similar findings, but so far it has been impossible to secure propagation of the virus from rabbit to rabbit beyond one or two passages. Dr. Eagles is again attacking this problem of adaptation. If a method of propagation succeeds, it may be the means of securing new strains of vaccinia at will from small-pox cases and investigating their properties.

Poliomyelitis and Encephalitis.

Research on poliomyelitis, subsidised by the International Committee for the Study of Infantile Paralysis, includes the study of the path of spread of the poliomyelitis virus in the experimental animal by Dr. R. W. Fairbrother and Dr. E. W. Hurst, who have also investigated a number of cases of post-vaccinal encephalitis, and two cases of a similar condition occurring as a complication of small-pox. It was not found possible to excite nervous lesions in the monkey or the rabbit by intradermal inoculation of ordinary vaccine lymph or neurovaccine of rabbit or monkey origin; on the other hand, intracerebral inoculation of monkey or rabbit neurovaccine was effective in both species of animals. In the monkey the reaction is primarily and mainly meningeal, with secondary changes in the cortex underlying the areas of most severe meningitis. These lesions differed entirely from those of post-vaccinal encephalitis and the characteristic perivascular demyelination of that disease was never reproduced. Virus was present in large amount in the nervous tissues and also in the spleen, which was the seat of marked alterations. Smaller amounts were present in various other organs.

The cases of paralytic accident arising in the course of antirabic treatment have sometimes shown a histological picture closely resembling that in post-vaccinal encephalitis. Many observers have ascribed these accidents to the toxic action of the foreign brain material introduced during treatment, and have claimed, usually without adequate histological control, to have reproduced the condition in experimental animals, particularly rabbits. Dr. Hurst has made inoculation experiments designed to test the importance of these observations, if confirmed, in throwing light on the causation of disseminated encephalomyelitis. He concluded that while paralysis might occur in the rabbit injected with foreign nervous substance, such paralysis could not be brought into relationship with the paralytic accidents in man and that the histological picture seen in man could not be reproduced in rabbits by such means.

With Dr. Fairbrother, Dr. Hurst has started experiments to determine whether coincident infection with vaccinia has any power to modify the reaction of the central nervous system to poliomyelitis.

Immunising Properties of Bacteria.

Studies on antigenic constitution and immunising properties of bacteria have been continued by Dr. J. A. Arkwright, F.R.S., and under his direction by Miss R. M. Pitt and Dr. N. C. Graham. Dr. H. L. Schütz, continuing immunity studies in mice, has shown that only the O or somatic content of the bacterial vaccine is capable of conferring protection

against *S. aertrycke* and *S. enteritidis* infections. The presence or absence of H or flagellar antigen in the vaccine is without effect on the prophylactic value. An efficient vaccine may be prepared from an alien species so long as the somatic antigen in each is identical. For example, a *paratyphoid* B vaccine will protect against an *aertrycke* infection and *typhoid* vaccine will protect against a *Gaertner* infection.

Dr. Muriel Robertson and Dr. A. Felix have tried to produce passive protection against anaerobic infections by antibacterial (anti-O) sera. The anti-O serum was found to be strictly specific, affording protection only against infection with *V. septicæ* of the same serological group. Work is now in progress with *B. tetani* and *B. welchii*, but up to the present the titre of the O immune serum to *B. tetani* has not been sufficiently high to protect mice against infection with spore-calcium suspensions.

It has recently been asserted that tubercle-infected rats on a diet deficient in vitamin A are particularly sensitive to tuberculin, on the ground that the lethal dose of tuberculin for such rats is considerably smaller than that for rats on a similar diet but not so infected. Dr. Schütze and Dr. S. S. Zilva have been able to show that this phenomenon is a purely non-specific one; rats infected with *B. tuberculosis* are hypersensitive to the toxic action of tuberculin, but they are equally hypersensitive to other bacterial toxins.

B.C.G.

Calmette and his school consider that there is complete safety in using the avirulent strain of the tubercle bacillus known as B.C.G. as a living inoculum for prophylaxis against tuberculosis, since the strain has completely lost its virulence for man and laboratory animals. Dr. Moti Malkani, of Karachi, India, working in this department with a strain obtained from the Pasteur Institute, has come to the conclusion that the virulence of the strain is not completely gone, and that when introduced into the less resistant animals it may be capable of causing widespread and even fatal infection. Some 28 guinea-pigs and 18 rabbits were inoculated by various routes. Of these animals 18 showed extension of infection beyond the site of inoculation to glands and other organs. In one of them the lesions were particularly pronounced and of a caseous nature. Two guinea-pigs died, to all appearances, as the result of infection with B.C.G. The report adds: "This strain, therefore, though much attenuated, cannot be regarded as avirulent for laboratory animals. It will depend on the degree of resistance it meets with in the animal whether it disappears from the system or leads to a process that may terminate fatally."

(To be concluded.)

LONDON HOSPITAL MEDICAL COLLEGE.—Prizes will be distributed at this college on Tuesday, June 24th, at 3 P.M., by Lord Rayleigh.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL.—The isolation block, the first portion of the new hospital at Hammersmith, will be opened by Princess Mary on July 10th. The annual report states that on many occasions during the past year the hospital was overcrowded, and patients presenting themselves with orders of admission had hastily to be accommodated elsewhere, while others wishing to come in had to be refused. Of the 2360 patients, 2151 were "booked" and 209 "emergency" cases. Of the booked patients seven died, being at the rate of 3.2 per 1000, but there were nine deaths among the emergency patients, a rate of 43 per 1000. Moreover, in booked cases the infantile death-rate was only 25 per 1000, while in emergency cases it was 153 per 1000. The pressure upon accommodation has become so acute that the committee has converted an empty house on the Hammersmith site into an auxiliary hospital with about 20 beds, which will probably be ready next month. It is hoped that it will now be possible for every patient to receive an anæsthetic during her confinement. When the new buildings are completed Queen Charlotte's will be the largest maternity hospital in the Empire with at least 358 beds, of which between 80 and 100 will be in private paying wards for middle-class patients of small means.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

The following are 1929 statistics of an English and a Scottish county, of a metropolitan borough, and of two modern colliery districts.

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Youngchild (1-5 yr.) mortality.
Wiltshire (300,300)	14.9	12.5	0.59	1.65	1.9*	2.6	55/—	—
Roxburghshire (10,492, landward area)	15.9	13.7	0.36	1.63	1.7	2.7	71/30	23
Stoke Newington (50,040)	16.1	13.4	0.94	2.04	2.6	2.6	47/26	17
Doncaster R.D. (44,680)	26.7	10.9	0.90	0.56	2.6	1.5	88/—	—
Adwick-le-Street U.D. (19,230)	23.3	11.1	0.94	0.64	3.5	1.0	131/—	—

* This figure would probably be about 2.0 if "other respiratory diseases" were included.

Registered stillbirths per 100 live births: Wiltshire 4, Stoke Newington 3.8, Doncaster 4.6, and Adwick-le-Street 7.1.

Wiltshire.

Dr. Claude E. Tangye says that, apart from a large amount of preparatory work in anticipation of the Local Government Act, the year has been an eventful one. A permanent women's ward has been built at Harnwood tuberculosis hospital. The old Trowbridge cottage hospital has been purchased for clinic purposes. The county small-pox hospital at Ogbourne was progressively enlarged to cope with the small-pox outbreak, which only ceased at the end of the year. The county pathological work has, with great advantage, been concentrated at the Salisbury infirmary. In continuation of the policy of appointing whole-time local medical officers for county purposes, Dr. Jean Murray, M.O.H. for Trowbridge and Bradford urban and rural districts, has been appointed an assistant county M.O.H. The scheme for better supervision of pre-school-children has progressed, and arrangements are being made to secure more continued treatment at the venereal disease centres. The public medical services are being coördinated in such a way that the new responsibilities under the Local Government Act will be met by simple and natural development of the county health department. Progress has been made in pooling infectious hospital accommodation by the closure of the Cricklade and Wootton Bassett hospital and an arrangement for the cases from this area to be admitted to the Swindon hospital. Swindon is badly off for a general hospital, and the county council proposes to utilise a poor-law institution at Salisbury for non-notifiable diseases and to establish a subsidiary unit at Swindon.

The rainfall was more than three inches less than in the previous year and there was a shortage of water in many districts during the dry summer. The summary of analysts' reports shows that of 30 effluents from sewage disposal systems in six rural districts the effluent was definitely bad; of these three were in Chippenham, two in Pewsey, and one in Tisbury. Five were described as poor; one being in Swindon, two in rural districts—Bradford-on-Avon and Devizes

Dr. F. D. Ross-Keyt says there has been no extension of the public health services in this metropolitan borough, but those in operation continued to progress favourably. In October, 1928, the council approved a scheme for the appointment of a panel of four obstetrical consultants, who may be called in by medical practitioners in difficult midwifery cases. The following are the conditions: that the patient be a Stoke Newington resident; that the medical practitioner immediately inform the medical officer of health as to the particulars of the call; and that the consultant's fee of £5 5s. be inclusive. The scheme is intended for the use of persons who cannot afford the consultant's ordinary fee, and the council reserve to themselves the right to recover the fee if the patient's circumstances permit. Only one consultation took place under the scheme during 1929. This was a case of puerperal pyrexia which was removed to a fever hospital and recovered. There were fewer L.C.C. houses available during 1929 and only 17 families were removed from Stoke Newington as compared with 30 in the previous year. Of these two families went to the Lewisham estate, eight to the Hendon estate, and seven to the Becontree estate. Many desirable tenants are unwilling to travel the distances to and from work necessitated by the removal. Others living in an overcrowded state cannot

be recommended owing to poverty or low standards of cleanliness. Twenty-two tenants who had recently had their rentals increased applied for certificates that their houses were not in all respects fit for habitation, under the Increase of Rent, &c., Acts, 1920 to 1923, and in every instance the certificate was granted. Owing to the lack of alternative accommodation cases of overcrowding have to be dealt with leniently.

Immunisation against diphtheria has been carried out on a small scale, and 102 children completed the preliminary course of three immunising injections in 1929. The number of children protected shows an increase of the previous year's work. Of the 10 notified cases of ophthalmia neonatorum, one who received hospital treatment for some months resulted in permanent loss of vision but it is not mentioned at what stage the case came under hospital treatment. The severe epidemic of influenza during the first quarter chiefly affected the older members of the community.

Doncaster.

Dr. A. B. Dunne says his rural district has never wholly recovered from the coal stoppage in 1926. There are five collieries of the largest class. Work has been irregular and there has been unemployment and distress. Agriculture still employs a large number of men in the district and Messrs. Pilkington have a large glass works. Much of the charm of the district has been spoilt by ribbon building. Industrial atmospheric pollution is on the increase, and the smoke from the collieries adversely affects the trees. The district council has not become a member of the regional smoke committee. About 2500 milch cows are stalled in the district, and amongst these were found 11 cases of tubercle of the udder. Of the 11, two were reported by private veterinary surgeons, one by the owner, and eight were found by the county veterinary surgeons. In addition to the foregoing, 19 cows and two bullocks with tuberculous emaciation, and 22 cows and one bullock with open pulmonary tuberculosis were slaughtered.

Adwick-le-Street.

Dr. A. B. Dunne shows that when the standardising factor is applied the death-rate of 11.1 becomes 13.8. (The use of the same factor in the rural district of Doncaster, it may be noted, made little change.) The water-supply of this urban district is derived from a well sunk in the limestone and softened by the council from 38 degrees to 10 degrees of hardness. The council have had some difficulty with the sand filters of the softening plant resulting in the deposit of much lime in the service pipes. Flooding in the Bentley moor neighbourhood has been lessened by the raising of the bank of the Ea Beck, but Dr. Dunne points out that the flow of water down the beck is still liable to obstruction by a road bridge. The housing conditions are good; in fact, building has ceased and there are approximately 50 empty houses.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

JUNE 7TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 237 (last week 327); scarlet fever, 1743; diphtheria, 1085; enteric fever, 64; pneumonia, 898; puerperal fever, 39; puerperal pyrexia, 116; cerebro-spinal fever, 14; acute poliomyelitis, 1; encephalitis lethargica, 15; continued fever, 2; dysentery, 2; ophthalmia neonatorum, 92. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 10th–11th was as follows: Small-pox, 434 under treatment, 25 under observation (last week, 449 and 15 respectively); scarlet fever, 2002; diphtheria, 2174; enteric fever, 25; measles, 687; whooping-cough, 73; puerperal fever, 22 (plus 14 babies); encephalitis lethargica, 122; poliomyelitis, 1; "other diseases," 20

At St. Margaret's Hospital there were 17 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox or enteric fever, 54 (12) from measles, 10 (4) from scarlet fever, 20 (4) from whooping-cough, 34 (7) from diphtheria, 48 (15) from diarrhoea and enteritis under two years, and 22 (5) from influenza. The figures in parentheses are those for London itself.

Eight fatal cases of measles were reported from Southampton, 6 each from Birmingham and Liverpool. Liverpool also reported 6 deaths from diphtheria.

The number of stillbirths notified during the week was 304 (corresponding to a rate of 41 per 1000 births), including 65 in London.

Correspondence.

"Audi alteram partem."

BRITISH MOSQUITOES.

To the Editor of THE LANCET.

SIR,—In your report last week (p. 1312) of a visit paid by members of the Royal Institute of Public Health to our mosquito control laboratory, the writer states that "in most inland places six species of mosquito are found." This statement requires modification; the actual fact being that in most inland places not more than six species of mosquitoes are likely to be met with to any appreciable extent. The so-called household mosquitoes, *Culex pipiens* and *Theobaldia annulata*, are common in all parts of the country, the latter being a fierce and poisonous biter. To these we must add eight other common species which breed in inland waters (*Anopheles maculipennis* and *bifurcatus*, *Aedes annulipes*, *maculatus*, *rusticus*, *punctor* and *cinereus*, *Culicella morsitans*), as well as two species which breed chiefly (*Aedes caspius*) or exclusively (*Aedes detritus*) in coastal districts. Since each of the above-mentioned species selects some particular kind of environment in which to breed, it is very unusual for more than three or four species (over and above the two household ones) to be at all prevalent in one and the same locality.

I am, Sir, yours faithfully,

JOHN F. MARSHALL,
Director, British Mosquito Control
Institute, Hayling Island.

June 16th, 1930.

"DISCARDED METHODS" IN LARYNGOLOGY.

To the Editor of THE LANCET.

SIR,—In Mr. Lawson Whale's book on modern treatment of diseases of the throat, nose, and ear, reviewed in your issue of June 7th (p. 1238) I find under the heading of Discarded Methods the "complete or partial removal of the uvula" and the "indirect (original laryngoscopic) method" for laryngeal work. It will be a sorry day for certain patients when the shortening of the uvula is discarded. We know that an inordinately long uvula may be present without any symptoms and we know that a cough may coexist with a long uvula and be due to some other cause altogether; but we also know—or, at least, I know—that in many cases a cough is caused by an elongated uvula and is removed at once and, often, for all, by the shortening of that appendage.

As regards the discarding of the original laryngoscopic or indirect method in favour of the direct endoscopic method for laryngeal work, the latter may be much easier for the operator, but it is certainly not easier for the patient, unless under a general

anæsthetic. For the most common innocent new-growth in the larynx—namely, the so-called fibroma on the edge of a vocal cord, at or near the junction of the anterior and middle thirds, the specialist ought to be able to effect the removal by means of the ordinary forehead and laryngeal mirrors and laryngeal forceps, without the paraphernalia of the endoscopic apparatus, and without general anæsthesia. This applies still more to the electro-cauterisation of tuberculous ulcers in the larynx, as it may have to be repeated on several occasions.

I am, Sir, yours faithfully,
London, June 18th, 1930. JAMES DUNDAS-GRANT.

THE CAUSATION OF ECLAMPSIA.

To the Editor of THE LANCET.

Sir,—In his letter last week Dr. Theobald makes it clear that his theory of the causation of eclampsia is that the detoxicating action of the liver fails and that this failure is "because the fœtus requires 8 g. of calcium, and relatively large supplies of sugar, iron, and iodine during the last four weeks of pregnancy." It is true that some interference with the intestines from the bulk and weight of the pregnant uterus is also admitted, but these possibilities, as also the psychological trauma, are thrown in as a kind of make-weight. The essence of Dr. Theobald's theory is that the demands of the fœtus for calcium, sugar, iron, and iodine cause the detoxicating action of the liver to fail.

How can this theory account for the greater incidence of eclampsia in primipara, and in primipara, also, who appear particularly fit right up to the onset of eclampsia? I suggest that the anxieties and psychological trauma are likely to be greater in a woman bearing her seventh or eight child than in a primipara. Mr. Paramore's theory of the increased intra-abdominal pressure, due to powerful and unstretched abdominal muscles causing serious interference with the circulation of blood in both the liver and kidneys and thus impairing their functions, fits the facts far better. Even if the existence of increased intra-abdominal pressure in later pregnancy can be disproved experimentally, could there not be an alternative explanation of the impeded liver circulation—namely, that in pregnancy? One of the changes—not mentioned in Dr. Theobald's list—is the broadening of the base of the chest and the flattening of the diaphragm and a limiting of the up and down movements of the diaphragm. These effects would be greater in proportion as the abdominal muscles were powerful, as in primipara, or in proportion as the abdomen were bound in by tight lacing, as in unmarried pregnant women for purposes of concealing their condition. Thus the important suction action of the diaphragm on the contents of the great abdominal veins would be much diminished and the circulation in the liver and kidneys impeded and their functions impaired. Doubtless, the most important result of such impairment of liver function would be the loss of the detoxicating power.

I am, Sir, yours faithfully,
Bridlington, June 8th, 1930. P. D. H. CHAPMAN.

To the Editor of THE LANCET.

Sir,—Whether Dr. Theobald's conception of eclampsia has been rendered more acceptable by his letter in your issue of to-day (p. 1264) seems to me questionable. I must confess I am not sure now whether he believes the fits are due to toxins of intestinal origin or not. He says that when the liver fails toxins absorbed from the gut enter the general circulation and poison the tissues of the body—"the kidneys as well as the heart." It would thus be reasonable to believe that they poison the brain and even thus produce the convulsions; but Dr. Theobald does not say so, and a definite statement

would have helped. His idea that "the fits are probably caused by a sudden drop in the level of the blood-sugar associated with a hypo-calcæmia" (p. 1119) still simmers in the mind.

And especially is this so since, according to his letter, these toxins which poison the kidneys as well as the heart do not apparently poison the liver—at least, they do not occasion the hepatic failure. The liver "fails because the fœtus requires 8 g. of calcium, and relatively large supplies of sugar, iron, and iodine . . ." (p. 1264)—which suggests an inability of the liver to comply with foetal demands. But if the foetal demands should become too great for the mother, foetal atrophy, not a maternal disaster, should occur. The view put forward in the paper is more reasonable: in that Dr. Theobald attributed the hepatic failure in part to toxins absorbed from the gut. "The liver, carrying out metabolic functions for both mother and fœtus and overwhelmed by an excess of toxins, fails . . ." (p. 1119). But now, Dr. Theobald not only repudiates or neglects the possible play of these intestinal toxins on the liver, which he has declared are being absorbed in excess; he also denies that increase of work by the liver has anything to do with its failure—which seems incompatible with the conception that its failure is due to foetal demands. To the question, "whether the failure of the liver is due to overwork, I will answer in the negative" (p. 1264).

In view of Dr. Chalmers's letter and the statement that the intestinal tract of Chinese is swarming with all sorts of unwholesome bodies, coupled with the further statement of the absence of eclampsia amongst these people, it was perhaps well to discount the supposed rôle of intestinal toxins in the causation of eclampsia. The conception creates the difficulty to which Dr. Chalmers referred—that if eclampsia is due to "a breakdown in the defensive barrier to intestinal toxins . . . such a condition might conceivably arise apart from pregnancy" (p. 1209). Dr. Theobald gets over this difficulty by attributing the failure of the liver to the absorption by the fœtus of calcium. But if that be so, how is it that in China where osteomalacia is common, eclampsia is rare? How is it that in hydatidiform mole, in which there is no fœtus, the liability to the toxæmias of pregnancy and even eclampsia is increased? How is it that in hydramnios the same effect is produced? Are we to believe that the sudden or abrupt distension of the uterus with blood—in concealed accidental hemorrhage—produces eclampsia by robbing the maternal system suddenly of calcium—when a venesection in the arm may save an eclamptic?

And if a loss of calcium—or an exaggerated absorption of calcium by the fœtus—is the cause of the hepatic failure, why not attribute the failure of the kidneys and that of the heart to the same change? According to Dr. Theobald, the kidneys and the heart are damaged by toxins; but Stroganoff seems to have taught that it is the violence of the fits which damages the heart—during a fit the peripheral resistance is enormously increased, and according to Stroganoff it is each fit which renders the heart worse.¹ It is the physical strain, not a chemical blood change, which in eclampsia damages the heart. In the same way are the kidneys physically damaged by the fits, being rendered worse. The liver is equally involved in the damaging compressions occasioned by the fits. Similarly, it is the physical changes produced by pregnancy, of less intensity but of like nature, which initiate the visceral disturbance. Such a view, naturally enough, must be repugnant to Dr. Theobald; but it is one which a study of some years has done nothing but demonstrate its truth. For Dr. Theobald, the pressure in the abdomen is not increased in pregnancy. One reason for this, from his letter, is plain: "I ought to have said," says he, "that my observations on the pressure in the abdomen were made with the woman flat on her back and under anæsthesia" (p. 1264). What a conception

¹ Jour. Obst. and Gynec. Brit. Emp., 1925, xxx. See p. 12.

of the intra-abdominal pressure does this aside portray! Naturally, if one anaesthetises the individual, even if the abdominal wall muscles do not become atonic, their tone is greatly diminished. How, from such a base, Dr. Theobald can state that in the active pregnant woman, even during rest—even during sleep, which has not the same effect as anaesthesia—the intra-abdominal pressure is less than atmospheric, and is not increased by pregnancy, surpasses my comprehension. Has Dr. Theobald considered the effect of muscle tone? Does he know that when striated muscle is actively elongated (as, for example, in the case of the abdominal wall and thoracic diaphragm by rapid distension of the abdomen), its tone becomes greater?

I told Dr. Theobald he had burnt his boats: he answers he has built a bridge. But its foundations are incomplete, and its structure contains contradictions. It is a bridge over which scientific thought cannot pass; nor does it seem to be one by which the eclamptic woman may be saved. Even though it should be true that "the injection of saline or air" into the udder of cows affected with *l'éclampsie vitulaire* (as Delmar called it)—a condition in the cow which resembles very closely eclampsia in man, as indeed Dr. Theobald tells us (p. 1264)—should raise the blood-calcium, that is not the reason why the procedure cures the animal. The distension of the udder with air in affected animals has a more subtle effect than that, one which veterinarians, as far as I am aware, have not yet fathomed.

I am, Sir, yours faithfully.

CHEMICAL TESTS OF PANCREATIC EFFICIENCY.

To the Editor of THE LANCET.

SIR,—I think that no one, and least of all those who have had much experience of pancreatic affections, will disagree with Dr. Harrison's statement that there is no specific chemical test for pancreatic efficiency, or dispute his conclusion that the functional tests at present available are frequently equivocal. But this is equally true of chemical tests for the functional efficiency of other organs, and is an inevitable result of the interdependence of the chemical changes which go on in the body. The functions of the pancreas in metabolism, although highly specialised, are so intimately bound up with those of other organs that a sharp differentiation is difficult in practice, and, as a consequence, a diagnosis of disease of the gland can usually be arrived at only by considering the results of as varied and comprehensive a series of investigations as possible in the light of all the available clinical data, as I pointed out many years ago.

It is remarkable that glycosuria and hyperglycaemia are so rarely met with in pancreatic affections, and then mainly in acute lesions and chronic disease involving the whole gland. This may be due, as Dr. Harrison suggests, to a large reserve power, or may arise from other causes, but the absence of these signs in the less acute and more limited conditions does not necessarily mean that the storage and utilisation of carbohydrate are being carried out in a normal manner, in fact, it is exceedingly likely they are not, and that intermediate products of imperfect carbohydrate metabolism appear in the blood and are excreted in the urine in such circumstances. These intermediate products, being of the nature of dextrins, would not react to the ordinary tests for sugar, and would consequently escape detection unless they were specially sought. The detection and estimation of such dextrin-like bodies is the basis of the test with which my name is associated, and, although Dr. Harrison does not apparently use it, I can assure him it is still being regularly employed, in its quantitative form (THE LANCET, 1927, ii., 1386), by other observers as an aid to diagnosis and treat-

ment. Originally devised simply to assist in the clinical differentiation of impacted gall-stones in the common bile duct from malignant disease of the head of the pancreas, it was subsequently found to be helpful in the detection of inflammatory affections of the pancreas arising from other causes, but it was not until a "positive reaction" was proved to be dependent upon the presence of an excess of dextrins in the urine, and a quantitative method for estimating them was contrived, that its uses and limitations were fully defined. It was never claimed to be pathognomonic, and experience has shown that dextrinuria, like glycosuria, may arise from other causes than disease of the pancreas, but, as dextrins appear in the urine at a much earlier stage than dextrose, their detection affords a means for recognising defects of carbohydrate metabolism while they are still of a comparatively mild type. Dextrinuria is also of importance in treatment, since it is an indication that the metabolic powers of the patient are inadequate to deal with the diet he is taking. This is well seen in diabetics who are being treated with insulin, for a dextrinuria usually persists for some time after all traces of sugar have disappeared from the urine, and reappears again before hyperglycaemia and glycosuria develop if the dose of insulin is reduced, or the diet is increased, in such a way as to over-tax the patient's tolerance to a slight extent.

I am, Sir, yours faithfully,

P. J. CAMMIDGE.

Nottingham-place, W., June 16th, 1930.

THE ROTUNDA HOSPITAL.

To the Editor of THE LANCET.

SIR,—I am afraid that your annotation (p. 1301) on the work of the Rotunda Hospital, although accurate, may be a trifle misleading. You mention that there were 963 obstetrical operations performed. As this includes 602 perineorrhaphies, 2 cases of spinal anaesthesia, 11 of Gwathmey anaesthesia, 3 of underpinning the cord, 3 sterilisation (done at the same time as Caesarean section), 2 venesection, 1 puerperal douche, and 5 Hobbs's treatment, this leaves 333 to be accounted for. These are made up of:—

Forceps	141	Version	20
Induction	123	Other manoeuvres ..	15
Caesarean section ..	34		

I feel that the Rotunda Hospital can still claim to be in the forefront of those who believe in conservative methods. I am, Sir, yours faithfully,

BETHEL SOLOMONS.

June 16th, 1930.

Master, Rotunda Hospital, Dublin.

LEFT INFRAMAMMARY PAIN.

To the Editor of THE LANCET.

SIR,—Dr. Doris Baker's paper in your issue of June 14th is a welcome addition to communications which seek to differentiate the causes of pain in the region of the left breast. If it assists in preventing those suffering in this manner from being put to bed for six weeks, and from being labelled angina pectoris—one of the terms so terrifying to the public—it will have served a most useful purpose.

Dr. Baker has not attempted to give an explanation of the mode of production of this pain. If a detailed investigation of the submammary region is made, one or more small areas of maximal tenderness is found in the fifth or sixth intercostal space. Pressure here accentuates the pain, induces recognition as the pain, and if continued causes radiations of pain in the directions and areas peculiar to that individual. I described some of these areas (THE LANCET, 1921, ii., 1257) under the title the Origin of the Angular Syndrome, contending that these pains are of muscular origin. In the Lumleian

lectures, 1927 (THE LANCET, 1927, 1, 637, 749, 857), I brought forward instances of these muscular pains in various conditions—trauma, pleurisy, gastric distension, static, and functional, &c. A recognition of diversity of causes producing similar symptoms helps to establish a pathology and to indicate a treatment.

The fifth or sixth interchondral space, whichever is the highest space containing an interchondral balk and joint, acts by virtue of that joint, as the hinge of the movement of the lower thoracic ribs 6, 7, and 8 on the upper, hence that intercostal muscle is liable to strain. Such stress arises in the upper thoracic type of breathing seen in functional cases, and in certain cases of failing heart, as well as in the eversion of the lower thorax coincident with affections of the stomach and probably of other organs—e.g., the œsophagus. Strain on this muscle is also caused by static conditions. Lateral spinal curvature, the convexity being to the left in the mid-dorsal region, opens the intercostal space and stretches the muscle. Conditions in which the shoulders are held backwards diminish the concavity of antero-posterior curve of the lower thoracic vertebrae and open the space anteriorly. The former variation frequently follows changes in the level of the crests of the ilium from whatever cause, and the latter such conditions as pregnancy, over-nutrition, myxœdema.

Excessive contraction of an intercostal muscle will also occur in pleurisy, and in the neighbourhood of torn muscle-fibres. If such is in this area pain will be as described. Starting a car has been responsible for several cases, no doubt of rupture of muscle followed by intense pain radiating widely.

Bromide relieves the cases of psychic pain and exaltation of reflexes. Recognition and treatment of the psychological factor requires more than reassurance, and without such fuller mental treatment the abnormal upper chest over-action and irregularity will not be restored to the normal. Amelioration sometimes follows re-education of diaphragmatic action. Treatment of the stomach to obviate flatulence, as by creosote or small doses of calomel and rhubarb and soda, is most valuable. The static cases yield favourably to measures which restore the natural posture—shoes, dieting, thyroid extract, &c. Pleuritic pains, acute or subacute, and trauma yield to measures restricting movement or assisting the action of the muscle.

The most troublesome type to treat is the individual about 50-63. There is no functional element except anxiety to know that the heart is not the cause. These people have reached the period in which calcification of costal cartilages has commenced, entailing more work by interchondral and intercostal muscles. The pain lasts for 18 months to 3 years and then disappears simultaneously with the alteration of the mode of breathing from the thoracic to the abdominal. A chest with a broad thoracic angle is characteristic of this type. Massage epigastric is characteristic of this type. Massage to the intercostal muscles is helpful. Successful treatment based on a theory derived from anatomical and physiological concepts goes some way to establishing the correctness of the theory, and I am firmly convinced that the immediate origin of the pain lies in the muscle.

I think Dr. Baker's summary and opinions on treatment are too pessimistic.

I am, Sir, yours faithfully,

CHARLOTTE BRISCOE.

Harley-street, W., June 18th, 1930.

To the Editor of THE LANCET.

SIR,—The chief impressions I received from a perusal of Dr. Doris Baker's paper were (1) that a cardiological clinic is not the proper treatment centre for patients suffering from this condition, and (2) that the apparent limited amount of material for the study of this condition at these centres reflects a

certain amount of credit on the diagnostic acumen of general practitioners.

Pain under the left breast, unassociated with any other symptom, subjective or objective, is the most common of all complaints of pain found in a consulting room (I am writing with the assistance of a carefully indexed study of symptomatology extending over many years), and in association with other symptoms ranks in frequency among the first three pain areas. The pain varies in intensity from a mild discomfort to all the manifestations of a mild primary angina pectoris, apart from situation. Hyperæsthesia is present in a certain number of cases, and the feeling of constriction in some, being due most probably to contraction of the intercostal muscles. Just as pain in the lumbar region is usually associated in the lay mind with kidney trouble, so pain in this region is associated with heart trouble, and that in part may explain its high frequency among patients, but we should unfailingly look for abdominal lesions. It has been found as the outstanding complaint in diseases of the gall-bladder, appendix, uterus, and ovary, and cured by proper surgical interference.

The relationship between hyperæsthesia and gross abdominal lesion, unfortunately, does not appear to be constant, as it has been found absent in some with lesion and present in some where no lesion has ever manifested itself. Its chief associated symptom is constipation, and that may explain why it is more common in women than in men, because constipation is more common in women than in men. It is a mistake to say that "treatment is unsatisfactory." It is all a question of correct diagnosis, for it is found in association with so many different causes, but, failing evidence of definite disease, the most efficacious treatment is "Mist. alba." Why this should be so effective as compared with other and more elegant preparations I do not know. It is especially effective in those cases where the patient states that the habits have been regular.

While it may be that the pain in all cases can only be explained by a complicated reflex mechanism, it seems to be a good rule of thumb in the majority of cases to regard it as being due to the mechanical drag of a loaded bowel. There is one other point: it is necessary to reassure the patient in regard to her heart, but as the lady is likely to have discussed the trouble with her friends, the "rheumatism round the heart" diagnosis of the old family doctor is not without its good points; it sounds much nicer, and is more flattering than "constipation," and is just as safe.

I am, Sir, yours faithfully,

Halifax, June 17th, 1930.

A. GARVIE.

GAS-OXYGEN AS A ROUTINE ANÆSTHETIC.

To the Editor of THE LANCET.

SIR,—I am much interested in Dr. A. H. Macklin's report in your issue of June 7th (p. 1231) on the routine use of gas and oxygen for major operative work. There is no doubt that he has realised the importance of using an efficient machine. I see that he is attempting to devise a facepiece which will deal satisfactorily with edentulous cases. There is no need for him to trouble to do that, as if he will get a McCordie or London pattern airway and use it to keep the nose from coming into contact with the chin, and then cut a piece of Gamgee tissue of suitable size with a hole for the nose and mouth, thoroughly wet it with water, and then use the facepiece he has, inflated so as to be very soft, there is very little difficulty in maintaining an airtight contact. McKesson himself leaves the dentures (if full upper and lower) in, and I have seen for myself, over in the States, that this method answers very well. Of course, in this country it would not be allowed us; the ward sisters and theatre staff would be worried to death if they caught a patient in the theatre with loose teeth. I agree with Dr. Macklin's opinion of the Boyle apparatus,

about which I have already expressed my opinion.¹ There is no doubt that when the public realise the advantages, to themselves, of gas anaesthesia the present opposition to it will speedily break down.

I am, Sir, yours faithfully,

E. J. CHAMBERS,
June 13th, 1930. Anaesthetist to Rotherham Hospital.

CÆSAREAN SECTION UNDER SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—The communication in your issue of May 10th on Cæsaean section under spinal anaesthesia prompts me to the following comment. A patient suffering from congestive heart failure is clearly unfitted to withstand inhalation anaesthesia, but in my experience rachianæsthesia has not been without its ill-effects on the circulation. Under these circumstances local anaesthesia seems to me the method of choice, and by local infiltration with 1 per cent. novocain together with block of the lower intercostal nerves I have been able to carry out the operation with ease. The uterus is, of course, quite insensitive to cutting and handling.—I am, Sir, yours faithfully.

L. F. O'SHAUGHNESSY, F.R.C.S. Eng.,
Sudan Medical Service.

Omdurman, May 27th, 1930.

Obituary.

ROBERT MCKENZIE JOHNSTON, M.D.,
F.R.C.S. EDIN.,

CONSULTING SURGEON TO THE EAR AND THROAT DEPARTMENT,
EDINBURGH ROYAL INFIRMARY.

WE regret to record the death of Dr. McKenzie Johnston, the well-known Edinburgh surgeon, which occurred on Sunday, June 1st, at a nursing home, in the seventy-fourth year of his age.

Robert McKenzie Johnston was born in Edinburgh in 1856, the son of a surgeon in the H.E.I.C., whose other sons included the distinguished Scottish lawyer, Lord Johnston, and Sir Duncan Johnston, of the Ordnance Survey. Robert was educated at Clifton and the Edinburgh Academy, entered the University for his medical training, and graduated in medicine in 1881, proceeding to the M.D. in 1883, after holding the post of resident physician at the Royal Infirmary. He obtained the F.R.C.S. Edin. in the following year, and went into general practice. But in 1890, having in the meantime taken special interest in diseases of the ear, nose, and throat, he was appointed assistant surgeon to the Royal Infirmary, where a special department of laryngology had been formed under the late Prof. Peter McBride. The department was then quite a small one, but it gradually developed, more accommodation was found for patients, with a complete out-patient department and lecture theatre, and by 1903, when McKenzie Johnston became full surgeon, the annex to the infirmary was completely up to date. It has since regularly received all necessary complements to its utility, for McKenzie Johnston was extremely well informed on the technical side of his specialty. When ill-health led to his cessation of work in 1906, he was established by practical performance as a professional leader. He did not, however, allow the break in his career to become a tragedy, and although he resigned his hospital and university appointments, he shortly afterwards returned to work, when other organisations and institutions benefited from his freer energies. He had joined the board of management of the Infirmary in 1907, and for 12 years he was manager of the institution, where his services proved of the utmost

value. He was also an indefatigable member of the University Court. At the Royal College of Surgeons he acted for a time as secretary, and when in 1917 he was elected President it was felt that he had obtained the eminent professional position as a reward alike of industry, capacity, and learning.

We owe to Sir Leslie Mackenzie the following appreciation of Dr. McKenzie Johnston's character:—

"At once a man of culture and of serious views on all serious questions, he was tenacious of his opinions, yet gracious in argument. He was fearless and ready in action, yet not insistent or aggressive. He was, from the standpoint of many younger medical 'reformers,' very conservative. But then he showed in his whole dealings the deeply rooted sense of honour that made him a force in the profession and in all the public bodies on which he served—the Royal Infirmary, Fettes College, the University Court, and others. It was in the nature of things that such a man should come into the Presidentship of the College of Surgeons. He carried into all his life a reverence for the past, but his mind was always subtle and alert and, if he did need to be persuaded of the value of new changes, he 'played the game' when his persuasion was complete. He took all his work with grave seriousness, and that was, no doubt, the main secret of his great influence. His quiet, undemonstrative manner gave no immediate indication of his personal force but, once known, McKenzie Johnston was seen to be a man of intense grip and invincible will. He leaves a gap in the life of Edinburgh, perhaps he should say in the life of the 'older Edinburgh,' when the conditions were still simple enough to enable a cultured doctor to take his share in civil administration as well as in his professional specialty. Edinburgh is fortunate in having had many such men; but Johnston was one of the best."

In addition to the work done for the Infirmary, the College of Surgeons, and the University, McKenzie Johnston gave much time and thought to the affairs of the British Medical Association, being for two periods on the Council and an assiduous member of the Building Sub-Committee which over 20 years ago took over the rebuilding of the Strand premises of the Association. He was also a governor of Fettes College, and a member of the Royal Company of Archers.

Dr. Johnston married a daughter of the late Mr. Henry Younger, of Benmore, Argyllshire, by whom he was predeceased, while he is survived by three sons and a daughter.

ANGHEL GASTER, M.D. BUCHAREST,
M.R.C.P. LOND.

Dr. Anghel Gaster, whose death at the age of 66 was announced in a recent issue of THE LANCET, died at his residence, 33, Devonshire-place, W., on May 31st.

Anghel Gaster was born at Bucharest and received his general and medical education in his native city. His father was a man of importance in Bucharest, and one of his brothers, who entered the Jewish priesthood, was well known as an ethnologist and a learned student of divinity. Anghel Gaster, after obtaining his medical degree at Bucharest University, became resident at one of the chief hospitals in the city, where he began to study closely diseases of the chest and the therapeutics of tuberculosis. In the year in which he graduated in medicine, the Rev. Dr. Moses Gaster, the theologian brother, came to England to take up a high appointment in the Jewish Church, and Anghel Gaster, after post-graduate study in Paris and Berlin, joined him in London. He obtained the diploma of M.R.C.P. Lond. in 1891, held a resident appointment in the City of London Chest Hospital, and then went into general practice in a characteristic manner—that is to say, he worked in Hampstead and in the East End of London simultaneously, devoting a large proportion of his time to gratuitous labour among the poor in Stepney and the adjoining districts. He was equally successful

¹ Brit. Med. Jour., 1929, i., 1099.

in both classes of practice, his sterling qualities of character being backed by high professional skill. In 1890, having become a naturalised British subject, he married Miss Leah Mocatta, and shortly afterwards his position both as doctor and philanthropist was consolidated by the leading part which he played in the foundation of the London Jewish Hospital in Stepney. Of this hospital he was treasurer from the outset in association with his wife, and in the 20 years of the life of the institution it has developed from 10 to over 100 beds.

Throughout the war he was commanding officer of the Tudor House Military Hospital in Hampstead, while he also held appointments in Kensington, at the Kensington and Fulham General Hospital, and in Hampstead as medical officer to the Baroness de Hirsch Convalescent Home.

One of his colleagues on the staff of the London Jewish Hospital sends us a warm appreciation of Gaster's work there. "As a physician," he writes, "he had charge of both in-patients and out-patients, and the latter flocked to him in great number, while he never spared himself. His fluency in many languages was here of great value; it may be said truly that he was loved by his patients, and he is deeply regretted by his colleagues and many friends."

THE LATE DR. COOPER PATTIN.

Dr. Soothill, the medical officer of health for Norwich, has sent us the following tribute to the qualities of his predecessor. Of Dr. Cooper Pattin he says: "He was a leader of thought in many ways, the cubicle block at the Norwich Isolation Hospital being one of the first in the country, and the inclusion of school-children of 10 years and 13 years of age in the routine groups for school medical inspection being an unusual advance. In fact, starting from the small beginnings usual in those times, he left a public health department which could compare favourably with any authority of similar size in the country, while the results, as shown by the diminishing death-rates published in his last annual report, testify to the quality of the work done. As the figures are of general public health interest, it is as well to mention them here. Dr. Pattin said: 'It is of interest to myself to state that in my first year of service and in my last, . . . the corrected death-rates (were) 18.1 and 10.4 per 1000. The infantile mortality-rates, 106.25 and 58.1 per 1000 births. The death-rates from tuberculous diseases, 2.4 and 1.1 per 1000. The notifications of enteric (typhoid) fever, 314 with 30 deaths and 14 with 2 deaths—of puerperal fever, 15 with 10 deaths and 9 with 3 deaths.'

"Dr. Pattin was a fluent and witty speaker with a great fund of humour, but was not at all shy of making the same jest repeatedly in public—and it always 'went down.' He labelled himself an improvident philosopher, stated that he had lived more for the life he had enjoyed than the livelihood, and was indeed generous beyond his means, while his will is concerned with a scholarship for medical education. All the arts and sciences were discussed with gusto, and in many cases with close knowledge, while he thoroughly enjoyed a game of bridge or bowls. He never appeared flurried; he was shrewd, able, upright, and advanced a long way in Norwich along the path of the education of the 'vested interests' to the point of view that improved conditions are to their own advantage."

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—

A general meeting of this society was held at the London Jewish Hospital on June 12th, the President, Dr. J. Burford, in the chair. The following officers were elected for the ensuing year: President, Dr. L. Mandel; vice-president, Mr. M. Sourasky; treasurer, Dr. L. Turiansky; hon. clinical secretary, Dr. H. Avery; hon. general secretary, Dr. L. Phillips; committee, Dr. Appel, Dr. Dyvien, Dr. Kaplan, Dr. D. Krestin, Dr. Robinowitz, Dr. Rosenzvit, and Mr. A. Sorsby.

Medical News.

UNIVERSITY OF OXFORD.—Patrick Corbett Mallam, B.M., has been elected to a Schorstein research fellowship.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—An ordinary meeting of the Council was held on June 12th, with Lord Noylman, the President, in the chair.

Diplomas of Fellowship were granted to the following candidates who were successful at the recent examination:—

Charles Edward Kidderley, St. Bart.'s; Arnold Guy Harsant, London; Philippa Parry Martin, Univ. Coll.; Henry Richard Rishworth, St. Mary's and London; Louis Amos Bennett, Otago and St. Bart.'s; Arthur Elliot Smith, Univ. College; Terence Edward Cawthorne, King's College; Thomas Smith Donovan, Birmingham; Arthur Edgar De Chazal, Univ. College; Frederick James Theodore Foenander, Ceylon and Middlesex; John Giddings Milner, St. Bart.'s; John Geoffrey Yates Bey, King's College; Arthur Charles Copley and James Rudd Ratcliffe, St. Mary's; James Cosbie Ross, Liverpool and Guy's; Thomas Holmes Sellers, Oxford and Middlesex; Gavin Hamilton Livingstone and Hubert Lyon-Campbell, Wood, King's College; Hugh Desmond Blarwell, Edinburgh and London; Arthur Capel Herbert Bell, St. Bart.'s; Robert Ruthford, King's College; Mahmood Ismail Ashmawi, Cairo and St. Bart.'s; Archie Murrell Acheson Moore and John Foster, London; Arthur Eggle Torritt, Otago and St. Mary's; Kenneth Harold Watkins, Manchester and Guy's; Henry Hamilton Stewart, St. Thomas's; David William Currie, Leeds and St. Bart.'s; Venkatachari Srinivasan, St. Bart.'s; Hernon Taylor, Camb. and St. Bart.'s; Thomas Glibin, Melbourne and Guy's; John Gordon Sander, Sydney and St. Bart.'s; Robert Henry Hadley, Melbourne and London; Shantilal Jannadas Mehta, St. Bart.'s; Sangham Lal, London; William Donald Bedford, Leeds and London; Myles Landseer Formby, Adelaide and Guy's; Robert Grainger, Belfast and St. Bart.'s; Kinsey, Sydney and Guy's; Eric Ian Alan Macdonald, Otago and St. Bart.'s; John Mark, Otago and Guy's; Robert John Cecil Maxwell, Belfast and St. Bart.'s; and Hector Hamilton Stewart, Melbourne and St. Bart.'s.

Diplomas of Membership were granted to: Mabel Eileen Grace, Joyce MacIntosh, Ruth Milne, and Helen Elizabeth Rodway (Royal Free), who had previously passed the final examinations in medicine, surgery, and midwifery of the Examining Board in England and had now complied with the regulations.

At the primary examination for the Fellowship, held from June 3rd to 14th, for which 158 candidates presented themselves, 64 were approved. The following are the names and schools of the successful candidates:—

S. Ahmad, M.B. Punjab and London; G. A. Alexander, M.B. Edinburgh; D. R. Bharucha, M.B. Bombay, King's Coll. and Middlesex; B. W. Billington, Cambridge and Middlesex; V. G. Bormann, M.B. Bonn, London and Guy's; M. Coleman, M.B. Univ. Coll.; T. G. B. Crawford, M.B. Trin. Coll. Dublin; A. W. Cubitt, B.M. Oxford and King's Coll.; M. P. Ellis, M.R.C.S. Univ. Coll.; B. E. Fernando, L.M.S. Ceylon, Middlesex and King's Coll.; D. J. Fitzpatrick, M.B. Melbourne and King's Coll.; G. H. V. Frost, M.R.C.S. Sheffield and Middlesex; E. Gallinsky, Univ. Coll.; P. H. R. Ghey, Cambridge; B. Gilbert, St. Thomas's; A. El S. Handouss, M.R.C.S. Cairo and St. Mary's; J. B. Harman, Cambridge and St. Thomas's; B. P. Harris, Cambridge and Middlesex; G. J. Hollis, M.R.C.S. Guy's; J. F. Jarvis, King's Coll.; A. N. Jones, M.B. Liverpool and Middlesex; K. D. Kele, St. Bart.'s; T. King, M.B. Melbourne and King's Coll.; R. Lal, M.B. Lucknow and Middlesex; M. Leggett, M.B. Liverpool; A. H. Lendon, M.B. Adelaide; F. R. Leonard, M.B. Otago and King's Coll.; H. G. Letcher, M.B. Adelaide, King's Coll. and Middlesex; A. L. Light, M.B. Leeds and St. Mary's; M. B. Lyndesay, M.B. Perth; E. G. Macdonald, M.B. Sydney, Middlesex, and St. Mary's; K. M. Masani, M.B. Bombay and Middlesex; Mary H. Mayeur, Lond. Sch. Medicine; D. M. Mitchell, M.B. Otago; N. St. C. Mulligan, M.B. Sydney and Middlesex; G. G. Murphy, Univ. Coll.; J. H. North, M.B. Otago and King's Coll.; J. O'Donnell, M.B. Leeds; J. Penry, M.R.C.S. St. Mary's and King's Coll.; G. Qvist, Univ. Coll.; C. T. Rawle, M.B. Sydney, King's Coll. and St. Mary's; R. N. Richards, M.B. Sydney, King's Coll. and St. Mary's; L. N. Ross, M.B. Belfast; J. E. Sempie, M.B. St. Thomas's; E. J. Smith, King's Coll.; B. R. Sworn, M.B. St. Thomas's; G. R. A. Syme, M.B. Melbourne and St. Mary's and King's Coll.; G. G. Talbot, M.B. Otago and King's Coll.; W. H. Tandy, M.R.C.S. Birmingham and Middlesex; Lilian E. Tracey, Lond. Sch. Medicine; E. N. Vardle, M.B. Liverpool; J. C. F. L. Williamson, M.B. Cambridge and St. Bart.'s; I. Zieve, Cape, St. Mary's and King's Coll.

Mr. Max Page, surgeon to St. Thomas's Hospital, was elected a member of the court of examiners for five years in the vacancy occasioned by the retirement of Mr. Graham Simpson, of Sheffield. The following examiners were elected for the ensuing year:—

Dental Surgery.—(Surgical Section)—L. Bathe Rawlinson, H. S. Clegg, T. P. Legg, Russell J. Howard, Gwynne

Williams, John Murray, C. E. Shattock, and Cecil P. G. Wakeley.

Examiners for the Fellowship.—(Anatomy)—P. N. B. Odgers, William Wright, J. Ernest Frazer, and J. Basil Hume; (Physiology)—H. E. Roat, C. A. Lovatt Evans, R. J. S. McDowall, and John Mellanby.

Conjoint Examining Board.—(Elementary Biology)—James P. Hill and T. J. Evans; (Anatomy)—R. Bramble Green, W. E. Le Gros Clark, and H. A. Harris; (Physiology)—E. B. Verney and Hamilton Hartridge; (Midwifery)—Clifford White, T. B. Davies, A. W. Bourne, and Sidney Forsdike.

Diploma in Public Health.—(Part I.)—John Eyre; (Part II.)—C. W. Hutt.

Diploma in Tropical Medicine and Hygiene.—(Pathology and Tropical Medicine)—David Harvey.

Tropical Medicine and Surgery.—G. Carmichael Low.

Diploma in Ophthalmic Medicine and Surgery.—(Part I.)—H. Willoughby Lyle and W. S. Duke-Elder; (Part II.)—R. Aflleck Greaves.

Diploma in Psychological Medicine.—J. G. Greenfield.

Diploma in Laryngology and Otology.—(Part I.)—W. M. Mollison and Norman Patterson; (Part II.)—W. G. Howarth.

Diploma in Gynaecology and Obstetrics.—J. D. Barris.

Dr. Harold Dew was elected a Hunterian Professor for the ensuing year, and will deliver a lecture on Hydatid Disease—some Interesting Complications, on Thursday, July 10th, at 2.45 P.M.

It was decided to proceed with the arrangements for holding the primary examination in anatomy and physiology for the Fellowship in Canada, at Montreal, and Prof. William Wright and Prof. Lovatt Evans were appointed to conduct the examination.

Sir Holburt Waring was appointed to represent the College at the ceremonies of the inauguration of the buildings of the University of Brussels and of the School of Medicine from June 23rd to 25th.

UNIVERSITY OF BRISTOL.—At recent examinations the following candidates were successful:—

CH.M.

Robert Victor Cooke.

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—K. P. Beaubrun, L. C. Holland, and (completing examination) A. J. B. Miall.

Part II.—With Second Class Honours: *J. F. Coates and †G. F. Langley. *Pass:* H. F. G. Corfield, R. D. Jones, R. A. Lattey, R. P. Lucas, H. M. Strover, and (completing examination) R. M. Norman.

* Distinction in Medicine and Obstetrics.

† Distinction in Medicine and Public Health.

FINAL EXAMINATION FOR B.D.S.

Pass.—Muriel E. S. Cosh and William Forsyth.

FINAL EXAMINATION FOR L.D.S.

A. N. Moon, T. A. Satchwell, C. G. Westlake, and Idwal W. Williams.

D.P.H.

Part II.—W. W. S. Sharpe.

UNIVERSITY OF LONDON: University College.—Mr. R. K. Cannan has resigned his lectureship in biochemistry on appointment to the chair of chemistry in New York University, and Mr. G. F. Marrian has been appointed lecturer in his place.

UNIVERSITY OF DURHAM.—The honorary degree of D.C.L. is to be conferred on Lieut.-General H. B. Fawcus, Director-General of the Army Medical Services.

EPSOM COLLEGE: St. Anne's Scholarship.—The Council of Epsom College will shortly elect a girl to a St. Anne's scholarship of £120 a year. Candidates must be at least 9 and not more than 12 years old on July 30th, and must be orphan daughters of medical men who have been for not less than five years in independent practice in England or Wales. Application must be made by July 3rd on a form to be obtained from the secretary of the College, at 49, Bedford-square, W.C. 1.

PHYSIOLOGICAL SOCIETY.—This society is holding a meeting at 2.30 P.M. on Saturday, June 21st, at University College, London, with Sir Charles Sherrington, O.M., in the chair. At 3.30 Dr. Georges Bourguignon will demonstrate the technique of chronaxie measurements on human subjects and Dr. Léon Brillouin will explain his new apparatus for making such measurements. These demonstrations will be preceded (at 2.30 P.M.) and followed (from 5.15 to 6.15) by a discussion on Chronaxie and Central Nervous Activity. The speakers will be Prof. Louis Lapicque, Dr. Henri Laugier, Dr. Catherine Veil, and Prof. Henri Fredericq, and members of the medical profession are invited to attend. In the evening a dinner in honour of Sir Edward Sharpey-Schafer will be held at the Trocadero Restaurant.

SOCIETY OF APOTHECARIES OF LONDON.—Mr. Reginald Silby Lewis, LL.B., has been appointed medical registrar to this society.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At a recent meeting of the Faculty the following were elected to honorary Fellowships: Dr. Robert Muir, professor of bacteriology in the University of Glasgow; Dr. William Loudon Reid, formerly president of the Faculty; and Lieut.-Colonel Laurence Austine Waddell, I.M.S. (retd.).

ROYAL SUPPORT FOR HOSPITALS.—On Thursday last week the Prince of Wales visited Edinburgh in connexion with the bi-centenary of the Royal Infirmary. He first formally opened the Murray Home for wounded and invalided soldiers and sailors, and planted a commemorative tree. The home, which accommodates 20 residents, and contains a surgery and a sick room, has been provided at a cost of £22,000 under the will of the late Miss Helen Murray. The Prince then went to the Royal Infirmary, where he visited the wards, planted another commemorative tree, and after lunching with the City Council, made a speech supporting the appeal for £500,000 for an extension of the hospital. On the same day Princess Mary opened an enlargement of the East Surrey Hospital at Redhill, and the Duke of York presided over a festive dinner at the Mansion House in support of the fund of £100,000 which is being raised for extensions to the Royal National Orthopaedic Hospital, and for the provision of better equipment and the creation of a maintenance fund. There are 1000 child patients on the waiting-list.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—The forty-eighth annual dinner of this society was held at the Trocadero Restaurant, London, on June 12th, and was well attended. The chair was taken by Dr. J. F. Halls Dally, who gave an interesting historical account of the origin of the society, whose first two dinners were held at the Star and Garter Hotel, Richmond. Their membership he said, now numbered 360 and 32 new members had been added during the year. Lord Moynihan congratulated the society on having held aloof from amalgamation in the Royal Society of Medicine, an advantage, he suggested shared by both parties. Medical London, he remarked had been behind the provinces in the acceptance of Listerism and generally in progress and enlightenment. With undergraduates it had been successful; the school had taught them all the medicine and more than all the surgery that they knew, and had inspired them with the right principles of conduct; but although the isolation of its several schools happily had now broken down London had not yet realised its opportunities for post-graduate medical teaching. He desired to see a great research centre at the Royal College of Surgeons with its home at Down in Charles Darwin's old house, and he looked to the foundation of an Academy of Medicine. Dr. A. Knyvett Gordon proposing "Kindred Societies and Guests," offered the Agent-General for Queensland, who was chief guest, medical exports in the form of his neurasthenic patients to populate the broad spaces of the State, accepting in return the radium which he believed might be mined there. Sir Edward Macartney, in replying, admitted the mineral wealth of Queensland, but disclaimed a knowledge of the existence of radium, although he would willingly assist Dr. Gordon and his friends with a concession for obtaining it. Dr. P. Montague Smith, President of the Harveian Society of London, and Major Hugh Wakefield also replied, the latter with inimitable stories in Lancashire and Cockney vernacular. Sir Dennis Herbert proposed "The Chairman" in happy terms. Mr. Finlay Dunn, at the piano, entertained the company.

MATERNITY AND CHILD WELFARE.—A national conference on this subject will be held at Friends House Euston-road, London, N.W., from July 1st to 3rd. At the opening meeting Dame Louise McIlroy will take the chair. Miss Susan Lawrence, M.P., Parliamentary Secretary to the Ministry of Health, will give a presidential address, and a debate on Infant and Pre-school Child Mortality will be opened by Dr. T. H. C. Stevenson, of the General Register Office. On the second day Mr. Neville Chamberlain, M.P., will take the chair, and the subject before the meeting will be the Relationship between Housing and Child Welfare introduced by Sir John Robertson. In the afternoon Sir Robert Jones will preside at a session at which the two subjects of discussion will be the Relationship between the Orthopaedic Clinics and Child Welfare Centres, opened by Dr. T. Hartley Martin, and the After-care of Non-notifiable Infectious Diseases, opened by Dr. K. H. Tallerman. On the evening of the same day Prof. S. J. Cowell will lecture on Present Research in Nutrition. On July 3rd the chairman will be Lady Lawrence, and the first debate, on the Care of the Pre-school Child, will be opened by Dr. G. C. M.

M'Gonigle, Dr. J. Middleton Martin, and Dr. H. W. Pooler. Among those contributing in the afternoon, when Sir Arthur Stanley will preside, will be Sir P. Truby King, who will speak on Progressive Developments in the Feeding and Care of Infants. At 5 P.M. Dr. J. A. Stephen will give his presidential address to the maternity and child welfare group of the Society of Medical Officers of Health. During and after the conference visits will be paid to child welfare centres of various kinds. Particulars may be had from Miss J. Hallford, 117, Piccadilly, W. 1.—A post-graduate course in this subject will be held at various centres in London from Monday, June 30th, to Saturday, July 6th. It is being arranged in connexion with the annual meeting of the M. and C.W. group of the Society of Medical Officers of Health, but there will be a few vacancies for practitioners not in the public health service. Particulars may be had from the Fellowship of Medicine at 1, Wimpole-street, W. 1.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
THURSDAY, June 26th.—8.30 P.M. Urology. Paper, Mr. Swift: Urology. Cystoscopy Diathermy for Villous Growths of the Bladder.

FRIDAY AND SATURDAY.—OTOLOGY: Summer Meeting at Nottingham. The following have been named by Dr. Muir Evans: Prof. Guido Guida, Dr. Densham, and Mr. Lowndes Yates. Cases and demonstrations by Mr. Alexander Tweedie, Mr. Bell Tawse, Mr. Sydney Scott, and Mr. George Wilkinson. Exhibition of mechanical and electrical Aids to Hearing. Discussion on the proceedings of the Committee for the Consideration of Hearing Tests.

LONDON CLINICAL SOCIETY.

THURSDAY, June 24th.—9 P.M. (at the London Temperance Hospital), Sir Robert Armstrong-Jones: The Evolution of the Human Mind. (Illustrated by lantern slides.) (Fifth annual Macalister Lecture.)

MEDICO-LEGAL SOCIETY.

THURSDAY, June 26th.—8.30 P.M. (at 11, Chandos-street, W.). Annual General Meeting. Prof. J. S. Haldane: Carbon Monoxide Poisoning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.
FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, June 23rd, to SATURDAY, June 28th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Special M.R.C.P. Lectures at 8.30 P.M. Tues. and Fri., Dr. W. J. Adie, Diseases of the Nervous System. NATIONAL SOCIETY FOR DISEASES OF THE HEART, Westmoreland-street, W.: Mon., 2.15 P.M., Dr. Strickland Goodall, Demonstration in O.P. Department. HOSPITAL, 234, Great Portland-street, W.: Thurs., 1.30 P.M., Mr. R. Y. Paton, Demonstration in O.P. Department. No fee.—BLACKFRIARS SKIN HOSPITAL, Blackfriars-road, S.E.: Afternoon Course, second week. Special Demonstration on Tuesday.—CHICHESTER HOSPITAL FOR WOMEN, Arthur-street, S.W.: Second week of Course in Gynecology, mornings and/or afternoons.—HOSPITAL FOR TROPICAL DISEASES, Gordon-street, W.C.: Second week of course. Instruction from 11-12 noon, 2-3 P.M.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N.: Intensive Course in Medicine and Surgery. Further particulars from the Fellowship of Medicine.

NATIONAL HOSPITAL, Queen-square, W.C.
MONDAY, June 23rd.—12 noon, Dr. Greenfield: Cerebro-spinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Varieties of Peripheral Neuritis.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Spinal Tumours and Compression Paralysis.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Gordon Holmes: Lesions of the Cerebellum.

FRIDAY.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of the Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3-3.30 P.M., Dr. Walshe: Disorders of the Motor System.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.
WEDNESDAY, June 25th.—1.15 P.M. at St. John's Hospital, 49, Leicester-square, W.C.: Annual General Meeting and Cases.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, June 23rd.—11 A.M. Medical, Surgical, and Gynecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M. Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M. Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations. Medical, Surgical, Throat, and Ear Clinics. 2.30 P.M. to 5 P.M. Medical, Surgical, and Children's Diseases Clinics. Operations.

Appointments.

GOV. J. M.B., C.M. Glasg., D.P.H., has been appointed Medical Officer of Health for Edinburgh.
TATTERSALL, S. R., L.R.C.P. Lond., M.R.C.S., Deputy Superintendent of Prestwich Mental Hospital.

Vacancies.

For further information refer to the advertisement columns.

Barnsley, Beckett Hospital and Dispensary.—H.P. £200.
Bath, Royal United Hospital, H.P., £125.
Bethnal Green Hospital, Cambridge-road.—Asst. M.O. £400.
Birkenhead County Borough.—Asst. M.O.H. and Bacteriologist. £750.
Birmingham, City of.—1st Asst. M.O. £600.
Birmingham General Hospital.—Res. H.S. to Throat and Ear Dept. £70. Also Anaesthetist. £120.
Birmingham, Midland Hospital, Easy-row.—H.S. £150.
Bolingbroke Hospital, Waulsworth Common, S.W.—H.P. At rate of £120.
Bristol General Hospital.—Temp. Asst. Hon. Surgeon. Also Rectifier.
Bristol General Hospital.—H.P.'s, H.S.'s, Res. Obstet. O., also Cas. H.S. At rate of £60 and £80 respectively.
Bristol Royal Infirmary.—Hon. Reg. to Ear, Nose and Throat Dept. Also Hon. Asst. Radiologist.
Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.
Out-Patient O., £200.
Cheshire and North Derbyshire Royal Hospital.—Cas. O. At rate of £200. Also H.S.'s. At rate of £100 to £175.
Colchester, Royal Eastern Counties' Institution for Mentally Defective.—Clin. Research Worker. £600.
Colindale Hospital, Hendon, N.W.—Sen. Asst. M.O. £650.
Committee of Dufferin's Fund, Women's Medical Service for India.—Two Medical Women. 550 and 750 pesos per mensem.
Coventry and Warwickshire Hospital.—Res. Asst. H.S. £125.
Dudley, Derbyshire Royal Infirmary.—Asst. H.S. and Cas. O. £150.
Dorset, Guest Hospital.—Hon. Gynaecologist and 2 Anaesthetists. Also Asst. H.S. £150.
Dumfries and Galloway Joint Sanatorium.—Res. Med. Supt. £700.
East London Hospital for Children, Shadwell, E.—Dermatologist. Edinburg Royal Infirmary.—Med. Reg. for Statistical Research. £250.
Egyptian University Faculty of Medicine.—Prof. of Hygiene. £2,1500.
Eveling Hospital for Children, Southwark, S.E.—H.S. At rate of £100.
Gloucester, Gloucestershire Royal Infirmary.—2nd H.S. At rate of £100.
Guy's Hospital Medical School, S.E.—Gull Studentship. £250.
Hampstead General and N.W. London Hospital, Haverstock Hill, N.W.—Cas. Surg. O. At rate of £100.
Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £50.
Hull Royal Infirmary.—H.S. At rate of £150. 3rd H.S. At rate of £150.
Huntingdon County Hospital.—H.S. £125.
Hull Borough.—Asst. M.O.H. £600.
Indian Medical Service.—Commissioned.
 Ipswich, East Suffolk and Ipswich Hospital.—H.P. £120.
Lambeth Hospital, Brook-street, Renshaw-road, S.E.—Jun. Asst. M.O. £200.
Leamington Spa, Warwick General Hospital.—Res. H.S. £165.
Leicester Royal Infirmary.—H.S. At rate of £125.
Leicestershire Hospital, Leicestershire, S.E.—Asst. M.O. £200.
Lincoln County Hospital.—Jun. H.S.
Liverpool, Mill-road Infirmary.—1st Asst. M.O. £200.
Liverpool, Good Children's Hospital, Myrtle-street.—Res. H.S. At rate of £60.
Liverpool, Royal Southern Hospital.—H.P., H.S. Also M.O. to Spec. Depts. Each at rate of £50.
London General Hospital Service.—1st Asst. M.O. £145.
London University.—External Examinerships.
Manchester, Baguley Sanatorium.—Asst. M.O. £350.
Manchester, Booth Hall Hospital for Children, Charlestown-road, Blackley.—1st Asst. M.O. At rate of £250.
Manchester, Ear Hospital, Grosvenor-square, All Saints.—Non-Res. H.S. At rate of £150.
Manchester Northern Hospital for Women and Children, Park-place, Chetham Hill-road.—Sen. H.S. and Jun. H.S. At rate of £100 respectively.
Miller General Hospital, Greenwich-road, S.E.—Cas. O. £150.
Nelson Hospital, Merton, S.W.—Res. M.O. At rate of £100.
Newark General Hospital.—Res. H.S. At rate of £150.
Newcastle-upon-Tyne, Education Committee.—Asst. School M.O. £300.
Newcastle-upon-Tyne General Hospital.—Surg. Director. Also Med. Director. Each £200.
Newcastle-upon-Tyne, Hospital, N.W.—Jun. Asst. M.O. £200.
Northampton General Hospital.—Asst. H.S. At rate of £150.
Oldham Royal Infirmary.—H.S. At rate of £175.
Plymouth, South Devon and East Cornwall Hospital.—H.S. At rate of £250.
Quebec, Charlotte's Maternity Hospital, Marjolebone-road, N.W.—Res. M.O. £200.
Reading, Battle Infirmary.—Asst. Res. M.O. £300.
Reading, Royal Berkshire Hospital, H.P. Cas. O. and Res. Anaesthetist. Each at rate of £150.

Rotherham Hospital.—Sen. H.S. £200. Also H.P. £180.
 Royal Free Hospital, Gray's Inn-road, W.C.—Res. Cas. O. £150.
 Royal London Ophthalmic Hospital, City-road, E.C.—Sen. H.S. At rate of £150.
 St. Bartholomew's Hospital, E.C.—Surgeon to Throat Dept. Also Asst. Physician.
 St. Helens County Borough.—Asst. M.O.H. £600.
 St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.
 St. Marylebone Hospital, St. Charles-square, Ladbroke-grove, W.—Second Asst. M.O. £300.
 Salford Royal Hospital.—Hon. Asst. S., also H.P. and H.S.'s. Each at rate of £125. Also Anaesthetist, 1 gn. per session.
 Sheffield Children's Hospital.—3rd Res. M.O. £100.
 Sheffield, Jessop Hospital for Women.—3 Asst. H.S.'s. Each at rate of £100.
 Sheffield Royal Hospital.—Res. Anaesthetist. At rate of £80.
 Sheffield Royal Infirmary.—H.P., H.S., Ophth. H.S., Asst. Aural and Ophth. H.S. Also Asst. Cas. O. All at rate of £80.
 South-Eastern Hospital for Children, Sydenham, S.E.—Two Res. M.O.'s. At rate of £100 and £75 respectively.
 Southampton Free Eye Hospital.—H.S. £150.
 South Shields, Ingham Infirmary.—Sen. and Jun. H.S.'s. £200 and £150 respectively.
 Stafford, County Bacteriological Laboratory.—Locum Tenens Bacteriologist. 12 gns. weekly.
 Stockport Infirmary.—Visiting Asst. Ophth. Surgeon for Eye Dept.
 Sunderland, Durham County and Sunderland Eye Infirmary.—Locum.
 Surrey County Council.—Asst. M.O. £600.
 Swansea County Borough.—Asst. M.O. £600.
 Truro, Royal Cornwall Infirmary.—H.S. £170.
 Victoria Hospital for Children, Tile-street, Chelsea, S.W.—H.P. and H.S. Each at rate of £100.
 Wallacey, Victoria Central Hospital.—Jun. H.S. At rate of £100.
 Walsall General Hospital.—Cas. H.S. At rate of £120.
 West African Medical Staff.—M.O.'s. Each £660.
 West London Hospital, Hammersmith-road, W.—Two Clin. Assistts. Res. Asst. Phys. £300.
 Wigan Royal Infirmary.—Res. Med. and Surg. O. and Reg. £250. Also Two H.S.'s. Each at rate of £150.
 Willesden General Hospital, N.W.—Res. H.S. £110.
 Windsor, King Edward VII. Hospital.—H.S. At rate of £100.
 York County Hospital.—Res. Anaesthetist. £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Cupar (Fifehire), and Tonbridge (Kent).

Births, Marriages, and Deaths.

BIRTHS.

EAST.—On June 8th, in London, the wife of C. F. Terence East, M.D., F.R.C.P., of a daughter (stillborn).
 HAWKINS.—On June 9th, the wife of B. E. Hawkins, M.R.C.S., of a son.
 PEYTON.—On June 13th, at 19, Bentinck-street, W., the wife of Dr. Peyton, Harley-street, of a daughter.
 RAMMELL.—On June 13th, at Brickett House, St. Albans, the wife of Dr. John Wootton Rammell, M.C., of a son.
 REYNELL.—On June 10th, at 26, Nottingham-place, W., the wife of W. R. Reynell, M.D., of a son.

MARRIAGES.

ANDERSON—SINCLAIR-MACLAGAN.—On June 11th, at St. Mary's Episcopal Church, Kiriemuir, John Anderson, D.S.O., F.R.C.S., to Isobel Sinclair MacLagan, only daughter of Major-Gen. E. G. Sinclair-MacLagan.
 BUCKTON—MEZ.—On June 11th, in Basel, Philip Rhoades Buckton, M.A., M.B., of Wymondham, Norfolk, to Annemarie Charlotte, only daughter of the late Professor Mez, of Basel University, and of Mrs. Mez.
 DODD—OPENSHAW.—On June 14th, at St. Andrew's Church, Kensington, Harold Dodd, F.R.C.S., of Harley-street, to Kathleen Openshaw, of Madge Hill, Hanwell.
 MACAfee—LOWRY.—On June 4th, at Newtownbreda Presbyterian Church, Charles Horner Greer Macafee, M.B., F.R.C.S. (Eng. and I.), to Margaret Crymble, only daughter of Prof. C. G. Lowry, M.D., F.R.C.S., and Mrs. Lowry.
 WATSON JONES—COOK.—On June 11th, at Princes-gate Baptist Church, Liverpool, Reginald Watson Jones, M.Ch., F.R.C.S., to Muriel, only daughter of Mr. and Mrs. C. W. Cook, of Mossley Hill, Liverpool.
 WILLIAMS—COURON.—On June 12th, at the Oratory, Brompton, Dr. Leslie Williams, M.D., M.S., F.R.C.S., to Patrice, elder daughter of the late Mr. and Mrs. Hatton Ronayne Couron, of Mayfield, Sussex.

DEATHS.

DODD.—On June 11th, Col. John Richard Dodd, A.M.S., retired, of Killarney, Richmond Park-road, Bournemouth.
 MINCHIN.—On June 5th, in London, Edward James Minchin, L.R.C.S.I., L.R.C.P.I., in his 75th year.
 SKIRVING.—On June 14th, at 6, Rothesay-place, Edinburgh, Archibald Adam Scot Skirving, C.M.G., F.R.C.S.E., aged 61.
 WHITFOUR.—On June 15th, at 26, Sandymount-drive, New Brighton, William Whitfour, M.D., J.P., in his 86th year.

N.B.—A fee of 1s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Notes, Comments, and Abstracts.

STERILISATION OF THE UNFIT.

A Report to the Lancashire Asylums Board

By FRANK A. GILL, M.D. ABERD.

MEDICAL SUPERINTENDENT OF THE CALDERSTONES CERTIFIED INSTITUTION FOR MENTAL DEFECTIVES, WHALLEY.

STERILISATION by castration has been known and practised as early as there are historical records. Unrestrained by public opinion which was, no doubt, dealt with by equally drastic means, our ancestors were actuated by a certain clarity of purpose which left no room for scruples or sentiment. For the creation of eunuchs, as a punishment for crime, and as a deterrent for prostitution, it was undoubtedly practised, but there is only legendary evidence that it was ever enforced for the improvement of the human race. Eugenic sterilisation, as it is called, is a modern practice which has met with a large measure of approval in California, and to a less extent in other American States, and elsewhere.

Historical.

Sterilisation for race improvement was first advocated towards the end of the eighteenth century, and again in the latter half of the nineteenth century public interest was aroused and discussions appeared in a few medical journals. The first actual operations, so far as I am aware, were performed without legal sanction in Kansas, U.S.A., towards the end of the last century. Legislation authorising it was first passed in Pennsylvania in 1905 and next in Indiana in 1907. A few other States in U.S.A. followed their example, but the practice fell into disuse from lack of public support, and at a later date it was declared unconstitutional and illegal. It was declared unconstitutional, as the law was made applicable to criminals and held to be a "cruel and unusual" form of punishment and, therefore, contrary to the Constitution.

More recently the sterilisation law in U.S.A. has been amended and declared constitutional, with the result that up to July 1st, 1929, the following 22 States have passed laws sanctioning its practice: Arizona, California, Connecticut, Delaware, Idaho, Iowa, Kansas, Maine, Michigan, Minnesota, Mississippi, Montana, Nebraska, New Hampshire, North Dakota, Oregon, South Dakota, Utah, Virginia, Washington, West Virginia, Wisconsin. In Canada, the Province of Alberta has legalised voluntary sterilisation of certain inmates of institutions, and British Columbia is investigating the question.

The Canton of Vaud, Switzerland, last year passed a law prescribing compulsory sterilisation for certain patients. In Germany discussion has been active, and the law seems to permit sterilisation of the unfit, when done with the consent of the patient, or near relative, or guardian. It has been recommended to the New Zealand Parliament, after consideration by an Official Committee.

The Operation.

The surgical operation in both sexes is eminently satisfactory, the danger to life is practically nil, and very few failures are recorded. In the male vasectomy is performed, a section of the cord is removed, and the cut ends tied. It can be done under a local anæsthetic and does not incapacitate the patient for work for more than one day. In the female the abdomen is opened under a general anæsthetic and a section cut from both Fallopian tubes. It involves 14 days in bed, but the danger to life is negligible. In over 2500 operations in the California State hospitals there have been only three deaths, one from anæsthetic and two from infection. Sterilisation by X ray and radium has been considered, but is of doubtful merit, both these agents being too uncertain in their action and not without risk. No doubt in course of time, as their properties are better known, they may become a valuable means of producing eugenic sterilisation without operation and without risk.

Californian Experience.

While many of the States of U.S.A. have laws permitting at the State's expense the sterilisation of mental defectives and insane patients, the Californian law makes it compulsory before discharge from certain institutions. Up till Jan. 1st, 1929, 6255 operations for sterilisation have been performed in this State, the operations being vasectomy or salpingectomy, no glands or organs are removed, and no adverse effects as a sequence are recorded. Sexual life and

reports from California indicate no increase of immorality, though they do not claim any improvement as a sequence. It is interesting to note that in the Californian experiment 125 feeble-minded sterilised women were married with the consent of the authorities, and the marriage has been considered successful in two-thirds of the cases. A second argument by opponents of sterilisation is the probability that public opinion may seize on sterilisation as a cheap and economic remedy for dealing with the problem of the unfit and so cease to make adequate provision in the way of institutions and hospitals. If the problem of the unfit is properly understood this seems to me a futile argument.

Conclusions.

My own view is that: (1) Sterilisation of either sex is a safe and efficient operation. (2) A policy of wholesale sterilisation of the mentally unfit is neither necessary nor desirable. (3) Sterilisation of selected cases of both sexes is desirable before release from mental defective institutions. (4) Certifiable women who become pregnant or are immoral should be sterilised forthwith. (5) Sterilisation of the recurrent insane is desirable and justifiable both in the interests of the race and as a therapeutical measure which relieves them of the anxiety of child-bearing and maintaining a family.

THE SUPPLY OF PASTEURISED MILK.

TWENTY years ago the passage of milk from the cow to the consumer was a comparatively calm one. A conscientious dairymen might occasionally take a sample to a vacant corner of his premises, estimate the fat content by the depth of the cream line, the cleanliness by the colour, and the quality by taste, but even so short a time ago as this there was almost no scientific investigation. To-day the passage is stormy. The milk sold by United Dairies, Ltd., is tested chemically and bacteriologically at the rural centre, at the urban distributing centre, and at any time of the day or night and in any part of its journey by a "flying squad." It is collected and transmitted with close attention to cleanliness and temperature, and is distributed in special bottles, which are soaked and washed for 40 minutes, and then rinsed with Czapevski's fuchsin to make sure that no film of dirt remains.

At the opening of the company's new research laboratories by Sir Andrew Balfour, on June 10th, the guests were shown the whole process of milk collection and distribution at the large central depot in Willesden. No less than 50,000 gallons, or 1200 tons, are handled here daily, and over 500 samples are examined in 21 laboratories in London every day. From the small lorries which collect it from the farms the milk is transferred to glass-lined tanks, where it is kept at a temperature below 40° F. throughout the rest of its journey. It is pasteurised at the London depot at a temperature of 145° F., and then bottled. Over 8,000,000 bottles are distributed every week, and the organisation employs a staff of 12,000 men and women.

In the laboratories the milk is tested for contamination and the fat percentage by chemical methods, and for its general bacterial content by the reductase test with methylene blue. A recent introduction of the microscopic lantern, through which milk samples magnified 225,000 times are projected on to a screen and bacteria are thus revealed. In practice it is found that the result of a test depends on the level from which the sample is taken in the churn. As an example may be cited one specimen of milk which revealed 400,000 organisms per cubic centimetre and the presence of *Bacillus coli* in one-hundredth when the sample was taken from the top of the churn with a dipper. When the same milk was properly mixed in the churn, the bacterial count was reduced to 40,000, and no *B. coli* were found. The suggestion is made that chemical tests should be done at the same time as bacteriological, for if a fat percentage of over six, for instance, is discovered, it will be obvious that the sample is not a representative one.

All the United Dairies' milk is pasteurised. Their authorities hold that the tuberculin test for cattle is not sufficiently reliable, either in a negative or a positive sense, and that pasteurisation is the only way to avoid the risk of the tubercle bacillus in the milk. Moreover, partial sterilisation covers also the risk of infection from an unhealthy dairymen. In support of their policy they say that if vitamin C is destroyed, it is very easily added in a teaspoonful of fruit juice, and there is considerable evidence to show that the milk of stall-fed cattle does not contain this vitamin in any case. Pasteurisation, it is stated, causes no radical chemical change, and the small amount of calcium that is rendered non-dialysable is unlikely to make any great difference to the human child, considering that the cow's milk is intended for an animal with much larger and heavier bones.

An interesting piece of research has recently been carried out on thermophilic organisms in milk. These were first discovered as a result of a breakdown in the plant. If the machinery stands still for a time at pasteurisation temperature these organisms multiply and form acid. They are non-pathogenic; some are spore-formers and protein-splitters, others are vegetating, non-sporulating lactobacilli, which produce large quantities of lactic acid. The important practical point about them is that the Ministry of Health tests are all based on a temperature of 98° F., and the difference of a degree or so in the temperature might permit the multiplication of the thermophile group. The result would be a high bacterial count, and a quite false suggestion that the milk was unhygienically collected. The organisms are present in all raw milk, but they are depressed or attenuated by refrigeration. To destroy them the milk should be kept at 33° F. for 44 hours. Hence the lowered temperature in the glass travelling-tanks, and hence also the practice of shutting down and sterilising the pasteurisation plant every five hours.

In declaring the new laboratories open Sir Andrew Balfour said that the United Dairies had helped the rural medical officer by clean milk competitions in young farmers' clubs, and had done a public service by transferring a large part of the milk supply of the metropolis from the open can to the sterile bottle.

ACCEPTABLE ADVERTISING.

THE wealth of faultily addressed and unattractive material which reaches the average practitioner is not merely irritating but absurdly wasteful, since as often as not it is discarded without examination. The Addressing Company, of 8, Stone Buildings, Lincoln's Inn, London, W.C. 2, has made an attempt to remedy the present casual methods of commercial firms, and undertakes to circularise the medical profession as a whole, or specified groups of members in a manner which shall be accurate and acceptable. The chief points for which the company claims credit are absolute propriety of address, with accurate qualifications and postal direction, and the distribution of ethical material only, following the standard set by the medical journals. The service includes, in addition to the British Isles, the greater part of the Empire. A daily corrections service undertakes to supply to those firms who undertake their own addressing information of changes of address, new degrees and qualifications, and changes of name by marriage. The service can obviously perform a useful function in the prevention of waste by the manufacturer and annoyance to the recipient.

BLOOD GROUPS AND THE SCHICK REACTION.

The relation of the various blood groups to the Schick diphtheria reaction has been studied by Dr. J. E. Sola,¹ who reports the results of observations on 17 families with 45 children. The conclusions at which he arrives are briefly: that blood grouping is transmitted hereditarily on Mendelian lines, and that the Schick reaction may be found indifferently in any group. If both parents give a positive reaction all the children do the same, supposing their blood groups are the same, and this is also true of a negative reaction; but if the group varies, or there is recessivity amongst the children, the correspondence breaks down. Susceptibility to diphtheria as regards parents and children depends on their both belonging to the same blood group, hence, in Sola's opinion, it is probably due to an hereditary constitutional factor and not to transmitted acquired immunity. The results of the Schick reaction on parents and offspring were held to show that susceptibility to diphtheria is transmitted on Mendelian lines. The conclusions are interesting, but Sola admits that the numbers investigated are small, partly because of the difficulty of getting whole families to consent.

A PANEL OF TRANSLATORS.

THOSE who require the services of a translator often have difficulty in finding one who has both a knowledge of the language and also of the special subject concerned, and the difficulty increases where the language is uncommon and the subject highly technical. In order to meet this need the Association of Special Libraries and Information Bureaux (20, Bedford-square, London, W.C.) has prepared a scheme for establishing a panel of translators having both linguistic and technical qualifications, the part taken by the association being to act as a connecting link between the translator and the user. Names of approved qualified persons are now being registered, and those who are interested, in either capacity, are invited to write for particulars to the secretary of the association.

Hunterian Lecture

ON THE

PAPILLOMA AND ITS MENACE.

Delivered before the Royal College of Surgeons of England on Jan. 31st, 1930,

By W. SAMPSON HANDLEY, M.S. LOND.,

FELLOW AND COUNCILLOR OF THE COLLEGE; SENIOR SURGEON TO THE MIDDLESEX HOSPITAL.

THOUGH the subject of this lecture has never been entirely divorced from surgery it has been in the main handed over to the special attention of dermatologists. My reasons for choosing it are several. In the first place, I believe that the accepted theories of the pathogenesis of warts are superficial and unsatisfactory, owing to their neglect of certain basic facts in the minute anatomy of the skin and mucous membranes. In the second place, warts are not confined to the skin. Essentially similar neoplasms, described as adenomata or papillary adenomata or papillomata, are found not only upon the mucous membranes but also in the mucous lining of the narrow excretory ducts, even in channels so narrow that the full morphological development of a papilloma is impossible. These internal warts are of much greater frequency and importance than the warts of cutaneous origin. The subject, then, is a wide one, and concerns the pathology of many of the internal organs. Its main interest, however, lies in this: that recent work by many investigators has shown with continually increasing emphasis the closeness of the relationship between papilloma and carcinoma. The papilloma, though it may remain innocent for many years, would appear on the evidence to be a precancerous phenomenon. The connexion may be obscured by the slow *adagio* of the processes which intervene. The first part of my lecture will be occupied in establishing the relationship between papilloma (or adenoma) and malignancy in particular varieties of cancer. In so doing I will give only a brief outline, with special attention to the more recent work.

A REGIONAL SURVEY.

Tongue.—Leukoplakia, which is a state of papillomatous hyperplasia, precedes cancer of the tongue in three cases out of ten. At the margin of a tongue cancer papillary hypertrophy can generally be recognised.

Larynx.—It is the rule for laryngeal cancer to begin as a papilloma, as in the classical case of the Emperor Frederick.

Stomach.—An association between polypi of the stomach and carcinoma has long been suspected. Cruveilhier (1835-42), quoted by M. J. Stewart, figured an example of multiple gastric polypi in his atlas, and thought that cancers of the pylorus not infrequently originated in such polypi. P. Menetrier and Clunet emphasised this view. H. Brunn and F. Pearl (1926) collected 84 cases of diffuse polyposis of the stomach, of which ten (12 per cent.) were malignant. G. A. Mills (1922-23) found malignancy in four out of twenty cases of diffuse gastric polyposis. Prof. Stewart, of Leeds, from whose paper¹ I have abstracted the early history of the subject, has recently placed the precancerous quality of gastric polypi beyond cavil or question. Among 11,000 necropsies performed at the Leeds Infirmary between 1910 and 1928 he found 47 cases in which gastric polypi were present; single in 27 cases, numerous in 10 cases, and few in number in 10 cases. In six of the cases where a single polyip was present, and in seven of the cases of multiple polypi, carcinoma was also present. In three cases it could be said with certainty that the carcinoma had originated in a polyip, and in no case could such an origin be excluded. Thus in 28 per cent. of cases of polyposis

of the stomach a carcinoma is also present. Prof. Stewart says the association of these conditions in the stomach is much less intimate than in the large intestine, but it appears to me not less decisive and unmistakable.

As Prof. Stewart insists, these ostensibly harmless growths have a sinister significance. Do most gastric cancers originate in adenomata? In the 11,000 cases reviewed by Prof. Stewart there were 263 cases of cancer of the stomach, but only 47 of gastric polypi. This fact might appear to relegate polyposis to a minor rôle in the production of cancer, as compared with chronic ulcer. But it must be remembered that in the bowel, and possibly also in the stomach, carcinoma tends as it grows to destroy the evidence of its origin. The margin of a chronic ulcer of the stomach, as of the leg, is exactly the site in which a local septic lymphangitis must frequently produce papillomatous hypertrophy. It must also be remembered that in the bowel, at any rate, as J. P. Lockhart-Mummery and C. E. Dukes have shown, the evolution of a carcinoma is accompanied by the disappearance of papillomata in adjoining parts of the mucosa. In the breast, as I shall show, a papilloma only just visible to the naked eye may have already become a carcinoma. Until a practical gastroscope is evolved it is unlikely that such evidence will be obtainable in stomach cancer. But the assumption that all gastric cancers originate in adenomata contradicts no fact at present known. Hauser,² in 20 cases of stomach cancer, found one which was associated with polypoid overgrowth and five which had arisen from chronic ulcer. Polypoid overgrowths were thus found in only 3.5 per cent. of stomach cancers, while they were present in 20.8 per cent. of cancers in the large bowel. But Hauser finds that all forms of cylindrical cancer arise from adenomatous gland proliferation, which is at first simple in character, and presents itself as a small rounded thickening of the mucosa not much raised above the level of the surrounding mucosa and with a slightly uneven or warty surface. The adenoma is at first not ulcerated. Hauser describes these adenomatous changes as sometimes found in a high degree at the margin of chronic ulcers. There is evidently no essential difference between these flat areas of adenomatous proliferation and the stalked adenomata of similar structure, though the former may escape the observation of the naked eye. The edge and not the floor of a chronic ulcer is the part in which cancer arises, and the ulcer leads to cancer because it favours the production at its edge of adenomatous proliferation of the mucosa. I shall later suggest how gastric ulceration produces these precancerous adenomatous changes at its margin.

When it is remembered how small an adenoma may give rise to cancer and how rare are the opportunities of examining early gastric cancer, and when Hauser's observations on the adenomatous changes round chronic gastric ulcers are taken into account, there seems no difficulty in accepting the view that gastric cancer always begins as an adenoma strictly comparable with the warty growths seen on the skin in lupus or around a chronic ulcer of the leg. Konjetzny states that chronic polypoid gastritis precedes most cases of gastric cancer. P. Menetrier, after prolonged researches on the origin of stomach cancer, states that the sequence: chronic gastritis—adenoma—cancer is a constant one, and firmly believes that "cancer is a transformed adenoma; it succeeds to the adenoma and takes its place." I think we must accept this conclusion. He goes on:

"What we have said about the formation of cancer in the gastric mucosa, we could repeat for the liver, the kidneys, the uterus, the skin and its glands, the breast, and for all epithelial organs and tissues. . . . but we have gone more into detail concerning gastric neoplasia because it was the subject of our particular study, and because the stomach lends itself better than any other organ to this kind of demonstration."

Small Intestine.—This part of the intestine, by its high absorptive power, is subject in a maximal degree

¹ The Relation of Malignant Disease to Benign Tumours of the Intestinal Tract, Brit. Med. Jour., 1929, ii., 561.

² Das chronische magengeschwür, Leipzig, 1933.

to irritations arising from food products, yet is almost immune to carcinoma except at its lower end. I want to associate this fact with the unique activity of lymphatic absorption in this part of the intestine, a physiological fact which surgeons can frequently verify during laparotomies when they see the white lines of the lacteals. It can hardly be an accident that where the lymph circulation is at its maximum the incidence of carcinoma is minimal. The converse of this proposition is my theme to-night.

Large Intestine.—It has long been known that intestinal polyposis, in which multiple-stalked adenomata are found along the large bowel, is a familial disease the tendency to which is strongly hereditary. Lockhart-Mummery, Jüngling, and others have published striking family histories, covering several generations. Its connexion with malignant disease of the bowel is so close that Lockhart-Mummery states that he has never known a case which did not develop malignant disease. In one family, he records, seven out of nine children of a father who had cancer of the bowel also died of cancer of the bowel between the ages of 30 and 54. A grand-daughter at the age of 31 submitted to complete colostomy for multiple polypi. Intestinal polyposis appears to be a rare disease, while cancer of the rectum is a relatively common one. Nevertheless Lockhart-Mummery suggests it as possible that all cancers of the bowel arise in a polypus. "A careful examination of specimens of cancer of the rectum shows that in quite a number part of the tumour is a simple non-malignant adenoma, though the remainder may be typical adenocarcinoma."³

It must not be forgotten that a single very small polypus or flat adenoma may form the basis of a carcinoma of the bowel. On two occasions I have seen a tiny polypus appear at the margin of a colostomy opening. In the first case I left the polypus alone, and when I saw the patient again, some months later, carcinomatous stricture of the colostomy had developed. In the second case I excised the polyp a few weeks after it first appeared. It was already becoming broad-based and indurated, and on section, though only $\frac{1}{4}$ in. in diameter, it was an early carcinoma.

Dukes has investigated the frequency of coincident papillomata in a series of 75 specimens of cancer of the rectum, dividing the cases into three classes: (a) sub-mucosa only infiltrated; (b) muscular coat infiltrated; (c) the perirectal tissues infiltrated. Class A contained one case, which was associated with papillomata, Class B contained 18 cases, nine of which were associated with papillomata. Class C contained 56 cases, of which 17 were associated with papillomata. For the early, intermediate, and late cases the respective percentages were 100, 50, and 30. Thus papillomata are commoner in the early than in the late stage of rectal cancer, and are not a secondary product of the irritant discharges of the growth. Furthermore, according to Dukes, these facts indicate that soon after a carcinoma originates, papillomata in its neighbourhood tend to atrophy and disappear under some obscure process of immunisation.⁴ Dukes has furthermore clearly shown that carcinomatous degeneration may occur in very small polypi. The change appears to begin at the free end of the polyp. W. Susman, of Manchester, among 883 necropsies, found 38 cases (4.3 per cent.) of polypi of the colon. Polypi were associated with gastro-intestinal cancer in 14 of these cases, with cancer elsewhere in three cases. Carcinoma of polypi of the colon was observed in four instances of multiple polyposis. In Dr. Susman's opinion there is a common cause for gastro-intestinal cancer and polypi.⁵

Breast.—Sir Lenthal Cheate, by patient and accurate work with a giant microtome for cutting sections of the whole breast, has placed our knowledge of precancerous conditions of the breast epithelium upon a secure footing. He shows that these changes

are often confined to one particular lobe of the breast, a fact suggesting the intrusion of some extrinsic agent such as a parasite or bacterium, and furthermore that they affect mainly the small ducts just before they open into the acini. He divides epithelial hyperplasia as seen in the breast into two varieties, desquamative and dysgenetic, and he appears to regard the first variety as the precursor of the second. In desquamative hyperplasia the cells are cast off into the interior of the ducts and the process does not appear to merit the term hyperplasia, but is rather a catarrh with retained products—probably, I suggest, due to bacterial infections along the ducts, and comparable to catarrh of the uterine cervix or of the nose. The "dysgenetic" hyperplasia of Cheate may be less equivocally described as a papillomatous hyperplasia. In it three stages are seen:—

1. The individual cells remain normal but papillomata are produced within the acini and terminal ducts. The acini are never thus affected alone.

2. The individual cells show the signs of incipient malignancy (hyperchromatosis, variation in size, mitosis).

3. Infiltration of the tissue around the ducts and acini by the altered epithelium is beginning.

Clinical carcinoma and precancerous papillomatous hyperplasia were frequently found in the same breast. Cheate points out the exact analogy of these processes with the changes seen in experimental tar carcinoma. In a case of tar carcinoma with papilloma formation but without infiltration, Dr. J. A. Murray inoculated the epithelium of the papilloma at a fresh site and produced a growth which metastasised. Cheate infers by analogy, and rightly I think, that in the second stage of the hyperplasia in the breast the epithelium of the papilloma is essentially malignant, though it has not found an opportunity to infiltrate.

It is possible, I find, to distinguish the simple from the malignant papilloma of the breast, not only by the character of the individual cells but by the picture presented by the papilloma itself. In the simple papilloma the pattern is regular and the vascular core, though branched and complicated, is easily traceable in continuity, and is covered by a regular and usually one-layered epithelium. In the following two cases I was able to demonstrate the occurrence of carcinomatous degeneration in a duct papilloma which had apparently only existed for a very short time. In the first case at the time of the operation the papilloma was affected by carcinoma, but the disease had not yet attacked the tissues of the patient herself.

CASE 1.—A married woman, aged 70, noticed a serous discharge from the left nipple a week before she was first seen on June 12th, 1928. The breast was normal on palpation except that, vertically half an inch below the left nipple, a tiny very superficial shot-like swelling could be felt. Pressure at this point made fluid exude from the nipple. No other nipple changes were found. There were no glands in the axilla. On June 15th, 1928, this lump was cut down upon, two dilated ducts were exposed, divided close to the nipple surface, and then again divided where they began to ramify in the breast substance. On section of the excised portion across the ducts a small papilloma, just visible to the naked eye and perhaps one-fiftieth of an inch in diameter, was found within the duct, attached to it by a slender pedicle. A section across the tissue showed that this minute and early morphological papilloma had already become a carcinoma within its own substance. The fibrous tissue of its core was infiltrated with carcinoma cells, though there was no evidence that the physiological tissues of the patient had been attacked by the disease. The pedicle of the papilloma, fortunately included in the section, was composed of fibrous tissue only, and showed no infiltration.⁶ An indication of the pathogenesis of the papilloma was, however, given upon examination of the pedicle. It showed several cylindrical groups of round-celled infiltration, some cut as circles, others as ovals. In company with one of the groups was a small artery. These are exactly the appearances given by blocked lymphatics which have lost their lumen by proliferation of their endothelium, as I know from my experience of lupus and elephantiasis. In other words, the patient had suffered from a chronic lymphangitis of the tissues of the breast, and it appears

³ THE LANCET, 1925, i., 427.

⁴ Brit. Med. Jour., 1929, ii., 196.

⁵ Ibid., 1929, ii., 196.

⁶ Illustrations of this growth will be found in my article on Lymph Stasis the Precursor of Cancer; Brit. Med. Jour., Oct. 5th, 1929.

highly probable that the resulting lymph stasis was the cause of the papilloma which so rapidly developed into a potential carcinoma.

CASE 2.—Aged only 38, a married woman with two children, the younger aged 4, and neither of them breast-fed, noticed a tiny lump just to the inner side of the right nipple; she remembered having felt a pain in this situation a year previously. Two months after its appearance the lump was excised by Dr. H. Simmons, of Bournemouth. It was as large as a small pea, and felt hard. Its wall was rather thick, and it contained two drops of fluid. A section showed a tiny group of papillomata springing from the wall and projecting into the cyst, which had the characters of a dilated duct. The papilloma group had an irregular and confused structure, and was composed mainly of epithelium. The fusion of two or more papillomata to form it was indicated by the presence of several distinct pedicles (Fig. 1). The erosive power of the papilloma is seen at C, where it has partly penetrated the epithelial lining of the duct, and at D, where the same process is complete. The point C is represented under a high power in Fig. 2, and at A in that figure the epithelium of the papilloma has begun to fuse with the epithelium lining the duct. At E in Fig. 1, incipient papillomata are seen, and at B in the same figure the epithelial lining of the duct is infiltrating the underlying connective tissue. B is represented under a high power in Fig. 3, where F marks the limit of the epithelial infiltration.

This early carcinoma, for as such it must be classified, was about two months old. Infiltration was present outside the wall of the duct at one point. The papilloma group showed its essential malignancy by (1) interfusion of adjoining papillomata; (2) infiltration of the vascular core of the papilloma by epithelium; (3) erosive action of the epithelium of the papilloma on the epithelium of the wall of the duct; (4) a simultaneous process of fusion of the two epithelia, and (5) hyperchromatosis and irregularity in size of the epithelial cells.

These two carcinomas are probably among the earliest ever removed at operation. Each was characterised clinically by a tiny mobile lump, unaccompanied by any other sign of cancer. The

FIG. 1.

Case 2.—Incipient malignancy in a group of papillomata lying within a duct of the breast.

first patient, however, had hemorrhage from the nipple. In the first case the carcinoma affected the papilloma only and had not attacked the tissues of the patient. The second case is a slightly later phase. The only rarity in these two cases consists in their very early detection and removal. They illustrate well the difficulty of early diagnosis in cancer of the breast, and the origin of the disease in duct papilloma of the large ducts. As Cheate has shown, it is more common for papilloma to start in the small ducts near the glandular acini. I may add that the first patient remains well two years after operation.

Lupus Carcinoma.—Lupus carcinoma was first recorded by Devergie in 1857, long before the discovery of X rays, and I have seen at least three cases which had never been subjected to radiation. The disease is not very rare, for K. Asihara was able to collect 122

FIG. 2.

Penetration of the wall of the duct by the papilloma seen at C in Fig. 1. ($\times 440$.)

cases. Persistent X ray treatment may no doubt accelerate its onset. In a case recently under my care a lupus carcinoma of the left cheek was associated with an innocent wart on the right cheek. The non-ulcerative forms of lupus usually show papillary hypertrophy, and when this is marked the name lupus verrucosus becomes appropriate. It seems probable that all lupus carcinomas originate in areas of papillary hypertrophy.

Carcinoma of Chronic Ulcers.—Carcinoma may arise upon the margin of an old chronic ulcer of the leg. The neoplasm is preceded by chronic thickening and warty hypertrophy of the surrounding skin. The papillomatosis may reach an extreme degree, as in a case recently published by W. Donald Bedford.¹ In this case the ulcer had been present for 25 years, and the papillomata presented no definite sign of malignancy.

Thyroid.—During the last few years brilliant work upon the thyroid gland and its relations to the lymphatic system has been done in this college, on the side of comparative anatomy by the physiological curator Mr. R. H. Burne, and on the side of pathology by Dr. G. Scott Williamson and Miss I. H. Pearce, whose studies have illustrated once more the unexhausted possibilities of morbid histology. They have shown that multiple adenomatosis of the thyroid, a condition which they prefer to call simple hyperplastic goitre, occur as the result of a process of focal perilobular fibrosis. I believe this term to be an alias for chronic lymphangitis. These adenomata present the appearances of a simple local hypertrophy of the gland tissue, and are a reaction against the lowering of the thyroid function which the fibrosis produces. This form of thyroid enlargement is the one particularly liable to lead to malignant disease. In four out of 20 such cases in Williamson's experience removal of part of the goitre was followed by cancer

¹ Brit. Med. Jour., 1929, II., 1108.

of the adenopapilliferous type. "In three other cases the central lobules . . . showed changes quite indistinguishable from adenopapillomata."⁸ The author goes on to state that in the thyroid the adenopapilloma and papilliferous carcinoma resulting therefrom are analogous to the similar growths seen

FIG. 3.

Represents the region AB in Fig. 1 under a high power, and shows infiltration beginning at the base of the papilloma. ($\times 440$.)

in the breast, prostate, ovary, and other organs. The scirrhus form of cancer is relatively rare.

The evidence for the onset of thyroid carcinoma from papilloma thus appears to be convincing. Even the scirrhus forms may have such an origin. I may remark in passing that the cramped conditions under which the thyroid adenomata grow are ideal for the aggravation of local lymphatic obstruction.

Occupational Cancer.—Percival Pott, who described sweep's cancer of the scrotum 150 years ago and thus laid the foundation of our knowledge that cancer is at first a local disease, pointed out that the malignant growth originates in a simple wart. Leitch, who has specially studied occupational cancer and who detected the action of the sebaceous secretion of the scrotum in dissolving an active agent from the soot particles, points out that the kangri cancer of Kashmir, the cancer of the cheek and gums which results from the habit of chewing betel-nut, arsenic cancer, and aniline cancer of the bladder, are all associated with preceding papillomatous formations.⁹

PAPILLOMA AND EXPERIMENTAL CANCER.

Fibiger, in 1913, showed that a squamous carcinoma of the stomach could be produced by feeding rats with cockroaches infected by a certain nematode worm. This form of cancer is called *spiroptera* cancer. He says: "The disease consists in its initial stage of epithelial hyperplasia and inflammation. In more advanced cases papilloma formation supervenes; it may reach a colossal development, and may fill up the whole cavity of the stomach. This may be the precursor of a malignant epithelioma with invasive heterotopic growth of epithelium. Metastases may occur, in which no parasites or eggs were found." The thread-like worms are found burrowing in the epithelial layer, and Fibiger lays no stress on the changes found in the submucosa. Nevertheless, he

says: "everywhere in the submucosa inflammatory appearances were seen in a greater or less degree." Examination of his photographs shows, below the epithelium in the superficial part of the submucosa, a band of round-celled inflammation which in my opinion indicates a lymphangitis, and this opinion is confirmed by the gigantic papillary hypertrophy, a clear indication of lymphatic obstruction. The rôle of the *spiroptera*, burrowing about in the epithelium, is exactly comparable to that of the infected needle, which may set up an acute or chronic lymphangitis. But neither in the *spiroptera* nor in the bacterial parasites it carries is there any specific carcinogenic agent. The specific factor, as I shall endeavour to show, is the resultant lymphatic obstruction.

The evidence that a papilloma or an adenoma is a very frequent precursor of cancer could be multiplied, if time allowed, by the consideration of other forms of cancer. There is, however, an earlier stage in the cancer process which we must now consider briefly.

Pre-Cancerous Inflammatory Changes in the Sub-Epithelial Tissues.—There is abundant evidence that the epithelial proliferation characteristic of carcinoma is preceded by chronic inflammatory changes of ancient date in the underlying connective tissue. Such is the testimony of Waldeyer, Ribbert, Bornmann, Menetrier and, in this country, of my colleague, Victor Bonney,¹⁰ who made a close study of the connective tissues in carcinoma. As Bonney says, the hypertrophy of the epithelium only develops after the sub-epithelial changes are established, and these changes are invariably characterised by increased cellularity. Billroth said: "Without previous chronic inflammation, cancer does not exist." These changes, it should be noted, precede papillomatosis. They must be significant. Their occurrence has remained a basic but isolated fact not related intelligibly to the rest of the story. Some observers, especially Lenthal Cheate, have minimised their importance. I want to suggest that they are the result of long-standing local chronic lymphangitis, a process which in elephantiasis produces extreme hypertrophic changes in the connective tissues, associated with papillomatosis.

PATHOLOGY OF THE PAPILLOMA.

If a papilloma is a very frequent forerunner of cancer a study of the pathology of the papilloma may be one line of approach to the most important and baffling problem of pathology, the origin of cancer, a problem which has hitherto defied all attacks. The genesis of a papilloma cannot be understood without a knowledge of the lymphatic arrangements of the skin. Some years ago, in the course of a lecture on lupus, I showed in this theatre a scheme of the arrangement of the lymph vessels of the skin, which I had inferred partly from my own direct lymphatic injections but mainly from a study of the skin lymphatics as mapped out by lupus or malignant disease. The main facts demonstrated were that the axis of each papilla of the skin is occupied by a central lymphatic vessel terminating blindly towards the apex of the papilla, but joining below its base with four or five more similar lymphatics from adjacent papillae as the fingers join the hand to form a single vessel. By the union of a group of these vessels in the superficial third of the thickness of the dermis, horizontally running lymphatics are formed which, uniting by groups and changing their direction, pierce the deeper layers of the dermis, again unite by groups in the subcutaneous fat, and run vertically through the fat to join the fascial lymphatic plexus (Fig. 4).

It is a satisfaction to me this evening that I can place before you independent evidence of the broad truth of this description of the skin lymphatics. Prof. D. T. Harris, of University College, drew my attention to a specimen of skin, showing the lymphatics injected, presented many years ago to the Museum by Prof. Hyrtl, of Vienna. The specimen attracted

⁸ Jour. Path. and Bact., 1925, xxviii.

⁹ Cancer Control: Report of Lake Mohonk Symposium, 1927, p. 208.

¹⁰ Arch. of the Middlesex Hosp., 1908, xlii.

no particular attention, though it is a beautiful example of the "lost" art of lymphatic injection, and so far as I know Hyrtl never published a description of the minute lymphatics of the skin. It confirms in all important particulars the description of the skin lymphatics which I gave in 1921, and places the minute lymphatic anatomy of the skin upon an unassailable basis. The entire pathology of diseases of the skin will require reconsideration in the light of this specimen (Fig. 5).

Each papilla of the skin is provided with a separate drainage system, and the lymphatic vessel lies in the axis of the papilla but is always separated from the overlying epithelium by a thin layer of connective tissue. Furthermore, if the fibrous layer of the skin is considered, nearly all the lymphatic vessels are found in its superficial third. In the deeper two-thirds of the dermis the lymphatic vessels are comparatively scanty, and run vertically, in company with the blood-vessels.

With these anatomical facts I want to correlate certain pathological facts. In elephantiasis a band of round-celled infiltration is often seen in the superficial third of the dermis. Lupus affects, at first exclusively, the superficial third of the dermis. In Paget's disease of the nipple a band of round-celled infiltration is often found in the superficial third of the dermis. In moles the characteristic cells, called by the Germans "nevus cells," affect the superficial third of the dermis without ever quite reaching the epithelium. I ask you to infer that all these conditions are genetically related to the lymphatic system. In the case of elephantiasis no proof is needed. In favourable cases of lupus and Paget's disease I have given direct visual proof in earlier lectures in this theatre. Lupus is a tuberculous lymphangitis. Paget's disease depends initially upon cancerous

Accepted Views on its Pathology.

To obtain these views we must turn to the volumes of dermatological pathology dominated by the oracular Unna, who decides questions of cutaneous pathology by an intuitional process.

Unna objects entirely to the term papilloma, and

FIG. 5.

A section of skin under a low magnification in which the papillary lymphatics, completely injected, are seen above. This specimen was presented to the Museum of University College many years ago by Prof. Hyrtl, of Vienna.

wishes to substitute the word acanthoma, because he considers that the primary factor in a papilloma is a proliferation of the prickly epithelium.¹¹ In my opinion this sterile conception must be replaced by one based on anatomy and physiology. As I said in an address given last year in New Zealand, "the papilla is a little physiological engine. From its blood capillaries there exudes into its connective tissue a constant nutritive stream of dilute blood plasma at a certain pressure. The excess of fluid is removed and the equilibrium maintained by the drainage action of the central lymphatic. Block this lymphatic and what will happen? The first effect will be a rise in the pressure in the intercellular spaces of the papilla, and on ordinary hydraulic principles the papilla will increase in size until the intercellular pressure is equal to the pressure in the capillary blood-vessels.

A second effect will be overnutrition and consequent proliferation of the papilla itself, and of the overlying epithelium."

This view is based upon certain observations made in cases of warty or non-ulcerated lupus which I must briefly summarise. They are simple and, I think, convincing. In such an area of lupus, if the length of the papillae is measured they are found to be slightly hypertrophied at the edge of the patch, but as its centre is approached they show a gradual increase in length up to ten times the normal. If now the skin is examined immediately beyond the edge of the patch of lupus there is no definite papillary hypertrophy, but the central lymphatic of each papilla, though still anatomically recognisable, is seen to be blocked by proliferative tuberculous lymphangitis (Fig. 6). There is no other abnormality to be detected in the tissues. The inference I draw, and it seems an inevitable one, is that the blocking of the papillary lymphatic has established the necessary conditions

for papillary hypertrophy and wart formation—changes which in the centre of the patch of lupus have had time to reach their full development. It is true that I have not blocked a papillary lymphatic and seen a papilloma arise but, short of experimental demonstration, the proof of origin could hardly be more conclusive. The elongation of the papillae in a papilloma is not due to the downgrowth of the

FIG. 4.

To show the lymphatic arrangements of the skin. A schematic vertical section of the skin and subcutaneous fat, with a small horizontal shelf of deep fascia projecting forward from it. Below this is muscle in vertical section. AB and BC are two of the primary lymphatic arcs of the skin. These arcs measure one-third to half an inch in diameter, and the only lympho-vascular communication between them appears to be by way of the subcutaneous fascial lymphatic plexus DDDD which is seen on the flat. The lymphatic end-sacs of the skin papillae unite by groups of five or six to form small lymphatic vessels, which again unite in the superficial third of the dermis (plane of primary confluence EEE) to form other lymphatic vessels which pierce the dermis vertically and unite just beneath the plane of secondary confluence FFF into a smaller number of vessels which run down through the subcutaneous fat to discharge into the fascial lymphatic plexus DDD. (Handley: "Lupus in its Surgical Aspects," Annals of Surgery Jan., 1922.)

permeation of the lymphatic vessels of the skin, and later shows fibrotic destruction of these vessels with the typical band of round-celled infiltration. Now all these conditions are associated with papillary hypertrophy or with the appearance of papillomata. This can hardly be an accident. There is evidently some very close relation between lymphatic obstruction and the genesis of a papilloma. Here we may turn aside for a moment to consider the accepted views upon the pathogenesis of a papilloma.

¹¹ Histopathology of the Skin, trans. N. Walker, 1896, p. 671.

interpapillary cell columns for, as has been noted by other observers, the relation of the deepest part of these columns to the hair follicles deeper down remains unaltered. Moreover, in conditions of papillomatosis the interpapillary epithelial cell columns tend to atrophy and disappear, a clear proof that their rôle is a passive one. They are the victims, not the agents, of pressure.

If the tubercle bacillus, by setting up a local area

FIG. 6.

A section ($\times 95$) taken from near the edge of an area of non-ulcerative lupus, lying beyond the visible edge of the disease in apparently normal skin. The lymphatics of the skin nevertheless show advanced proliferative lymphangitis. A group of the lymphatic end-sacs, which lie in the skin papillae, is seen uniting in the plane of the section to form one of the vertically running lymphatics which pierce the dermis. To the left is seen another Y-shaped lymphatic junction, which also is converted into a solid cord of cells by proliferation of its endothelium. (Handley: "Lupus in its Surgical Aspects," *Annals of Surgery*, Jan., 1922.)

of chronic obstructive lymphangitis, can produce papillomatosis and finally carcinoma, is it not likely that other bacteria which are known to produce a subepithelial chronic inflammation, followed by papilloma and cancer, also act by producing a local lymph block?

Malignant Tumours Arising From Congenital Skin Malformations.

The local congenital malformations of the skin called nevi in France and Germany, and in this country described as nævi only if vascular but otherwise as moles or warty moles, are known to be seats of election for malignant tumours, especially if they are subjected to irritation.

But malignant tumours may arise in nævi without any precedent process of chronic inflammation, such as is usually seen in other cancers. There would appear, therefore, to be a factor at work in nævi which acts as a substitute for chronic irritation and inflammation. What is it? A study of the minute anatomy of the pigmented nævus shows that the characteristic nævus cells, closely aggregated pigmented or unpigmented connective tissue cells, occur chiefly in the superficial third of the dermis, the layer which we have already recognised as the lymphatic zone. This

fact suggests that the nævus is an area in which the cells which should produce the lymph vessels have proliferated irregularly and have failed to form the normal lymphatic network. This conclusion is confirmed by the frequency of papillary hypertrophy, which in the typical warty nævus reaches a high degree of development. The excess of pigment in nævi also indicates some defect in metabolism, and can also be interpreted as due to a defective circulation of tissue fluid, such as would result from lymph stasis.

You may look upon these arguments as special pleading. Let me therefore say that a number of distinguished pathologists have independently come to similar conclusions. Von Recklinghausen, Bauer, and Borst¹² all hold that the peculiar nævus cell groups found in moles are produced by proliferation of the endothelium of the lymph vessels and spaces. Von Recklinghausen gave to moles the name lymph-angiofibromata. Borst found in moles lymphatic vessels still recognisable but partly filled up with nævus cells, pigmented and unpigmented. He could also recognise thickening and proliferation of the endothelium of the lymph vessels. On the other hand, he found no such changes in the blood-vessels. Warty or papillomatous moles are liable to give rise to squamous-celled carcinoma. Renoul,¹³ among 121 examples of tumours arising from nævus, found 34 carcinomas. Melanotic sarcomas arise from them even more frequently, and mixed carcino-sarcomas have been recorded.

There is very good reason for considering that the liability of moles to malignant change is due to a local lymph block of congenital origin.

RECENT CANCER THEORIES.

The two most recent general theories of the origin of cancer are those of L. Kreyberg, of Oslo, and A. Lumière, of Paris. Kreyberg has shown by very neat methods that areas irritated by tar exhibit, in the precancerous stage, a dilatation of the cutaneous vessels associated with increased transudation of serum into the tissues. This hyperæmia comes immediately after the tar application and after the first application disappears within 48 hours, but after later applications is more and more persistent. It is not of reflex origin but is ascribed hypothetically to local injury of the contractile apparatus of the small vessels. Capillary ectases appear at the end of a month and precede the development of warts. The affected vessels are capillaries and venules, and thrombi are frequently seen within them, without any evidence of proliferation of the vascular endothelium. Polymorphic leucocytes, later replaced by lymphocytes, wander into the tissue of the corium and subcutaneous fat within two days of the first tar application, and the fibrous bundles increase, so that the corium becomes fibrous and rich in cells. A diffuse hyperplasia of the epidermis develops within a few days, but is later than the connective fibre changes. Painting with spirit of mustard or with hot water at 60° C. led, on the contrary, to a transient hyperæmia, with later degeneration of the epidermis and the production of scarred corium, poor in cells.¹⁴

Kreyberg finds in the power of tar to cause lasting hyperæmia the secret of its power to cause cancer, and ascribes to hyperæmia a predominant rôle in the production of malignancy. He finds in the persistent "irreversible" dilatation of the vessels the factor which may cause cancer even though the application of tar be stopped. He remarks that human cancers originate at the time of life when vascular degeneration is frequent and in organs which are intermittently functional and subject to great circulatory alterations, such as the uterus. His work takes no account of the lymphatic vessels, and it cannot be right to omit from consideration such an important anatomical element in the skin. Chronic hyperæmia seems too wide and general an agency to be invoked as the

¹² Die Lehre von den Geschwulsten, 1902, i., 117 and 453.

¹³ Thèse de Paris, 1892.

¹⁴ Virchows Arch., 1929, cclxxiii., 367.

cause of cancer. This is not to belittle the importance of Kreyberg's observations, but they may be an isolated chapter of the story of which I believe I have given a more complete and documented account.

It is evident that inflammatory hyperæmia must accompany the earlier stages of a chronic lymphangitis. As to the later persistent hyperæmia, it so happens that in my study of lupus I have already described the vascular dilatations, followed by vascular restriction, which Kreyberg has described in the later stages of tar-painting. I ascribed them in lupus to the comitance of lymphatics and blood-vessels. From this anatomical circumstance it inevitably arises that the fibrous changes of a chronic lymphangitis and perilymphangitis produce pressure at first upon the comitant vein with vascular congestion and increased transudation, and later upon the arteries with vascular constriction, followed by necrosis. It will not escape notice that the early changes in the corium described by Kreyberg precede the epithelial and vascular changes, and that they are precisely those which are already known to occur in a lymphangitis of tuberculous origin. Kreyberg's observations are thus an independent confirmation of my own, and are especially important as showing that the very first effect of tar-painting is seen in the lymphatic region of the corium, and that the earliest epithelial changes come later. Kreyberg's theory offers no explanation of the close association between papilloma and cancer, which on my view receives an easy and natural explanation.

According to Lumière¹² the essential preliminary for the production of cancer is a scar. This is untrue if the word "scar" is used in its clinical and ordinary sense. It is probably true, except in the case of moles, that microscopic processes of subepithelial chronic inflammation which lead to the formation of scar tissue invariably precede a carcinoma. That mere scar-formation is not the cause of cancer is, however, shown by the extreme rarity of malignant growths in the scars of "clean" surgical operations, where the conditions for the infection and subsequent obliteration of lymphatic vessels have been excluded by the surgeon's precautions. The hypothesis of Lumière fails by its vagueness and its limited applicability, though it contains an element of truth.

It is to be noted that not one of the theories of the origin of cancer hitherto current applies equally to cases originating in chronic infections, in chemical irritations such as those of tar, and in malformed areas of skin. Parasitic theories fail to explain tar cancer. Cohnheim's theory fails to explain the origin of cancer in such conditions as chronic gastritis. Chronic irritation and parasitic theories fail to explain the special liability of moles to become malignant.

The occurrence of papillomatosis preceding every variety of carcinoma suggests for all three classes of growth a similar pathogenesis, and points to chronic lymph stasis as the *x* of the problem. Congenital malformation of lymph vessels and pathological obstruction of them have, as might be expected, the same effect.

A. Leitch has stated that cancer is due not to one cause but to many. I believe this is a superficial view and that these multiple and alternative chains of causation will be found to converge to a single line of links which leads through local lymphatic obstruction—often manifested by papillomatous hypertrophy—and certain consequent metabolic changes to the onset of a carcinoma, and that not otherwise can a cancer be produced. The language and thought of mankind upon the subject of causation is in a singularly muddled condition. Any given consequence such as cancer springs from a chain of previous events stretching back to infinity, and not from a single cause. But if among those events one can be detected which for a given consequence is very frequently present, and has never been proved absent, the clue to the problem of causation has been

obtained, and this event may be provisionally and loosely spoken of as the cause. In this sense I am bold enough to claim that lymphatic obstruction is the cause of cancer, though the labours of generations may be required to trace the intermediate steps. The evidence for this view is so substantial that it may claim to rank not as a hypothesis but as an established theory—that is to say, as the solvent and unifier of all the relevant facts hitherto observed and the guide to future research upon the subject. My part in this theory has been to explain the real pathology of the papilloma and to demonstrate the lymphangitis-papilloma-carcinoma sequence in lupus carcinoma. Had this been all, the theory would have remained a plausible hypothesis proved only for lupus cancer. It has been raised to the rank of a theory by successive waves of evidence, coming in like a tide from independent observers and referring to distinct varieties of carcinoma, but all bearing testimony to the genetic relationship of papilloma or adenoma and carcinoma. Some of these observers have been surgeons, some pathologists, but I am glad to observe, as showing that the originality of our nation is not exhausted, that most of them have been English. I mention the names of Hurry Fenwick, Lenthal Cheatle, Cuthbert Dukes, Lockhart-Mummery, M. J. Stewart, G. Scott Williamson, and I. H. Pearse.

I rejoice in these facts for another reason, because they show the continued vitality of morbid histology. The phase of dangerous neglect through which this subject has passed is giving place to renewed interest, though academic recognition of its importance and dignity is still to seek. I continue to hope for the time when this building will contain a histological museum equal in importance and authority to its collection of naked-eye specimens. As Prof. C. Regaud¹³ said of morbid histology, "Not only does it lie at the bottom of all classifications that we make, and play a preponderant rôle in diagnosis, but it has also become the indispensable guide of all who devote themselves to the difficult problem of the biological action of radiations"—a subject of very immediate importance now that radium is coming into its kingdom.

DOES LYMPH STASIS PRECEDE SARCOMA?

The peculiar relations of epithelium to the underlying connective tissue provide, in the precancerous papilloma or adenoma, an early criterion of the existence of lymph stasis. No such criterion is available in the case of the sarcomas, which arise not upon surfaces but in the depths of the connective tissue. The problem of presarcomatous conditions has hardly been approached. Nevertheless there are indications that forces of the same order as those which produce carcinoma may also produce sarcoma. Warty moles may become the seat either of a carcinoma or of a sarcoma, or of a carcino-sarcoma. Some experimenters, while trying to produce carcinoma by injecting tar, have produced instead a sarcoma. It may at any rate be said that the application of the lymph-stasis theory to sarcoma presents no difficulty, except that in the sarcomas of young children the normal snail's pace of the genetic process of cancer must have been much accelerated.

CONCLUSION.

To sum up, the genesis of cancer has been linked up firstly with a predominant extrinsic factor—chronic irritation either of bacterial, viral, parasitic, or physical origin; secondly, with a predominant morbid anatomical factor—papillomatosis or adenomatosis; and, thirdly, if you accept my conclusions, with a predominant physiological factor—local lymphatic obstruction. Finally, if the work of Warburg holds good, the genesis of cancer is intimately linked with a biochemical factor, a change-over on the part of the precancerous cell from nutrition by oxidation to nutrition by hydrolysis. It is easy to imagine how this change may be imposed upon the cell by conditions of lymph stasis. Is it too much.

¹² A. Lumière: *Le Cancer, Maladie des Cicatrices*, Paris, Masson et Co.

then, to say that the main outlines of a solution of the retiological problem of cancer are visible through the mist? Concordant facts have an unmistakable music of their own, which even Beethoven cannot excel.

Menebrier has divided theories of the origin of cancer into two classes: (a) the parasitic theories, which seek the cause of cancer in a specific living agent reaching the body from without; (b) the cellular or cytophysiological theories, which lay stress upon the intrinsic modifications of organs and tissues. It will be seen that the apparently conflicting facts upon which the opposing views are based can be harmonised if it is admitted that various non-specific infections and chemical and physical irritations may set up a chronic local obstructive lymphangitis which in the course of years profoundly modifies the vital processes of the surrounding cells. The circulation of tissue fluid is impaired, and in the obstructed district the cells no longer receive their due share of the products of the other cells of the body. They are deprived of the hormones by which the cell society exercises its influence upon the cell individual, and particularly of the hormone which limits cell division. Under these conditions it is not surprising that they may ultimately revert to the condition of the primitive unicellular organisms from which they are all descended.

You all remember the story of Mowgli as related by Mr. Kipling. Cut off from the influence of his kind and from the apparatus of civilisation, Mowgli made shift in the jungle by reverting to the habits of the primitive man, his ancestor. The story of Mowgli is a parable of the origin of the cancer cell. The analogy is incomplete. The cancer cell has reverted to the very beginnings of life, when all living beings were single cells, to a time when egotism, modified by an urge to voluntary bisection, was the only virtue. Such was the moral code required to preserve life through the cataclysms of the prime, and such to-day is the code of conduct of the cancer cell.

It has been said, for I said it myself, that man is omnipotent till he is 30, omniscient till he is 40, and immortal till he is 50. In the 25 years which have elapsed since I first held my present office—and I have held it eight times—I have lost the support of these delusions. But the younger generation of surgeons, the future holders of this chair, will find, as I have found, that attempts to advance knowledge in the service of this College and to present the results in a form fit for this critical audience are a source of abiding satisfaction, a satisfaction which survives the delusions of youth, and perhaps even outlives the fire of personal ambition and the thrill of professional success.

CLINICAL EXPERIMENTS WITH OESTRIN.

By E. C. DODDS, M.V.O., M.D. LOND., PH.D.,

COURTAULD PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON;

AND

J. D. ROBERTSON, M.B. ST. AND., D.P.H.,

ASSISTANT CHEMICAL PATHOLOGIST TO THE MIDDLESEX HOSPITAL.

(From the Courtauld Institute of Biochemistry,
Middlesex Hospital.)

SINCE many monographs¹ and reviews^{2,3} dealing with the literature on the discovery, preparation, and physiological and chemical properties of this substance have appeared within the last year, it will only be necessary to refer very briefly to the outstanding points in this discussion. The fact that the ovaries play an essential part in the sexual cycle of animals has been known for generations in consequence of the

obvious effects of castration in animals. During the last 30 years a continuous series of attempts has been made at substitution therapy, and, as in the case of other hormones, the outstanding landmark was found at that particular time when a definite method of testing the potency of the extract was discovered. The earlier workers employed such phenomena as enlargement of the uterus and growth of the genitals as a sign of the activity of their products, but it can easily be seen that this type of observation can rarely, if ever, be developed into a quantitative study. The most important observation was made by Allen and Doisy,⁴ who were the first to apply Stockard and Papanicolaou's⁵ vaginal smear method to the study of the activity of ovarian extracts. This reaction is the one by which the material at present under discussion is standardised.

It was shown by these workers that if daily vaginal smears were made from small rodents, such as the rat and the mouse, a series of cyclical changes occupying about three days was found. This phenomenon is known as oestrus and can be divided into three stages—pro-oestrus, oestrus, and meta-oestrus. The cellular changes occurring in the smear are characteristic for each stage; in the resting stage can be seen leucocytes and degenerating cells; in pro-oestrus the leucocytes begin to disappear and epithelial cells in various stages of cornification take their place; at the height of oestrus the leucocytes have vanished and the smear consists of eosin-staining cornified cells which have lost their nuclei; in meta-oestrus retrogression appears, heralded by the appearance of leucocytes, and the reaction thus returns to the resting stage. If the ovaries are removed from the animal these changes cease, and the vaginal smear takes on the appearance of the resting stage, which is known as dioestrus. Allen and Doisy showed that the injection of extracts made with the use of volatile solvents would cause the cyclical changes to reappear, and this has been developed as a method of standardisation. The important point to realise is that there is a definite quantitative relationship between the amount of hormone injected and the changes in the vaginal smear, and that in this technique we have a certain method of assaying the hormone.

A great deal of controversy centred around the actual definition of the unit. The earlier workers employed the technique known as the "descending dose" method. This consisted of giving small quantities of the hormone to a series of rats and noticing the minimum quantity capable of producing oestrus in one or more animals. This type of method was vigorously attacked by Coward and Burn,⁶ who showed that the possibility of error was in the region of many hundred per cent. on account of the great individual variability in the response of the rats to the substance. They proposed that a statistical technique should be adopted in which a series of rats, say 20 to 50, were given approximately the amount required to produce oestrus, the unit to be defined as that quantity of hormone capable of producing oestrus in 50 per cent. of the animals so tested. By this means the highly sensitive rats in the group were balanced by the relatively insensitive ones, and thereby an accurate method was produced. Although the importance of this work has not been fully realised, it is safe to say that the time is not far distant when the principles of the method will form an essential part of any standardisation of this type of product. The material described in this paper has been standardised on this principle and the results of Coward and Burn were very rapidly confirmed in these laboratories.

The importance of this work can readily be seen, for it provided the biochemist with a method of estimating the strength of his preparations in a quantitative manner and enabled him to proceed with the purification of the hormone. For example, the preparations some years ago were in the form of a stiff oil, insoluble in water, with a rat unit of some 10–15 mg. This substance was administered to animals dissolved in olive oil or else in the form of an emulsion, and various local and general disturbances resulted from its irritating characteristics and slow absorption. An animal that had been injected for a considerable period lost weight and developed ulcerating sores at the site of injection. The very properties of this substance forbade its use in clinical medicine, and the few isolated attempts that were made to inject it were all followed by severe local and general reactions which quite masked any possible therapeutic action. The purification of the material, however, has proceeded rapidly, with the result that to-day it is possible to obtain material containing several

hundred rat units to the milligramme. The product is sufficiently soluble in water to enable considerable doses to be injected subcutaneously into human beings without any local or general reactions.

Effects of the Water-soluble Hormone on Animals.

The effects of this water-soluble and highly active material are: (1) The production of oestrus in ovariectomised animals. (2) The production of premature puberty in young immature female animals. (3) The abortion of pregnant rats and mice when given in large doses subcutaneously. (4) All these phenomena have been noted when the material has been injected subcutaneously. No effects can be observed by oral administration unless relatively enormous doses are given.

This substance, which has been termed oestrin, is therefore a very powerful agent, capable of producing profound changes in animals, and it is known from a careful study of its effects on blood pressure to be at least harmless when given to human beings.

The gynaecologist has sought in an ovarian extract a substance capable of inducing menstruation in amenorrhoea, and many have claimed that oestrin has this power. It must, however, be clearly understood that there is little *a priori* reason to suppose that a substance capable of producing oestrus in the lower animals will therefore produce menstruation in women. The significance of the menstrual process is not understood and the relation between oestrus and menstruation is certainly by no means clear. We must not, therefore, set out with the idea that oestrin to be of any value must cause the onset of menstruation. Also, the relationship between parturition in animals and man is obscure. It is a well-known fact that abortion is induced very easily in normal animals, but only with considerable difficulty in normal women. Then, again, it might be hoped that oestrin would be able to replace the lacking ovarian function in the climacteric, but here, also, a word of warning must be given, as it is not definitely proved that the whole of the symptoms of the climacteric period are due to deficient ovarian secretion. It is important to be quite fair to the extract and not to expect it to induce processes which possibly bear only a distant biological relationship to those occurring in the lower animals. In the few publications that have appeared on the clinical use of oestrin the views expressed vary considerably. Thus, Shaw,⁷ using the oily material, states, "the evidence that has been obtained shows that in some cases it is of no value whatsoever, and that its application is likely to be very strictly limited to but a few cases." Laqueur⁸ and his co-workers using the water-soluble preparation, report very favourable results in certain types of cases.

Preparation Used in the Clinical Experiments.

The preparation employed in the clinical experiments about to be described was made by the process already published from these laboratories (Allan, Dickens, Dodds, Howitt⁹), and the product is manufactured and standardised entirely in our own department. It contains 10 rat units per c.c.m. as estimated by the method of standardisation already described. (Allan, Dickens, Dodds¹⁰.) The solution is clear, sterile, and water-bright, and the potency of the material is on the average 50-100 units per mg. The solution is preserved by the addition of tricresol, and when injected produces neither local nor general toxic reaction. Since experiments have shown that the rat unit is in the region of ten times the mouse unit, and the ratio of their weight is about 10:1, it would appear, arguing on a body-weight basis, that 300 rat units would be required to produce a corresponding physiological effect on a woman of average weight. It was decided to use the strictly limited supply of material in a series of daily injections, the 1 c.c.m. (10 units) being given on each occasion. The treatment was carried on for two months, and between 500 and 600 units in all were given to each patient. The aim was to give a series of small doses spread out over a considerable period rather than frequent

large doses. This method was based upon animal studies, which had shown that a better response would be evoked by giving a series of small doses spread over a period of days than by giving one single large dose. The figure of 10 units per day was arrived at in a purely arbitrary manner and rests on no reasoned ground other than economic considerations. The production and standardisation is so extremely laborious and expensive that this was found to be the maximum amount of material that we could give to a series of cases.

Type of Case Treated.

The patients were referred to us from the gynaecological out-patient department, where they had been subjected to a careful pelvic examination, and from our point of view they could best be considered under the following headings:—

1. Patients with amenorrhoea; these for the sake of convenience may be divided into two classes: the unmarried and the married. These groups correspond roughly to primary and secondary amenorrhoea respectively.
2. Patients from whom both ovaries had been removed.
3. Patients in whom attempts were made to induce labour.
4. Patients at the menopause.

Results of Treatment.

In the Table given below will be found the results of the treatment of all the cases which were injected with the hormone. Every patient to whom the substance was given has been included, so that there can be no question of any attempt at selection. In all, 78 cases of amenorrhoea have been injected, and 18 of these were unable for various reasons to continue treatment. The results in these 18 have not been noted, as it was felt that their inclusion would be misleading. We thought it advisable to consider the results under two main headings: first, the direct objective result—namely, the establishment of menstruation—and secondly, the effect of the substance upon the general health and spirits of the patient. Whilst the former is a matter of fact and can be expressed in figures and percentages, the latter is very variable, and indeed, in our opinion, is of little or no value.

<i>Amenorrhoea.</i>		Unmarried.	Married.
Cases treated		40	38
Number having full two months' course		32	30
" in whom menstruation started		10	18
" feeling better		30	29

The Table shows that menstruation started in 10 of the 32 unmarried women and in 18 of the 30 married women. In the successful cases the periods usually commenced within a week or ten days of the treatment and consisted first of all of a very slight bleeding, but this amounted to a full period in some. The bleeding was followed after three or four weeks by a full period, described by the patient as perfectly normal. The periods continued for at least six months, and these patients all felt a great improvement in their general health. It must be admitted, however, that those women in whom the periods did not appear also felt very much better. A series of experiments was conducted on some of these patients to control the psychological effect of giving injections, and in many cases excellent effects were observed after normal saline injections when the patients thought they were receiving the active preparation. The general tonic effect appears, therefore, to be largely due to suggestion, possibly associated with the fact that the patient was coming every day to the hospital for treatment.

Patients from whom Both Ovaries had been Removed.

Four patients were treated. From the first, aged 29, both ovaries had been removed on account of cystic disease and the uterus had been left untouched. The patient was seen five months after operation and had not had any periods. After the standard treatment, menstruation appeared in three weeks, and was followed by another period one month later. In this case the injections were carried on for five

months and the periods continued normally. Cessation of treatment, however, was followed by abrupt cessation of the menses. In another similar case, aged 32, the ovaries had been removed three months previously and the patient was suffering from marked menopausal symptoms. The results obtained were similar to those in the first case. The remaining two patients had undergone complete hysterectomy, together with removal of the ovaries, and were suffering mainly from vasomotor symptoms. Their ages were 35 and 38 respectively. In the former patient there was a definite leukoplakia vulvæ. In both patients the vasomotor symptoms were controlled and the local condition of the vulva in the first patient was greatly improved after three months' treatment. Unfortunately, sufficient material was not available to continue the treatment or to raise the dose.

Attempts at Producing Premature Labour.

In collaboration with Mr. L. C. Rivett three cases were treated at the Queen Charlotte Maternity Hospital. The results of these cases are described in detail below, and it will be seen that in only one was there any evidence that premature delivery had been effected.

CASE 1.—Primigravida, aged 26, expecting July 15th, 1928. Induction for ? placenta prævia, associated with persistent vomiting.

July 7th, 12.15 P.M. .. Inj. 1 c.cm. placental extract.
 4.15 " " " 2 " " " "
 8.45 " " " 2 " " " "
 12.15 A.M. " " " 5 " " " "
 Few weak pains during night.
 " 8th, 11.0 A.M. .. Inj. 2.5 c.cm. placental extract.
 3.0 P.M. " " " 5 " " " "
 7.0 " " " " " " " "
 " 10th, 12.45 " " " No pains; general anæsthetic; bougie induction.
 " 12th, 7.0 " " " Onset of pains.
 " 14th, 1.30 " " " Normal delivery after a long labour assisted by pot. brom. and chloral, morphia and scopolamine, and pituitrin when the head was on the perineum.

CASE 2.—Multigravida, aged 25, expecting Sept. 15th, 1928.

July 20th, 3.0 P.M. .. Inj. 5 c.cm. placental extract.
 7.0 " " " 5 " " " "
 11.25 " " " Onset of pains. "
 12.0 " " " Cervix admitted two fingers.
 " 22nd, 8.0 " " " Dilatation 2/6.
 " 23rd, 7.45 A.M. " " " Dilatation 5/1.
 8.15 P.M. " " " Normal delivery, binovular twins, after morphia and scopolamine.

CASE 3.—Multigravida, aged 22, expecting May 12th, 1928. Induction for ? post-maturity and disproportion.

July 21st, 3.0 P.M. .. Inj. 5 c.cm. placental extract.
 7.0 " " " 5 " " " "
 11.0 " " " 5 " " " "
 " 22nd, 3.45 A.M. " " " 5 " " " "
 3.30 P.M. " " " 10 " " " "
 7.30 " " " 10 " " " "
 10.30 " " " 10 " " " "
 " 23rd, 3.30 A.M. " " " 10 " " " "
 " 25th, 12.30 P.M. " " " No pains; external cephalic version; bougie induction.
 " 26th, 4.50 " " " Onset of pains.
 " 28th, 5.20 A.M. " " " Normal delivery.

We came to the conclusion that very much larger doses of the material would have to be employed before definite results could be expected, and as at this time we heard that a more elaborate series of experiments was in progress elsewhere we decided to abandon this investigation.

Administration During Menopause.

A series of five cases was treated by daily injections of ten units of the hormone, and in all there was a marked improvement. It was found that the extract possessed definite powers of controlling the vasomotor and general symptoms of nervous irritability, but the number of cases was too few to produce anything definite.

General Conclusions.

These results do not at first sight indicate a very hopeful outlook for the use of this substance. Out of the 80 odd cases treated, only some 30 showed definite

objective improvement, although practically all of them showed general improvement. The series was, however, too small to give an opinion upon, and at least a thousand cases of amenorrhœa must be treated before spontaneous recovery and other incidental factors can be excluded. Much larger doses of the substance must be given before it is put aside as useless. A large series of cases should be treated with 50 to 100 units per day, and with this very definite results might be obtained, and many hundred units in a single dose will have to be tried before a definite answer can be given. This applies more particularly to the attempts to produce premature labour.

We should like to enter an earnest plea that the material be given a really fair trial before being abandoned. The question of expense should not be allowed to deter experiments, while at the same time the very greatest care must be taken to avoid being misled by general effects, such as the patient "feeling much better." It is well known that all these results can be produced with many of the samples of commercial material that are being given to-day by mouth, but which in the laboratory have no demonstrable action.

Summary.

1. The results of treating 86 cases with an accurately standardised preparation of oestrin are described. The conditions investigated were amenorrhœa, menopause symptoms, and attempts to produce premature labour.
2. The cases of amenorrhœa were divided into two categories, according to whether the patient was married or not. Out of 32 unmarried women receiving full term of treatment menstruation was re-established in 10, whilst 18 married women out of 30 responded. It is noted that the response is considerably greater in married women than in unmarried.
3. Five cases of naturally occurring menopause were treated, and all showed definite abatement in vasomotor and nervous symptoms.
4. Two cases of surgical menopause following bilateral ovariectomy were treated with similar results.
5. Experiments intended to procure premature labour in three cases by the injection of some 300 units each were unsuccessful in two but successful in one. These results are obviously inconclusive.
6. Over 90 per cent. of the patients injected showed great improvement in general health and spirits, irrespective of whether menstruation was induced or not. Experiments with saline indicated that very similar results could be obtained, and therefore it was decided to discountenance these findings.

We wish to express our gratitude to Messrs. Boots Pure Drug Co., Ltd., for their generous financial assistance which has helped us to carry out these investigations.

We gladly acknowledge the coöperation of Mr. Comyns Berkeley, Mr. Victor Bonney, and Mr. L. Carnac Rivett in allowing us to investigate their cases. Mr. F. Roques kindly supplied us with case-histories and examined some of the patients.

GENERAL ANÆSTHESIA

BY THE INTRAVENOUS INJECTION OF ETHYL ALCOHOL.

BY JULIEN D. CONSTANTIN, M.R.C.S. ENG.,

ANÆSTHETIST TO THE MILLER GENERAL HOSPITAL, GREENWICH,
THE FRENCH HOSPITAL, SHAFESBURY AVENUE, AND
BRENTFORD HOSPITAL.

SINCE June, 1920, a series of more than 40 operations has been performed with intravenous alcohol anæsthesia, using the method originally introduced into this country by Dr. Miguel Garcia Marin, of Mexico. With more data available, it is now possible to analyse the statements made in a previous article (THE LANCET, 1920, i., 1247) and, where necessary, to give the individual claims the benefit of personal observations.

The technique does not differ substantially from that previously described, but some slight modifications have been adopted, both in the solutions and the apparatus, for the convenience of the anæsthetist.

Preparation of the Patient.—It is of great importance for a successful anæsthesia that the patient should be in a perfectly quiet state of mind; and this, it has been found, can only be obtained by the administration of morphia hypodermically in doses of a quarter to half a grain, according to the nervous temperament of the case, not less than an hour beforehand. If it is given too soon the patient is sometimes inclined to be restless and talkative during the initial stages of induction, which is therefore prolonged and thus a greater amount of anæsthetic may be required. It is advantageous to give atropine as well, to counteract the depressing action of morphia on respiration. If careful attention is given to these preliminary recommendations, the induction is remarkably free from excitement as also, it has been observed, the stage of recovery.

Solutions.—The preparations required are: (a) an isotonic solution of glucose, which can be obtained in sealed ampoules of 300 c.cm.; and (b) rectified spirit (90 per cent.) which has been found just as efficient as the 96 per cent. ethyl alcohol originally suggested. The mixture of alcohol and glucose is now prepared in the following proportions: rectified spirit (90 per cent.), 40 parts; glucose solution (25 per cent.), 60 parts. This can be kept ready-made in amber-coloured bottles, as there is no alteration in either constituent of the mixture (there being no hydrolysis and the alcohol acting as a preservative). Naturally, the glucose solutions should be adequately sterilised, as for any other intravenous administration.

Apparatus and Administration.

For the majority of cases the gravity method was employed, but a more convenient arrangement has been devised. This apparatus works on the principle of the blood-transfusion flask. It consists of two bottles (A) and (B), each of 460 c.cm. capacity. (A) contains the isotonic solution of glucose and (B) the alcoholic mixture, (B) being graduated at 10 c.cm. levels. (D) is an air filter. The inlet tube (d) is connected with the bellows and round its inlet tube (p) a piece of sterile gauze is wrapped. The perforated end (a) and (b) have each a tap, and are joined by an Y-piece (f). To this is fixed a tube, having at its end an adapter (c), which will ultimately be fixed to the needle. All the bottles are capped with rubber stoppers through which are pushed the various metal tubes (as shown). The taps (a) and (b) are first shut, then pressure is introduced into (A) and (B); (c) is then opened and raised above the level of the bottles, the tap on bottle (B) is opened until fluid comes out at (c), and then both (b) and (c) are shut. Next the tap over bottle (A) and the tap at (c) are opened until all the air has been driven out of the outlet tubes. These taps are also shut, after the isotonic solution has flowed out at (c) for a few seconds. In this way it is made reasonably sure that the tube from (f) to (c) will contain isotonic solution only.

The apparatus is now ready for use. When the injection is about to be started, there must be sufficient pressure in the bottles and tap (a) is opened. The vein is punctured with a needle in the usual way and, when blood flows freely, tap (c) is opened and connected with the needle, care being

taken not to disturb the needle in doing so. When the isotonic solution is running freely, the needle is fixed with tape as described below. Tap (a) is turned off, and tap (b) immediately turned on. The rate of flow can be gauged by watching the level of the liquid in the bottle, and can be regulated by the outlet tap. Both taps must not be open at the same time for fear of one liquid mixing with the other through regurgitation into either bottle via the Y connector (f). The whole of the apparatus (except the bellows) can be taken to pieces and sterilised by boiling. The bottles are fixed securely in clips on a suitable base, and the whole apparatus stands easily on any small table or anæsthetic trolley. It is advisable to use tall slender bottles (say about two and a quarter inches diameter), as the level of the liquid is seen to drop more rapidly than in bottles of a wider diameter.

It is important to stop injecting as soon as the level of either liquid reaches the lower extremity of the outlet tubes, or air will be injected, with detrimental results.

Anæsthesia.—The patient lies on the table with the eyes covered. The arm to be injected is abducted on to a suitable rest, with the forearm kept extended by an assistant

Apparatus used for administration of alcohol intravenously.

as long as the needle is in the vein. The needle, which should be of a sufficiently large bore and with a short bevel is then introduced into the vein in the usual way. When the blood flows, the adapter is connected to the needle, allowing the isotonic glucose solution (solution A) to run in, and then the needle and tube are secured to the skin with adhesive tape. The needle should be left alone and the arm continually held in the same position. When the flow is satisfactorily established with solution A, this is turned off and then the alcohol mixture is turned on. The rate of injection of the alcohol mixture should be roughly about 10 c.cm. in 30 seconds, but it has been observed that this rate may be exceeded to the extent of 20 c.cm. in 30 seconds with safety. At first the patient may complain of a dragging pain in the arm, but this soon passes off. It is important that the patient should not be allowed to talk or be disturbed in any way with questions. When anæsthesia is considered sufficiently deep, the alcohol mixture is turned off and the isotonic glucose is administered again. This procedure can be reversed as often as required, but one should always bear in mind the patient's allowance of alcohol. This is reckoned to be 2 to 3 c.cm. of 90 per cent. alcohol per kilo of body-weight. If the anæsthetist becomes uneasy about the condition, colour or breathing of the patient, he turns off the alcohol mixture and gives the isotonic glucose solution; this will quickly remedy matters. The breathing as a rule is very quiet, and sometimes tends to be shallow especially when the alcohol mixture is given too rapidly, but does not lead to cyanosis except when the air passages are mechanically obstructed; the isotonic glucose, however, never fails to act as a prompt stimulant. The rhythm of respiration remains perfect throughout, and the colour during and after the anæsthesia is exceptionally good. The induction may take 5 to 15 minutes or more.

At the beginning of the operation it may be helpful to administer a few drops of ether or chloroform on the open mask (and this can be done at any time during the operation),

if a sufficient amount of alcohol has not been given or if the surgeon requires a greater degree of relaxation. A few drops are sufficient. As a routine, the alcohol mixture is stopped after the incision and the isotonic glucose given to finish up, in quantities up to 500 c.cm. if necessary. When the needle is withdrawn a tight dressing is applied. It is to be noted that there is never laryngeal spasm.

Post-operative Care.

The patient usually continues to sleep for some hours, and should be watched with the same attention as after any other anaesthesia; but, when the reflexes return, he may be left for short periods. At the least sign of restlessness sufficient morphia should be given so that when the effects of morphia have disappeared those of the alcohol have already passed off and the recovery is not unpleasant. Vomiting has sometimes occurred, in spite of the original claims to the contrary, but has never been persistent, and has generally taken place whilst the patient was in a sort of "twilight sleep." Incontinence of urine has been noticed in many female cases but much less frequently in men. Thrombosis of the injected vein is almost invariable, but, as in the case of injections for the cure of varicose veins, should not give cause for any anxiety.

The effects on the body are summarised below:—

Urine.—Specific gravity: no apparent change. Albumin: trace in one case only. Sugar: small amounts in four cases. Haemoglobin: in one case only. Deposits: never any renal casts. Where albumin, sugar, and haemoglobin were found they were detected only in the first urine and never in subsequent specimens. We may therefore safely say that there is no marked destructive effect on the blood corpuscles.

Blood.—No change in coagulability or bleeding time.

Blood Pressure.—There may be a slight initial rise, but this is transient and the pressure soon returns to normal and remains so throughout.

Pulse.—Generally remains normal; if there is a rise in the pulse-rate it does not go much over 100.

The quantities of the mixture required for an anaesthesia vary with the weight of the patient and with the nature of the operation (60 c.cm. to 400 c.cm.), but 300 to 350 c.cm. have been sufficient for most cases.

Indications and Contra-indications.

Alcohol is suitable in most instances where any other anaesthetic would be contra-indicated, and especially for patients who have lost a considerable amount of blood or those suffering from shock in toxic cases; for old and debilitated patients; for compensated heart conditions where both the alcohol and the glucose act as cardiac stimulants; and where a mask would be cumbersome, as for operations on the head and face.

Children under ten years of age, owing to their susceptibility to alcohol and also to practical difficulties are unsuitable subjects. Advanced and active pulmonary tuberculosis and serious uncompensated heart failure are definite contra-indications.

The following are typical examples of cases in which alcohol-anaesthesia could be used with advantage:—

CASE 1.—A married woman, aged 51, was admitted on account of severe bronchiectasis. As the level of the right side of the diaphragm was very high, a subdiaphragmatic abscess was suspected. The patient was much too ill for an inhalation anaesthesia and exploration was made under 60 c.cm. of intravenous alcohol-glucose with very satisfactory results. After a rib-resection nothing was found in the pleura or below the diaphragm, and the other side was explored with a trocar with the same result. The patient died next day, and autopsy showed both lungs riddled with abscesses; there was little lung substance left and the whole organ was markedly shrunk.

CASE 2.—A man, aged 60, weighing 15 st., was diagnosed as chronic cholecystitis and cholelithiasis. He had been intensely jaundiced for some months. Good muscular relaxation was obtained with 350 c.cm. of the mixture. Carcinoma of the gall-bladder, with metastases in the liver was found, and nothing radical was done. The patient was very comfortable on awakening, and had no vomiting. Death occurred a week afterwards.

CASE 3.—A married woman, aged 55, was diagnosed as acute intestinal obstruction. She had acute diffuse abdominal pain, with rigidity and free fluid. She was pulseless and in a moribund condition. Laparotomy was done under 250 c.cm. of the mixture and 500 c.cm. of

isotonic glucose; the cause of obstruction was not found but the peritoneal cavity was drained. She stood the anaesthetic very well, and her pulse improved. She died next day and autopsy revealed a perforated gastric ulcer on the posterior aspect of the stomach. A special note was made about the condition of the lungs, which showed no evidence of oedema.

CASE 4.—A spinster, aged 25, had advanced Hodgkin's disease with large masses of glands, both cervical and mediastinal, the latter giving rise to pressure symptoms, such as stridor and dyspnoea, with cyanosis. It was decided to remove some of the cervical glands under a local anaesthetic but this was not satisfactory. A general anaesthesia was suggested but the ordinary inhalation methods were thought inadvisable under the circumstances, and intravenous alcohol was used instead, with excellent results. Although the patient was sick once or twice, she was not conscious of it, and awakened feeling perfectly fit.

CASE 5.—A man, aged 32, was operated on as an emergency on Oct. 10th, 1920, under chloroform-ether anaesthesia. He had a prolonged febrile temperature after the operation, with a faecal fistula and a heavy purulent discharge from the wound. He was in a very toxic condition. A second operation was performed under alcohol anaesthesia on Nov. 20th for subdiaphragmatic abscess. Two large loculi of pus were found and drained. The patient stood the operation very well, was not shocked, and awakened in a better condition than before. As the temperature continued to rise, other abscesses were suspected, and another operation was performed on Dec. 4th, when more abscesses were drained. This time alcohol anaesthesia was again used with the same satisfactory results as before. On Jan. 7th the patient had a fourth operation. As the veins were collapsed and sclerosed from the previous injections and there was no time to dissect out a vein, open ether was used instead. The patient died from toxæmia ten days afterwards. In none of the many urine analyses made in this case was there found any sign of albumin, sugar, haemoglobin, or renal casts.

CASE 6.—A sister, aged 55, was diagnosed as cancer of the left kidney. Before the anaesthetic, albumin, casts, blood, and pus were found in the urine from both kidneys, but no *B. coli*. Induction took ten minutes. Satisfactory anaesthesia was obtained with 300 c.cm. of mixture. Nephrectomy took one hour and twenty minutes, starting at 2.30 p.m. The patient slept until 8 p.m., when she showed signs of restlessness. A dose of morphia (gr. 1/6) was then given, and she woke up at 12 p.m. quite comfortable, with slight vomiting. There was no anuria. It was found necessary to give 12 drops of chloroform during the operation on four occasions, in doses of three drops at a time.

CASE 7.—A woman for partial thyroidectomy (Graves's disease). Induction free from excitement. Anaesthesia, perfect. No stridor. Surgeon expressed entire satisfaction. Recovery uneventful.

Advantages and Disadvantages.

When administered with all due precautions and proper technique, alcohol anaesthesia is a great help where other anaesthetics are contra-indicated. There is no risk of coagulation of the blood. The glucose, apart from its diuretic action, is of great value to counteract operative or anaesthetic shock. In fact, no signs of shock have yet been observed. It is not unreasonable to claim that it is a relatively safe anaesthetic. There is no case on record where death could have been directly attributed to this anaesthetic.

Difficulty may be experienced in finding a suitable vein for injection, but in a serious case it would be of very small consequence even if the vein had to be dissected out before the injection.

The induction has been known to take up to 20 minutes, but from experience it is fair to state that when the patient is properly prepared and all other precautions are taken, the period ought to be considerably less. For this reason alone the method may not win favour for routine work where there are several other cases to be dealt with in a limited time.

The relaxation of abdominal muscles is not invariably perfect and there is always hypervascularisation of the tissues. The nursing staff may raise objections, because patients sometimes have incontinence of urine before they waken, and unless they are given morphia at the right moment they may be excited and noisy.

No doubt there is still room for improvement both in the technique and in the apparatus, and I am looking forward to the time when others publish favourable

reports on an anæsthetic which, in my opinion, may be recognised eventually as of considerable utility.

I have to thank Mr. Cairns Forsyth and Mr. R. M. Rowe, of the surgical staff of the French Hospital, for their courtesy in allowing me to use their cases; also Dr. Charles Dusseau, late resident medical officer of the hospital, for his care of the patients before and after the anæsthetics, for his practical assistance in more ways than one, and for his help in keeping the records necessary for the preparation of this article.

CHOLELITHIASIS AS A SEQUEL OF BLACKWATER FEVER.

By KEITH D. FAIRLEY, M.D. MELB.,

M.R.C.P. LOND.,

PHYSICIAN TO OUT-PATIENTS, MELBOURNE HOSPITAL.

(From the Walter and Eliza Hall Institute, Melbourne.)

RELATIVELY few reports of the post-mortem appearances in patients dying from blackwater fever have appeared, but the characteristic changes in the contents of the biliary passages have been recorded by different observers. Arkwright and Lepper¹ found the contents of the gall-bladder to be of such a consistency that they could be turned out as a solid mass. Dudgeon,² Yorke,³ Thomson,⁴ Stephens,⁵ and Manson-Bahr⁶ state that in fatal cases the gall-bladder is filled with dark green inspissated bile, while Whipple⁷ describes this viscus as being typically distended with a dry curdy or finely granular dark greenish-black bile. Ross,⁸ confirming the work of Kingsbury,⁹ found an increased bilirubinemia in 29 out of 30 patients with malignant malaria, the range being from below one unit of bilirubin up to 4.8 units in uncomplicated cases. Schachsuwary¹⁰ observed an increase in the serum bilirubin during and for some days after a malarial attack though in patients with latent malaria it was within normal limits. In 21 patients with blackwater fever Ross found amounts of bilirubin in the serum ranging from just over five units in a specimen 24 hours old to 59 units in a patient dying with suppression of urine. Unless anuria supervened, the reaction to the van den Bergh test was always an indirect one.

The hemoglobin liberated during an attack of blackwater fever is either excreted by the kidneys or is converted into bilirubin, which is dealt with as far as possible by the liver. Yorke and Nauss,¹¹ found that only one-fifth or less of the hemoglobin was injected intravenously into normal rabbits was excreted in the urine. When anuria results, Ross⁸ suggests that possibly obstruction of the whole biliary system may sometimes supervene, leading to a complete cessation of excretion of the liberated hemoglobin and its products.

In malignant malaria the hemolysis is apparently not of sufficient intensity to lead to the formation of pigment stones in the biliary passages, otherwise they would have been found frequently in the numerous post-mortem examinations performed on patients who have suffered from this disease. On the other hand, the findings detailed above show that in severe attacks of blackwater fever conditions are exceedingly favourable for the production of such calculi in the biliary passages, and it is remarkable that no report of the occurrence of biliary pigment stones following blackwater fever could be found in the literature. In the patient whose history is recorded below, a tentative diagnosis of a pigment calculus was made before operation, as it was considered that such an occurrence should be at least as likely a sequel of blackwater fever as of acholic jaundice (familial or acquired hemolytic splenomegaly), in which, according to Piney,¹² pigment calculi are almost

invariably present in all patients who live to a fair age.

A Case Related.

The history illustrates the occurrence of a subacute cholecystitis in a patient with a large biliary pigment calculus, formed presumably as a result of previous attacks of blackwater fever.

A single male, aged 34 years, was first seen on Oct. 4th, 1929, by the courtesy of Dr. E. W. Sutcliffe. The patient had been in New Guinea from 1920 onwards, and within two months of his arrival there he had a continuous fever for a fortnight as the result of an infection with *Plasmodium falciparum*. In 1922 he was ill for a month with another attack of malignant malaria. Thereafter he usually took a daily dose of a quinine salt as a prophylactic measure. However, in 1923 and again in 1929, after he had omitted to take the quinine on each occasion for some weeks, he developed blackwater fever. In 1923 and in 1929 he also suffered from attacks of dysentery, probably of bacillary type. Though some ten pounds below his former weight, he remained for the next three years in apparently perfect health, indulging in strenuous labour on the New Guinea gold-fields before the advent of the Air Service there.

In July, 1929, he was admitted to hospital with the diagnosis of pleurisy and pneumonia, the chief symptoms being a stabbing pain beneath the right scapula increased by deep breathing, a severe pain in the right hypochondrium and in the right umbilical region, greatly aggravated on coughing, and a cough with some pinkish and also some rusty sputum. After nearly eight weeks he sailed for Victoria, but on the third day out from Rabaul he was seized with a severe constant pain in the right umbilical region, radiating through to the back, accompanied by fever and anorexia. The administration of quinine, aspirin, and an unknown mixture was followed within 24 hours by a generalised itchy rash, so all drugs except quinine were stopped. There was no jaundice and vomiting occurred only once. By the middle of September he was apparently well, though he had lost 16 pounds in weight during his illness.

On Sept. 30th, he was again suddenly seized with a constant aching pain about the umbilicus, radiating through to the midline of the back about the level of the twelfth thoracic vertebra. The pain was exactly similar to that which had troubled him on the journey home. Nausea developed and was soon followed by vomiting, while regurgitation of sour fluid and gas into the mouth was troublesome. There was no rigor but chilly feelings were persistent. Within 24 hours of the onset of symptoms jaundice was noted, while the dark colour of the urine had been observed a few hours previously. The temperature at this time was 103.8° F. On Oct. 2nd the patient was admitted to hospital, and soon afterwards a mild rigor occurred. A slight degree of fever was present next day, and grs. 15 of quinine bichloride were taken, with subjective improvement. The patient came under observation on Oct. 4th. He had never previously suffered from indigestion or flatulence. There was no trouble with micturition, the bowels were regular, and there was no history of venereal disease nor of any over-indulgence in alcohol.

Examination revealed definite jaundice of the conjunctiva and skin, while the remains of a diffuse dermatitis, probably the result of the ingestion of some drug, were visible. The temperature was 98° F., the pulse rate being 96 per minute. No abnormality was detected in the heart or the lungs. On deep inspiration the spleen was palpable two fingers-breadths below the rib margin but was not tender. The liver edge could be felt at the costal margin, and there was a localised point of considerable tenderness immediately below the ninth right costal cartilage. The urine contained a trace of albumin and much bile-pigment, but no sugar, no urobilin, and no hemoglobin. Microscopic examination revealed the presence of bile-stained calcium oxalate and uric acid crystals. The stools were clay-colored. The hemoglobin estimation (Sahl) was 90 per cent., the red cells numbered 4,600,000 per cubic millimetre, and were apparently normal in the films, which on two separate occasions failed to reveal any malarial parasites. The differential leucocyte count showed 12 per cent. of eosinophilic cells, 60 per cent. of polymorphonuclear neutrophilic cells, 4 per cent. of basophilic cells, 20 per cent. of lymphocytes, and 4 per cent. of large mononuclear and transitional cells. No reaction followed the intradermal injection of hydatid fluid for the reason test, nor was any reaction obtained with complement-fixation tests for hydatid disease and trypan. The patient was given grs. 20 of quinine bichloride daily by mouth.

On Oct. 6th the general condition was apparently unaltered, but a small tender mass could now be felt in the region of the gall-bladder. No malarial parasites were found in the blood films. The leucocytes numbered 6500 per cubic millimetre, while a differential count showed 12 per cent. of eosinophilic cells, 66 per cent. of polymorphonuclear

neutrophile cells, 1 per cent. of basophile cells, 28 per cent. of lymphocytes, and 4 per cent. of large mononuclear and transitional cells. Microscopic examination of the stools revealed the presence of soaps but no neutral fats and no parasites. A very occasional structure was stained with bile-pigments, and chemical tests revealed the presence of bile-salts and stercobilin. There were ten units of diastase in the urine and 36 mg. of urea per 100 c.cm. of blood. The blood-serum yielded a biphasic van den Bergh reaction, the colour appearing in ten seconds and deepening for some minutes.

By Oct. 13th the patient had been afebrile for four days and the jaundice was less intense, but in the next five days the temperature rose every 44 to 48 hours to 100° F. and on the alternate days to 99.2° F. At midday on Oct. 18th a rigor occurred. The red cell count and hemoglobin percentage were unaltered but the leucocytes now numbered 9000 per c.mm. No malarial parasites were seen and the physical signs were unchanged. The dose of quinine was reduced to grs. 10 daily and in preparation for operation 15 units of insulin with 30 g. of glucose were given daily. Calcium chloride in doses of 5 c.cm. of a 5 per cent. solution was also given intravenously. By Oct. 24th the temperature had been within normal limits for four days and the jaundice was decreasing. Mr. Cedric Roche opened the abdomen and found a subcutaneously inflamed gall-bladder with thickened walls densely adherent to the bowel. The gall-bladder was drained after removing a large oval calculus, measuring 5 × 2.5 cm., which completely filled the gall-bladder. The calculus in bulk was black in colour, though when smeared on white paper it left a brown stain, while the smallest particles broken off had a reddish tinge. The superficial parts of the calculus were friable and on firm pressure the stone was easily fractured. There was no obvious nucleus and microscopic examination showed the mass to be amorphous. Analysis proved the calculus to be composed practically entirely of bilirubin with some calcium bilirubinate, though traces of cholesterol were detected chemically. No bile-salts were found.

A week after operation the fragility of the patient's red blood corpuscles to hypotonic saline solutions was tested. In the control, hemolysis commenced in 0.45 per cent. and was complete in 0.35 per cent. saline solution. With the patient's corpuscles, hemolysis commenced in 0.40 per cent. and was complete in 0.30 per cent. saline solution. There was thus definite evidence of increased resistance of the red cells to hypotonic saline solutions, exactly the reverse condition to that found in acholuric jaundice. A reticulocyte count a fortnight after operation showed only 0.1 per cent. of reticulocytes in the blood films. In acholuric jaundice the reticulocyte count is usually greatly increased. On Nov. 7th the jaundice had disappeared, the stools were of normal colour, the patient had made an uninterrupted recovery, the wound was almost healed, and the spleen was no longer palpable. No quinine had been taken since the operation. There was occasionally a little burning urethral pain on micturition, and microscopic examination of the urine showed calcium oxalate crystals, a few pus cells, and granular and hyaline casts.

The patient remained in excellent health for the next seven weeks, putting on 22 pounds in weight. On Dec. 26th, after exposure to a cold wind, he had a shiver and later vomited. Within the next two days an obstructive jaundice developed, with dark urine and clay-coloured stools. On Dec. 29th he was seen by Dr. I. H. Cowling, who has kindly supplied the following notes. Examination showed obvious jaundice. The temperature was 101° F., the pulse-rate being 90. The tongue was dirty and there was tenderness over the old wound, in the centre of which there was a stitch abscess from which a catgut knot was extracted. Calomel was given in divided doses, and also a mixture containing sodium salicylate, sodium bicarbonate, and sodium benzoate. Next day the temperature was normal and remained so for the next ten days, during which time the tenderness disappeared and the jaundice diminished slightly. In the next three weeks, however, the jaundice became progressively worse, while sleep was almost impossible because of the intense intractable pruritus.

On Jan. 28th, 1930, the patient again came under observation. He stated that for the previous week the temperature at 6 P.M. had never been below 100° F. and that on the day before it had reached 102.5° F. Constipation was very troublesome, and latterly there had been some irritation on passing urine. The jaundice was increasing in intensity and the pruritus was unbearable. Examination showed that the breath sounds were rather diminished at the base of the right lung, the liver edge was just palpable at the costal margin, and the spleen could be felt on deep inspiration about two fingers-breadths below the costal margin. There was no tenderness anywhere in the abdomen.

After preliminary treatment with glucose, insulin, and calcium chloride, Mr. Roche explored the abdomen on Jan. 30th, 1930. Two pigment stones, each about the size of a cherry, were removed from low down in the common

bile-duct, which was dilated behind the obstruction, its diameter being about half an inch. White bile was present in the duct, which was drained. The walls of the gall-bladder were thickened but the viscous was not dilated. A cholecystectomy was performed. Microscopic examination of the gall-bladder showed the presence of a chronic cholecystitis. Dr. R. Wright-Smith reported that the epithelium was intact and showed no increase in fat content. The submucosa was infiltrated with lymphocytes and large mononuclear and plasma cells, and contained numerous dilated capillaries. The muscle and serous coats were thickened and were infiltrated with lymphocytes and large mononuclear cells. All coats showed evidence of fibrosis, both mature and young fibroblasts being present. A fairly large collection of fat was observed in the subserous tissue. Analysis of the calculi showed that a thin outer crust of the stones was composed of cholesterol while the remainder consisted of bilirubin with a small amount of calcium bilirubinate.

Discussion.

The only disease in which biliary pigment calculi are commonly found is acholuric jaundice. In the case reported here the increased resistance of the red blood corpuscles to hypotonic saline solutions and the low reticulocyte count are sufficient to exclude this disease.

It is realised that one example of the occurrence of a biliary pigment calculus in a patient who had previously suffered from blackwater fever by no means proves the aetiological relationship of this fever to the formation of the calculus. However, on theoretical grounds it seems probable that such calculi should be not uncommon sequelae in patients who recover from a severe attack of blackwater fever. Evidence in favour of this is found in the results of the van den Bergh test in such patients and still more so from the results of post-mortem examinations in those dying from this disease.

In Victoria the opportunity of examining a patient who has suffered from blackwater fever rarely arises, and the object of this paper is to direct attention to a possibly not uncommon sequel of the disease in the hope that others with greater opportunities will be able to prove or disprove the views recorded here. Routine examination by cholecystography of patients who have in the past suffered from blackwater fever would give valuable evidence of the presence or absence of gall-stones. That such stones were pigment calculi would have to be determined after operation or post-mortem examination, though the fact that clinically these calculi were latent and failed to give rise to the usual symptoms of flatulent dyspepsia—so common in the ordinary case of gall-stones arising as a result of infection of the gall-bladder—would be evidence in favour of their metabolic origin. Should such calculi prove not uncommon sequelae of blackwater fever, appropriate treatment directed to flushing of the biliary passages might be valuable as a prophylactic measure.

Pigment gall-stones seem likely to occur as sequelae in other forms of hæmoglobinuria, more particularly as a result of the recurrent attacks of paroxysmal hæmoglobinuria.

I am indebted to Miss B. Splatt, who analysed the biliary calculi, and to Dr. R. Wright-Smith, who reported on the histological appearances of the gall-bladder.

A few cases of surgical tuberculosis were also tested; these included joint disease, tuberculous peritonitis, and renal tuberculosis. All the cases of active tuberculosis gave figures exceeding 40. An average figure of 103 was obtained, whilst five cases gave readings above 150, the highest recorded being 198. These high readings are of interest in view of Verne's statement that a figure of 150 was rarely exceeded in tuberculosis. Several serial tests were performed and as activity diminished so also did the figure for the optic density with resorcin. The average figure of 28 was obtained for inactive cases, whilst six sera from patients with tubercle bacilli in the sputum gave figures below 15, varying between 4 and 13. These cases were all inactive, but nevertheless tubercle bacilli persisted in their sputa. It is

neutrophile cells, 1 per cent. of basophile cells, 28 per cent. of lymphocytes, and 4 per cent. of large mononuclear and transitional cells. Microscopic examination of the stools revealed the presence of soaps but no neutral fats and no parasites. A very occasional structure was stained with bile-pigments, and chemical tests revealed the presence of bile-salts and stercobilin. view a series of determinations of the total protein, the total globulin, and the Vernes index were performed on 22 different sera. For the sake of simplicity the globulin and total protein figures for the sera were estimated photometrically, and the results shown in the following Table were obtained.

A = Optic density. C = Percentage albumin.
B = Percentage globulin. D = Total protein globulin $\times 100$.

A.	B.	C.	D.	A.	B.	C.	D.	A.	B.	C.	D.
7.5	3.3	7.3	45.8	51	3.7	8.2	44.9	125	3.9	4.4	88.7
10	2.66	7.3	34.1	61	4.7	8.5	55.3	125	4.3	8.0	53.5
17	2.7	8.8	30.7	66	4.0	8.8	45.5	134	5.0	6.1	77.8
17	3.72	8.6	43.3	71	4.0	6.5	60.9	134	4.2	6.0	70.0
21	2.8	8.2	43.5	77	3.8	7.4	51.8	121	4.2	5.6	74.4
21	2.8	8.6	43.5	81	5.2	7.4	69.8	165	4.6	7.6	60.3
31	3.1	8.4	36.9	94	4.6	8.8	52.3				
31	3.0	9.0	33.8	113	4.7	7.6	61.8				

Obviously the Vernes resorcin test is neither dependent on the percentage of globulin in the serum nor on the proportion of globulin to total protein. The most that can be said is that there is a general trend for the globulin to increase as the optical indices do. The high figures were obtained in cases of active phthisis. Sera denuded of globulin by saturation with magnesium sulphate gave no increase of density with resorcin, whilst artificial increases of the optical indices in normal sera were obtained by the addition of globulin. An attempt was also made to correlate the findings with the various fractions of globulins, such as eglobin and pseudoglobulin 1 and pseudoglobulin 2, but no definite relationship could be demonstrated. It seems, therefore, that the important factor is not so much the actual quantity of globulin present in the serum, or its proportion to the total protein as its colloidal dispersion. With an increase of globulin, the particles of which are larger than those of albumin, the circulating blood plasma is less dispersed. This was pointed out in 1927 by J. Daranyi in comparing the value of the physical colloidal chemical investigations of the blood with the "immune-diagnostic" methods in the diagnosis of tuberculosis.

With the decrease of the dispersion the flocculation of the serum by various physical agents is augmented, or the colloidal lability becomes greater. After several comparative examinations with different physical agents, Daranyi arrived at the conclusion that the method of colloid lability is best combined with that of refraction—the latter giving approximately the protein content. From the refraction the quantity and from the colloid lability the dispersion of the serum is estimated, both these values expressing the protein structure. In incipient cases refraction is normal and colloid lability in most cases, if not strong, is at least positive. In chronic cases both values are increased. In grave cases there is low refraction with very strong colloid lability. In serial examinations the increase of refraction and colloid lability indicate a progressive tuberculous disease and a decrease of both indicates healing. This is precisely what can be demonstrated both with the resorcin test and by means of the sedimentation rate of the red cells.

During the course of this work an attempt was made to apply the test to the blood of cattle. Blood made from both normal and tuberculous cows was obtained, but no results of diagnostic value can be recorded; indeed, some of the optical indices obtained from the infected animals were actually lower than the figures for the sera of normal animals. This is probably explained by the fact that there is a decrease in the globulin content of the plasma of cattle suffering from tuberculosis. No reliable results could be obtained on the sera of laboratory animals which had been inoculated with tuberculous material, and we were unable to confirm the statements of certain of Vernes's collaborators that the test could be usefully employed to expedite the diagnosis of

tuberculosis by the withdrawal of blood after 14 days from the experimentally infected animal.

With a view to further investigating the possibility of an increase in globulin affecting the optical index of fluids when mixed with resorcin, 100 consecutive specimens of cerebro-spinal fluid were examined and positive results were obtained in cases of tuberculous meningitis by applying the slightly different technique described by Vernes to the fluid itself. If a comparison with normal fluids be made, perfectly satisfactory results are obtained, but it is not possible to differentiate a tuberculous meningitis from any other meningeal infection by this means. In all cases where a globulin increase occurred a raised optical index was recorded. As in the case of the blood, the chief value of the test appears to be in a negative result. It seems that, in cases of suspected tuberculous meningitis where it is not possible to demonstrate the presence of the tubercle bacillus, an increase of globulin accompanied by a decrease in the chloride content and the amount of reducing-body present, together with a slight lymphocytosis, are better presumptive evidence of tuberculous meningitis than a raised optic density of the fluid with resorcin.

In conclusion, we should like to mention our very great indebtedness to Dr. E. Ofenheim, of St. John's Hospital, Lewisham, who introduced the Vernes syphilitic test and the resorcin test to this country and who has been so kind as to demonstrate the technique and explain the intricacies of the special photometer employed. It is only through his great interest in the matter that we undertook this investigation. We should also like to thank Dr. W. C. Fowler, superintendent of Pinewood Sanatorium, for sanction to carry out this work and for his valuable help and suggestions; Dr. J. C. Muir, medical superintendent of Whipps Cross Hospital, for supplying blood specimens from several cases of tuberculosis, and from patients suffering from diseases other than tuberculosis, also for his copious notes on the cases; and Mr. R. J. Parris for much of the technical work which he has most skillfully carried out.

Conclusions.

1. The Vernes test cannot be considered specific for tuberculosis. 2. Its chief value in diagnosis is that a figure below 30 contra-indicates active tuberculosis; the converse does not obtain. 3. The results are very valuable in prognosis and as a guide to treatment. 4. A persistently high figure, despite apparent clinical improvement and diminished activity, indicates an unfavourable prognosis, whilst a low figure accompanying an active condition permits of a more hopeful outlook. 5. Exacerbations and the return of activity are foreshadowed by a raising of the index before any change in the general condition of the patient or in the temperature chart are observed. 6. The test has no value in the diagnosis of tuberculosis in animals. 7. There is close agreement between the Vernes resorcin test and the suspension stability test (sedimentation rate of the red cells), and both probably depend on the altered colloid lability of the blood in tuberculosis.

Clinical and Laboratory Notes.

PRIMARY CARCINOMA OF LIVER IN A CASE OF HÆMOCHROMATOSIS.

By JOHN W. ORR, M.D., B.Sc. BELF.,

FIRST ASSISTANT PATHOLOGIST, ST. MARY'S HOSPITAL.

In the recorded cases of that comparatively rare condition, hæmochromatosis, cirrhosis of the liver appears to be a constant post-mortem finding. The association between multilobular (so-called alcoholic) cirrhosis of the liver and primary carcinoma of the liver has been demonstrated many times. The following case, in which all three conditions coexisted, seems to be of sufficient interest to record.

The patient, an engineer, aged 54, was admitted to St. Mary's Hospital on Dec. 24th, 1929, suffering from pain in the back, chest, and shoulders. This pain had started six weeks previously and had been continuous; the patient had collapsed several times. Flatulence and constipation were prominent symptoms. There was nothing of importance in the previous history apart from "indigestion" three years before, consisting of pain across the chest after meals; this had been relieved by medical treatment.

Condition on admission.—The temperature was 99° F., the pulse-rate 80, and the respiration-rate 20. The facial expression was rather anxious, the lips and ears showed marked cyanosis, and there was considerable dyspnoea; the teeth were bad, and the tongue furred. The abdomen was distended; the liver edge was palpable two inches below the right costal margin, but the spleen and kidneys were not palpated. There was no evidence of fluid in the peritoneal cavity. The chest showed some flattening of the right supraclavicular region and slight impairment of movement and percussion note on the right side, with harsh breath sounds in the right axilla; X-ray examination on Jan. 9th, 1930, suggested old chronic tuberculous foci in both lungs, with a more recent lesion at the right apex. The cardiovascular and nervous systems were normal. Urine examination showed a specific gravity of 1030, an acid reaction, and no abnormal constituents.

On Jan. 14th there was some increase in the abdominal distension, with evidence of fluid and the bowels were still very constipated. Weakness in the legs developed, especially on the left side, with loss of the knee, ankle, and abdominal reflexes; later the patient had to be catheterised. By Jan. 27th he was in a semi-comatose state, still very cyanosed, and showed marked abdominal distension and ascites. The temperature rose rapidly during the last day (Jan. 28th: 97°; Jan. 29th: 6 A.M. 102°; 10 A.M. 104°·5°; 2 P.M. 106°·8°; 5 P.M. 108°·2°), and he died at 6.50 P.M.

Necropsy.

No bronzing of the skin was observed, with the exception of some slight pigmentation of the legs. The abdomen contained about 40 oz. of clear, straw-coloured fluid. The liver was enlarged and weighed 2700 g.; it was reddish-brown in colour and showed the typical coarsely granular surface of cirrhosis over most of the right lobe. Areas of greyish-white tissue were seen in the left lobe (up to 10 × 4 cm.), and smaller and much more scattered foci (up to 2·5 cm. in diameter) of similar tissue were present in the right lobe. On section, these parts were of soft consistency, in contrast with the rest of the liver which offered a considerable resistance to the knife. The largest pale areas showed some central softening, and appeared to be formed by the confluence of smaller nodules. When placed in a mixture of potassium ferrocyanide and hydrochloric acid, the reddish-brown cirrhotic portions of the liver developed an intense blue colour, indicating the presence of free iron in considerable amount, whilst no reaction was obtained in the greyish-white zones. The pancreas and abdominal lymph glands were also reddish-brown and gave a strongly positive Prussian-blue reaction. The spleen was enlarged, congested, and tough, with an increase of fibrous tissue; no iron was demonstrated macroscopically. The kidneys were slightly congested, and did not react for iron. No changes of importance were found in the alimentary canal.

Pleural adhesions were present over the apices and diaphragmatic surfaces of both lungs, and on both visceral pleurae were numerous small grey nodules (3 mm. in average

diameter). At the apex of the right lung was a large pigmented scar, evidently an old tuberculous lesion; there was slight hypostatic broncho-pneumonia of the left lower lobe, and acid digestion of both lungs. The heart showed subpericardial petechiae, parenchymatous degeneration of the myocardium, and a patch of subendocardial hemorrhage on the left side of the interventricular septum. The arteries showed a moderate amount of atheroma. The brain and all other organs were normal. The degree of post-mortem decomposition of all organs was much greater than would be expected in winter 20 hours after death.

Histology.

Liver.—The reddish-brown tissue shows the histology typical of hæmochromatosis; the picture is that of multilobular cirrhosis, together with a heavy deposition of hæmosiderin pigment. Granules of hæmosiderin are present in the parenchyma cells and Küpfer's cells of the adult liver tissue, in the fibrous tissue, and in the cells of the regeneration nodules. The greyish-white tissue is a solid alveolar, polygonal-celled carcinoma, having the histological characteristics of a liver-celled carcinoma. No pigment is present in any of the essential cells of the tumour nodules, though it can be found in the cells of the stroma, even in the central parts of the largest deposits of growth. In sections stained for iron with a mixture of potassium ferrocyanide, potassium ferri-cyanide and hydrochloric acid, and counter-stained with lithium carmine, the growth can be differentiated with ease from the cirrhotic liver tissue and regeneration nodules by the distribution of the blue-stained pigment alone.

Spleen.—Hæmosiderin is present in the fibrous trabeculae and blood-vessel walls, and to a lesser extent in the reticulum cells of the pulp, especially round the Malpighian bodies. A considerable amount of hæmofuscin is also present. Otherwise the histological appearances are those usually found in portal venous obstruction.

Kidney.—Hæmosiderin is present in very small amounts in the lining epithelium of the second convoluted tubules.

Lung.—The scattered pleural nodules show the histology typical of old tuberculosis.

A few similar cases have been recorded, the most complete description, with an extensive review of the literature on hæmochromatosis, being that of Donaldson (1929), whose case differed from the above in that hæmosiderin was absent from the regeneration nodules as well as from the carcinoma cells. Bronzing and glycosuria were absent in his case as in this. Telling and Stewart (1921) mention two cases in both of which pigmentation of the skin was absent, but details are not given. In the case recorded by Blanton, Richmond, and Healy (1921), glycosuria was present and pigmentation of the skin absent. Hæmosiderin is stated to have been present in the carcinoma cells as well as in the cirrhotic liver tissue. Hibbs (1927) found pigment in the liver but not in the tumour; his case was a bile-duct carcinoma, all the others where histological accounts are given being liver-celled growths. Mills (1924) had two carcinomata of the liver in 17 cases of hæmochromatosis. Mallory, Parker, and Nye (1921) found the condition four times in 224 cases of cirrhosis of liver (the total presumably including all types of cirrhosis). Rowen and Mallory (1926), in an analysis of nine primary carcinomata of liver, seven of which were liver-celled growths, state that three of the latter were associated with "pigment cirrhosis." No cases have been found in continental literature.

My thanks are due to Dr. C. M. Wilson for allowing me to make use of the clinical case notes, and to Dr. W. D. Newcomb for his interest and helpful criticism.

THE USE OF EXTRACT OF HOG SPLEEN IN DERMATOLOGY.

By R. M. B. MacKENNA, M.A. CAMB.,
M.R.C.P. LOND.,

HON. DERMATOLOGIST, LIVERPOOL STANLEY HOSPITAL.

DURING the last few months some interest has been aroused by an article on the Instantaneous-physiologic Cure of Eczema and Urticaria by Dr. Thomas M. Paul, of St. Joseph, Missouri.¹ Apparently as the result of the publication of this paper, a leading firm who specialise in the preparation of animal extracts have put a preparation of 40 per cent. isotonic solution of hog spleen on the market, and have titillated the dermatologists with Paul's assertion that "hives (i.e., urticaria) will disappear in 15 minutes, that the itching and oozing of an eczema will cease in half an hour, and that an eczematous lesion, regardless of its degree of lichenification, will vanish in a few days as the result of a hypodermic injection" of this solution. As Paul admits, the statement "seems preposterous," but he adds that "such has been the writer's experience in a series of 61 cases."

On reading his paper one finds that 31 of his patients received one injection; "16 received two; 9 received three; 5 received four; 3 received five; 3 received six; 2 received seven; 1 received eight; 1 ten; 1 eleven; and 1 thirteen injections each." He has treated 44 cases of eczema and 17 cases of urticaria, and these apparently comprise the "series of 61 cases." He has also treated two cases of pruritus ani et vulvæ, and one case of pruritus perinei (sic), and these "recovered promptly," but one is not surprised to learn that one case of miliaria, three of lichen planus, and one of psoriasis failed to respond to this line of treatment.

The following is a record of merely six cases of dermatological conditions which I have treated by the injection of 40 per cent. isotonic hog spleen solution:—

1. Miss A., aged 19, was first seen on April 14th, when she presented a typical urticarial eruption of moderate severity on the trunk. This was her first attack of urticaria, and had persisted for six weeks. No history of dietary indiscretion was obtainable, and no obvious septic foci were found on examination. 5 c.cm. 40 per cent. hog spleen solution were injected intramuscularly. She reported two days later that there had been no improvement in her condition.

2. Mr. B., aged 26, presented a generalised urticarial eruption of moderate severity affecting the trunk and limbs. He had suffered from the disease for 18 months, and a series of protein-sensitisation tests had given no definite results except a mild reaction to wool and horse hair. On marking the skin with the blunt end of a penholder weals developed in 12 seconds and persisted for some minutes. On Feb. 8th 15 c.cm. 40 per cent. hog spleen solution were injected deep subcutaneously into the buttock. Five minutes after the injection the "weal-development-time" was unchanged. On Feb. 12th he was again examined. He stated that the lesions present on his body at the time of injection had disappeared in 24 hours, but 36 hours after the injection he "had a bad attack" during which his eyelids and lips swelled up. On examination the typical urticarial lesions were found on his body, and the eruption was quite as severe as at the time of the injection.

3. Mr. C., aged 60, had suffered from severe urticaria for years. There had been practically no intermissions of the disease during the whole of this time. On Jan. 21st 15 c.cm. 40 per cent. hog spleen solution were injected intramuscularly. No improvement whatever resulted.

4. Mr. D. aged 63, had acute vesicular eczema affecting the arms of one month's duration. On Feb. 28th, 15 c.cm. 40 per cent. hog spleen solution were administered deep subcutaneously. The affected areas were treated with 1-pastille dose of X rays, and he was given a solution of liquor carbolic detergens, and Lassar's paste with 1 per cent. ichthyol as local applications. One Kalzema tablet, thrice daily, after food was ordered. When next seen on March 7th his condition had improved considerably, but not more than one would have ordinarily expected had the injection not been given. The affected areas then presented a scaly erythematous eruption. He stated that no improvement

had occurred during the first three days after the injection, but that there had been a gradual improvement thereafter.

5. Mrs. E. was aged 41. On March 1st she received an injection of 16 c.cm. 40 per cent. hog spleen solution for a lichenified and pruriginous dermatitis affecting the arms and back. The condition had been present for two years, and had been remarkably resistant to treatment. No improvement resulted.

6. Mr. F., aged 74, had been under treatment since November, 1929, for an acute seborrhoeic dermatitis affecting the head, ears, neck, and body. His condition had improved but slowly, and on March 18th, 1930, he reported that there had been a fresh outbreak affecting the arms. On examination one found an acute seborrhoeic dermatitis of the arms with considerable serous exudation; 15 c.cm. 40 per cent. hog spleen solution were given intramuscularly, and dressings of calamine lotion were applied. Three days later he reported that "the arms had dried up within 24 hours of the injection." The condition had definitely improved; there was no exudation, but there remained a scaly erythematous dermatitis of moderate severity.

The six cases detailed above cannot be compared either in number or in effect with the series of 61 cases of "instantaneous-physiologic cures" which have been published in America. Despite the moderate improvement recorded in Case 6 I am extremely sceptical as to whether injections of 40 per cent. hog spleen solution are of the least value in the routine treatment of the commoner dermatological conditions.

NAUHEIM TREATMENT AND CARBON DIOXIDE FOAM BATHS.

By L. SHILLITO, M.B. CAMB.,

CHIEF ASSISTANT IN THE ELECTROTHERAPY DEPARTMENT,
ST. THOMAS'S HOSPITAL.

THE warm effervescing waters of Nauheim, in Germany, have become famous for their success in the treatment of cardiac weakness. The water is heavily charged with carbon dioxide, and also contains calcium chloride in solution, with other salts in smaller quantities, and various attempts have been made to introduce "Nauheim treatment" with artificially prepared solutions. Formulae for this purpose may be found in Kellogg's "Rational Hydrotherapy,"¹ or Martindale and Westcott's "Extra Pharmacopœia," but the recent invention of what is known as a bubble or foam "distributor" (Baderost), for use with a cylinder of carbon dioxide and a little saponin solution, makes the whole process far more simple and easy to administer efficiently. It is doubtful whether the calcium chloride used in the chemically prepared baths has any effect beyond raising the specific gravity of the solution, as it is not absorbed, the main physiological effects being due to the carbon dioxide and to the temperature of the bath. The so-called "foam bath" apparatus has only been introduced into this country within the last year, and so far has not met with the serious consideration that it deserves, though on the Continent, and particularly in Germany, it has been widely used for some while with good results.

As I have now had the opportunity of some experience of this new method of giving Nauheim treatment, a practical description may help to popularise a form of treating heart disease of which the good results have long been well known, but in which the practical difficulties of administration were too great for it to be very much used in ordinary practice. All that is now required to carry out this treatment is a foam distributor obtainable either in this country or, more cheaply, abroad, a cylinder of carbon dioxide and the saponin solution, which can be bought from any good manufacturing chemist.

Administration.

The distributor consists of three parallel pipes held together in a frame and perforated along their length with a series of holes. Over these apertures are a number of porous blocks

¹ Urologic and Cutaneous Review, 1929, xxxiii., No. 11.

of wood. The pipes are joined at either end and connected with the cylinder of gas, which escapes through the porous wood as very fine bubbles. If the bath is filled with water and the gas turned on, a simple aeration or bubble bath results; if, however, the distributor is only covered with a few inches of water, to which a little saponin solution has been added, a fine dense foam is formed which gradually fills the bath. The procedure is as follows.

1. Soak the distributor in water for some hours before use to allow the wooden blocks to swell and prevent leakage of gas between them. To prevent it scratching the bath, a rubber mat may be laid under it.

2. The bath is half filled with water at a temperature of 94-97° F. and 20 c.cm. of foam extract (saponin solution) is added. This is mixed well with the water before turning on the gas or air, a point of importance in securing fine foam free from large bubbles.

3. Compressed air is pumped through the distributor until a layer some inches thick of air-foam has been produced. In the absence of an electric air pump, an ordinary motor tyre pump can be used quite effectively. The air-foam cover prevents the carbon dioxide from escaping, as carbon dioxide foam will not last unless it is protected in this way.

4. Carbon dioxide is now bubbled through the distributor at a pressure of 0.15-0.2 of an atmosphere. The patient gets into the bath and remains there for 5-20 minutes, carbon dioxide being bubbled through the distributor the whole time. A rubber back rest and a folded towel as a head rest add to the comfort of the patient, who should be immersed in the bath up to his neck. The temperature of the bath is maintained by adding more hot water from time to time. No hard-and-fast rule can be laid down for the management of all cases, the duration of the bath and its temperature depending upon the degree and kind of disease, the pulse-rate, blood pressure, and personal idiosyncrasies.

5. Before, during, and after the bath its temperature and that of the patient are taken, and also the pulse, a fall of pulse-rate being aimed at. The blood pressure is also taken before and after the bath, a fall likewise being, as a rule, expected.

6. After the bath the patient goes to bed for an hour, and is not allowed to read, write, or talk during this period. The bed should be kept warm with a hot bottle. To destroy the foam in the bath, sprinkle with a jugful of soft soap solution.

7. At the beginning of a course of these baths, a bath for three to four minutes at 90-97° F. is given, and if the effect of this is satisfactory it may be repeated, and the period of immersion subsequently lengthened up to 15-20 minutes towards the end of treatment. The temperature is correspondingly lowered down to 94° or even 92° F.

8. Baths are given on two or three successive days, followed by a day's respite, and then repeated. The average number of baths in a course varies from 20 to 30, and the duration five to six weeks. Baths on alternate days may be found less fatiguing, and with women should not in any case be given during the menstrual period.

On the days when no bath is given "Schott" resisted exercises may with great advantage be carried out if the services of a skilled administrator are available. In the absence of such a person other suitable graduated exercise may be taken.

Physiological Effects.

1. The type of reaction obtained depends upon the temperature of the bath. Carbon dioxide baths are used practically solely for their effect on the circulation in cardiovascular disease, and in these conditions bathing above an indifferent degree of heat should be discouraged. At a neutral temperature a carbon dioxide bath has much the same effect on the surface circulation as a very hot bath, but has the advantage of avoiding the harmful, primary excitation and secondary depression produced by heat. As Hediger⁷ points out, the carbon dioxide bath is the only physical method of treatment in which the heart muscle is trained without at the same time increasing the frequency of the beat. The slowing of the pulse-rate extends the period of diastole and enables the coronary vessels to be better filled with blood, which must tend to improve the nutrition of the myocardium. The blood pressure may fall 20 mm. of mercury during the course of one of these baths. In baths under indifferent degrees of temperature the peripheral vessels are contracted, the blood pressure rises, and consequently the work of the heart is increased. By a gradual increase of the carbon

dioxide content and a reduction of the temperature of the bath, the heart can gradually be forced to do more work, and through this increasing exercise its musculature becomes strengthened, the tone increased, and reserve power augmented. The sensation of warmth produced by the strong circulatory reaction allows a lower temperature to be tolerated without shivering.

2. The powerful vasomotor effects are produced reflexly by the adhesion and bursting of myriads of small carbon dioxide bubbles against the skin, stimulating the superficial nerve-endings and producing redness and vaso-dilatation.

3. Viscera are relieved of congestion and the activity of the peripheral vessels greatly lessens the labour of the heart, and secures a better distribution and a more accurate movement of the blood throughout the body.

4. The increased activity of the skin lessens the strain on the kidneys, whereas diseased kidneys are likely to suffer serious injury from the temporary congestion which results from the contraction of the surface blood-vessels after either a hot or a cold surface application to the body.

5. A continuation in improvement of health for some months after the course of these baths is due, probably, to the comparatively slow and gradual process of repair in degenerated organs, provided, for the first time possibly for some years, with a more healthy and less abnormal circulation.

Indications.

The principal indication is myocardial weakness—for example, the dilated, feeble, and irritable heart following influenza and other fevers. Cardiac toxæmia or enfeeblement caused by excessive smoking or a prolonged illness such as typhoid or malaria, angina pectoris, and cardiac asthma are all benefited by this treatment, as may be also anæmia with dilated heart and high blood pressure.

The treatment is not suitable in heart cases with broken compensation, in very marked arterio-sclerosis, or in the very old.

Chronic nephritis may often be benefited, as in this disease the kidneys are likely to suffer serious injury from the temporary congestion resulting from the contraction of surface blood-vessels caused by very hot or very cold applications.

Neutral effervescent baths are also valuable in insomnia and mental excitement generally.

To conclude, the special advantages of the carbon dioxide foam baths are their simplicity, low cost, and the fact that the air-foam cover entirely conceals the patient's body from view, a practical point of some importance. They can be given in a patient's own home, and the distributor can also be used to give a sweating type of foam bath most useful in rheumatic affections.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN.—Last year the in-patients numbered 228, a small increase; there were 10,607 out-patients. The pressure upon accommodation necessitates extensions, and it is hoped to place the in-patient department on a more modern basis and to increase the number of beds from 33 to 64, including a children's ward. Plans for rebuilding on this scale have been approved by the King's Fund. The possibility of acquiring a central site which would comprise both in-patient and out-patient departments is being considered. At present the former is in the Uxbridge-road, and the latter in Leicester-square.

The PRESIDENT said that Dr. Crow's communication had shown that there were cases of foreign bodies in which the direct route was not successful. If the foreign body was large and had been in position a

considerable time, and especially if there were physical signs of rupture of the œsophagus, the direct method should not be attempted, and removal should be carried out by external operation. He had seen patients with surgical emphysema of the neck resulting from the use of the wrong method of extraction. The deeper planes of the neck should be opened as little as possible.

Mr. T. B. LAYTON assumed the coin-catcher would be condemned by Dr. Crow. Yet 9 of the 30 foreign bodies mentioned in his communication were coins. He (Mr. Layton) was generally able to remove a coin in five seconds, and neither chloroform nor any other general anæsthetic was required. There was no need to use the endoscope for coins except when a coin got below the cricoid. In using the coin-catcher there should be no psychological trauma.

Dr. FRASER said he never used the coin-catcher; but he had had cases to deal with after an attempt at removal had been made in the out-patient department, and he always regretted that such attempts should be made. He could not see why a coin-catcher was preferred to œsophagoscopy or endoscopy. It was always safer and better to remove a coin when it could be seen than to grope for it more or less in the dark. If one failed to extract a tooth-plate after a reasonable time, it was better for an external operation to be carried out, since much damage could be done by hooks. For those cases he recommended a general anæsthetic.

Mr. MUSGRAVE WOODMAN also deprecated the use of the coin-catcher. In 50 per cent. of the cases in which it was employed the coin was pushed into the stomach, and then gastrostomy might be needed for its removal. It was said that it was easy to cut tooth plates in half to remove them, but he found that very difficult.

Mr. HAROLD KISCH agreed with Mr. Layton that the coin-catcher had a definite use. He thought that every student ought to be taught how to use it properly, since many would be practising in regions out of the reach of experts. The mortality from inexpert use of the endoscope would be higher than from the use of the coin-catcher. During the war the latter instrument had enabled him to extract many metallic foreign bodies in the absence of an endoscope.

Dr. DOUGLAS GUTHRIE referred to extraction by tracheotomy when the foreign body was below the glottis.

Mr. W. S. THACKER NEVILLE gave reasons for considering that the coin-catcher should be relegated to the museum.

Mr. HERBERT TILLEY said he had not seen a coin-catcher for 20 years. Even in the depths of the country an expert at œsophagoscopy could be procured for a case within a reasonable time, and these cases were practically never desperately urgent.

Mr. E. WATSON-WILLIAMS said his own teaching to students was that both the coin-catcher and the probang should be in the museum. An analysis of Chevalier Jackson's cases showed that all the fatal cases but one were due to the unskilful use of either the probang or the coin-catcher before the patients were brought for skilled endoscopy. The speaker had had two bad experiences in cases in which the probang had been tried.

Dr. RITCHIE RODGER feared that if the use of the coin-catcher were taught to students they would not restrict its use to coins when they were in practice.

Dr. A. BROWN KELLY read a paper on

CONGENITAL STENOSIS OF THE ŒSOPHAGUS ASSOCIATED WITH HIATAL HERNIA.

He described four cases in young children of œsophageal stenosis associated with hernia in the lower end of the stomach and the hiatus œsophagus. In all four cases the pregnancy was normal and the infant

at birth was healthy; persistent vomiting and palpitation were the sole disabilities. One child was brought to hospital at the age of four weeks because of vomiting after its feeds; it did not take any food until the fourth day after birth. The obstruction was 20 cm. from the lips. Barium was given, and was shown by X rays in three large collections, one above the other. Special methods had to be used in these cases to dilate the sac—for example, with barium—otherwise the cause of the symptoms was likely to escape observation.—Mr. WATSON-WILLIAMS said this contribution provided him with the key to a case which had puzzled him, that of a patient aged 37 who had had swallowing difficulty for 17 years, and who was sent to him labelled carcinoma of the œsophagus. The patient when examined under general anæsthesia was found to have a constriction midway down the chest, which opened easily under the œsophagoscope, and the examiner found himself looking at the gastric mucosa.

Mr. WATSON-WILLIAMS read a paper on

GRANULOMA OF THE LARYNX FOLLOWING EXPOSURE TO IRRITANT GAS.

The general health of patients with granuloma due to mustard or other irritant gas might be good, but cough and expectoration would be present, and examination would show a semi-pedunculated, slightly crenated, reddish tumescence spreading from the sub-glottic region. Sometimes this tumescence was sufficiently movable to be blown up between the cords. Quite a long interval might elapse between the exposure to irritant gas and the formation of the tumour; in Mr. Tilley's case it was 15 months, in Mr. Bell Tawse's it was 14 years, and in the reader's own cases the intervals were 5½, 7, and 9 years. In all there had been some continuity of symptoms from the time of exposure to the gas to the discovery of the tumour. More definite knowledge showed that revision of pension decisions might justly be made.—Sir STCLAIR THOMSON thought some of these cases, which were quite rare, might be associated, in the first instance, with submucous hæmorrhage.—Mr. BELL TAWSE described a case, and asked whether members could support his present contention that the man should be granted his pension.

Dr. GUTHRIE and several other members of the Section agreed that he should.

Mr. NEVILLE contributed a paper on

AVERTIN AS A BASAL NARCOTIC IN LARYNGOLOGY.

He said avertin was most safely given by the rectum. Three contra-indications were kidney disease, low pressure, and grave sepsis and empyema. He claimed that it was non-toxic, harmless, quick in action, banished dread of the operation, and was especially suitable for children. Avertin was not itself an anæsthetic, but was a basis for a narcotic. He described in detail his method of procedure.

Sir STCLAIR THOMSON pointed out that the state of unconsciousness for two hours and sleepiness for three days was, especially in laryngeal conditions, something strenuously to be avoided. The absence of laryngeal reaction in these patients after the use of avertin was very alarming.

Dr. FITZGERALD POWELL described his use of the drug and concluded that it was not a safe anæsthetic.

Mr. V. E. NEGUS thought there were great objections to this drug; with the patient on the move and able to carry on a conversation it was hopeless to attempt any intranasal operation.

Mr. NEVILLE, in reply, agreed with some of the criticisms, but contended that its use was justified chiefly because of its psychological advantage, particularly in the case of children.

The afternoon session was devoted to the examination and discussion of clinical cases.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this Section was held on June 21st at the Jenny Lind Hospital, Norwich, the President, Mr. H. A. T. FAIRBANK, occupying the chair. The cases exhibited and discussed included the following.

Arrested Development: Neanderthal Physiognomy.

Dr. A. J. CLEVELAND showed a young man, aged 22, who, though healthy at birth, suffered retardation of growth in infancy. He never had the aspect of a typical cretin. When Dr. Cleveland first saw him 16 years ago his appearance was very much that of primitive ancestors, and the case illustrated Sir Arthur Keith's remark in his "Antiquity of Man" that certain types of primitive man and of pathological man closely resembled one another. At 4 years of age the patient had beetling brows, a bowed back, a shuffling gait, and a curved lower jaw. X rays showed that the well-developed superciliary ridges were due to large frontal sinuses. There was a defective mentality. The patient would not go to the dentist to have his teeth examined. Though in early childhood he did not respond to thyroid, he did so at a later stage, and between April, 1927, and October, 1929, he had grown $9\frac{1}{2}$ inches. The sella turcica seemed normal.

Sir HAMILTON BALLANCE showed a case of

Double Colon

in a girl aged 10. At the lower end of the posterior vaginal wall were two distinct rectal orifices, one on the right, the other on the left. One and a half inches behind the anal orifice was an anal dimple in the perineum. An attempt in London to cure the imperforate anus had failed, and a further attempt at a Norwich hospital had no better result. Sir Hamilton did a temporary colostomy in the transverse colon in order to secure a clear field for the perineal operation, and four months later the colostomy wound was closed. The operation disclosed that the doubling extended nearly to the cæcum. He excised some inches of the transverse colon, and he showed a specimen of it, with skiagrams. There was a perfect septum between the two coli, and the septum contained some fibrous tissue, but probably no muscle. Three examples of double intestine were in the College of Surgeons Museum; the only explanation Sir Arthur Keith could suggest for the present case was that it represented a feeble attempt at dichotomy, which had failed.

Dr. H. J. STARLING showed the following three cases.

Persistent Pyrexia.

The question arose whether a girl of 15 who had persistent pyrexia was the victim of Still's disease. In April, 1923, she was admitted to hospital because of a two years' history of persistent pyrexia, over a range from 99° to 104° F., accompanied by pain and swelling in most of the joints, and cardiac symptoms which suggested infective endocarditis. Her head was bent forward, because of fixation of cervical vertebrae, and, even under an anæsthetic, the full range of the opening of the mouth did not exceed $\frac{1}{4}$ inch. The left wrist was completely ankylosed, and movement in knee- and ankle-joints was restricted. With difficulty—owing to the partial closure of the mouth—the tonsils were removed, and treatment was carried out by means of polyvalent anti-rheumatic vaccine and intramuscular peptone injections, with great improvement for a considerable time. But last September she was readmitted because of a relapse during the preceding three months. Her white cells were now 32,500, and during attacks of increased temperature they varied between 56,000 and 7400. Blood culture and examination of feces and urine were negative, nor was there evidence of

focal infection. Protein shock was induced, the agent used being D'melos, and last January she was discharged much improved. She had since relapsed again.

Celiac Disease.

A boy 11 years old was healthy at birth, but at 9 months old, when weaned, he began to dwindle and became exceedingly thin. Some degree of rickets was present. He improved, but the abdomen was always large and the motions loose. In 1924 he had attacks of tetany. He was given a fat-limited diet, and some time after this was begun, though the stools were very bulky, they were normal in colour and less offensive than before. They contained much fatty acid crystal and undigested muscle-fibre. He was kept on a fat-free diet for four years, by which time he was going to school and playing games. He was now in a cadet corps, and ate eggs, meat, chicken, fruit, vegetables, rice puddings, and cornflour made without milk. No fats as such were eaten.—Dr. ENO FRUTCHARD raised the question whether in such a case as this the absence of fat from the diet, per se, was of great importance in regard to maintaining the nutrition. The important matter was the absence of fat-soluble vitamin, and that could be easily put right without supplying fat. He gave such cases cod-liver oil, carotene, and other substances. The manufacturers of a certain brand of margarine were deliberately incorporating in their products a tasteless fat-soluble vitamin. Suet-beef was excellent for these cases.

Syngomyelia with Retrobulbar Neuritis.

He had made this tentative diagnosis in a girl of 15, the chief feature of whose case was the marked remissions which occurred. The mother had an enlarged thyroid and was deaf, otherwise the parents were healthy. In July last this girl's leg began to drag, and she was in bed three weeks. Then she was able to walk normally for a month. At the end of the month leg-dragging was resumed, and only on two or three subsequent occasions had she been able to walk, and then only with difficulty. She said the legs felt numb. She had incontinence of urine in the night, and sometimes also in the day. Appetite had remained good, and the bowels were regular. Heart and lungs appeared to be normal. Her back was curved, with the convexity to the left in the dorsal region, the ribs on that side forming a prominence. Both knee-jerks were feeble; the left ankle-jerk was absent, as were also the biceps-jerks. In both hands there was a marked loss of power. The pupils reacted to light and accommodation, but the left disc showed partial atrophy, which Dr. G. Maxted attributed to retrobulbar neuritis. The left field showed a central scotoma. On lumbar puncture the fluid was clear, and globulin and sugar contents were normal. The Wassermann was negative in both blood and c.s. fluid. Coliform bacilli were present in urine obtained by catheter. After treatment at Norwich and at Guy's Hospital the girl could walk normally, but a week ago she relapsed; there was now no power in the limbs and both knee-jerks were absent.—Dr. WILKIE SCOTT suggested that the girl might have encephalomyelitis, which, in a subacute stage, could cause a patchy distribution, and this might be a forerunner of disseminated sclerosis. Dr. Starling did not think this likely.

Mr. F. K. HAYMAN exhibited a boy, aged 14, who was the subject of

Cerebral Hemorrhages.

When 10 years of age the boy found his left leg useless on dismounting from his bicycle. He was fully conscious and remembered all details. His pulse-rate was found to be 84, and there was no history of injury, yet he was found to have (1) complete flaccid paralysis of the left arm and hand; (2) partial spastic paralysis of the left leg, with feeble knee-jerk and extensor plantar response; (3) partial

paralysis of the left side of the face; (4) hemi-anæsthesia of left side (back and front) extending from head to foot. On the following day he had left oculomotor paralysis. Rapid improvement followed, and in 3½ weeks he could walk fairly well and use his hands. He was thought to have had a small hæmorrhage in the right crus cerebri. Last February, while doing clerical work, he had severe headache at the vertex, with vomiting, but there were no physical signs, and both pulse and temperature were normal. On the following day, however, the headache was worse and he had head retraction. Mr. Hayman thought the patient had a leaking congenital aneurysm at the base of the brain, and that the first symptoms were due to rupture of it, and the subsequent ones to leakage. The Wassermann was negative.—Dr. A. A. MONCRIEFF asked whether ligation of the right carotid artery might be of benefit; this might conceivably save the patient further hæmorrhages, with a possible fatal termination.—Dr. WILKIE SCOTT spoke of a patient, a boy, who had three recurrences of bleeding, the third being fatal. Blood was mixed with the cerebro-spinal fluid, and all his attacks came on after exertion. In another patient on two occasions attacks came on after riding a bicycle. A month ago Dr. Scott had made a post-mortem examination on a man, aged 25, who appeared quite healthy, was a teetotaler and non-smoker. He was suddenly seized with severe pain in the head and became unconscious. A month later he had a similar attack and died in it. A cerebral aneurysm half the size of a hazel-nut was found. Usually these were regarded as cases of meningitis.

Mr. G. MAXTED showed a girl 10 years of age who had

Unilateral Exophthalmos.

On the admission of the girl to hospital in July, 1927, because of carditis, proptosis of the right eye was noted. Since December of that year she had been in hospital with pericarditis and effusion, and general œdema. There was no accompanying diplopia; the pupil reacted normally and the disc appeared to be healthy. Vision in the right eye was 6/12, but there was a hypermetropia of 3D. The fellow eye was emmetropic. Globe movements were not hampered. There was no nasal abnormality. The heart was enlarged, and there was a loud systolic bruit at the apex, with systolic and diastolic bruits in the aortic area. Mr. Maxted thought she might have a non-malignant tumour of the optic sheath, since the condition was not becoming worse.—Dr. F. J. POYNTON suggested that she might be a rheumatic child with a tendency to hæmorrhages, which when they occurred were gradually absorbed.

Mr. MAXTED also demonstrated a girl aged 6 years with

Bilateral Congenital Dislocation of Lens.

She was brought to the hospital for advice six months ago because she held objects very close to her eyes. Each lens was seen to be partially dislocated and to be the seat of well-marked lamellar cataract. Five months ago the right eye was needled twice. Most of that lens was now absorbed, leaving a clear area in the outer half of the pupil. She was now wearing a correcting lens for this eye.

Mr. M. W. BULMAN showed a boy, aged 8, with

Congenital Scoliosis.

His back had been deformed ever since birth, and he presented a marked lateral curvature in the dorso-lumbar region which was not amenable to corrective efforts. On the right side there was only half a twelfth dorsal vertebra, and there was a twelfth rib on the left side. He asked whether the case called for an appliance to prevent the condition from becoming worse.—The PRESIDENT said these cases were not promising, and he had usually been content to put on a jacket of some kind, particularly for small children who were growing fast.

Dr. B. MORGAN showed a boy, aged 11, who had

Symptoms Associated with Cervical Rib.

He had had weakness in both hands for three years; the hands, with the lower third of the forearms, were blue and cold, and both, but especially the left, were claw hands. It was impossible to abduct the fingers of the left hand. There were no sensory, tactile, pain, or thermic disturbances. X rays showed a rudimentary cervical rib on the right side, and an enlarged transverse process of the seventh cervical vertebra on the left. There was also subluxation of the left sternoclavicular joint. Dr. Morgan said that it was very rare for symptoms to be attributable to cervical rib, and that in this case they were much more likely to be due to a fibrous band which ran to the first thoracic rib. He thought that surgery should be tried.—The PRESIDENT also commented on the rarity of symptoms due to cervical rib.—Mr. ERIC LLOYD referred to a case at Great Ormond-street Children's Hospital in which a child's symptoms had been attributed to cervical rib, but the diagnosis arrived at in hospital was syringomyelia.

In the absence of Dr. V. H. BLAKES his case of

Hirschsprung's Disease Treated with a Rectal Tube

was shown by Dr. MORGAN. The patient was a girl, aged 6, who when eight days old had had extreme constipation and had brought up a motion in the vomit. Castor oil relieved her, but she was always constipated, and the motion passed after a four or five days' interval was very offensive. The abdomen was much ballooned and the child was greatly emaciated. The rectal sphincter was very tight. The treatment adopted was to tie a small flanged empyema tube into the anus at night by tapes attached to a belt. After two nights of this the abdomen became flaccid, and its circumference was 6 inches less. Eserine and pituitrin were given for five months, followed by an enema and lavage in the morning. The patient was now strong and well and the bowels were functioning normally.

EDINBURGH OBSTETRICAL SOCIETY.

A MEETING of this Society was held on May 14th, with the President, Dr. H. S. DAVIDSON, in the chair. A paper on

The Value of the Dick Test in Pregnancy

was communicated by Dr. D. BAIRD and Dr. R. CRUICKSHANK (Glasgow). Last year, they stated, an investigation was conducted at the Glasgow Royal Maternity and Women's Hospital into the value of the Dick test—i.e., the cutaneous reaction to the intradermal injection of scarlatinal streptococcal toxin—as an index of susceptibility to puerperal sepsis. Because of the generally accepted view that the toxins produced by the scarlatinal and puerperal hæmolytic streptococci are identical, it was thought possible that sensitiveness to the one might indicate a similar degree of susceptibility to the other, and, if this were so, that the test might be of value in the prophylaxis of puerperal sepsis.

The Dick test was performed in a series of 600 pregnant women, either during labour or in the last few weeks of pregnancy. Careful histories were taken on cards specially designed for the purpose, particular note being made of previous streptococcal infection—e.g., scarlet fever, tonsillitis, puerperal sepsis—of the obstetric history, and of the health during the current pregnancy. Full particulars were subsequently obtained regarding the mode of delivery, the presence of lacerations, and the puerperium in 500 of these cases; where the puerperium was morbid, even although not notifiable according to the British Medical Association standard, it was classed as puerperal sepsis, care being taken to eliminate those cases of pyrexia due to other causes, such as urinary infection. A number of cases with a positive Dick test who developed pyrexia in the puerperium were retested immediately after the pyrexial

period to see if any change in the reaction had occurred. Some of these were again tested six months later.

It was found that 22 per cent. of pregnant women gave a positive reaction to the Dick test, primiparae giving a slightly higher rate than multiparae, 25 per cent. as compared with 21.5 per cent. The reaction seemed to be more intense in primiparae, irrespective of age, than in multiparae. In the latter there was a decrease in the intensity of the reaction in the older age-groups which might indicate that with each pregnancy the patient had a chance, by repeated slight infection, of becoming more immune. The incidence of puerperal morbidity also became less with advancing years in multiparae, but remained constant for all ages in primiparae.

The incidence of puerperal sepsis was so dependent on the general health of the patient and upon the type of delivery that any reliance on the Dick test as an indication of liability to sepsis would not be justifiable. It appeared, however, that in the present state of obstetric practice an attempt to produce a temporary immunity with a concentrated anti-scarlet serum in all suspect cases at the time of delivery might reduce the incidence of puerperal sepsis.

Drs. BARR and CRUICKSHANK also communicated a paper entitled

A Study of the Vaginal Flora in Pregnancy.

The physiological changes in the flora of the vagina were first reviewed, special attention being drawn to the apparently dramatic change at puberty from a sparse coccal flora and an alkaline reaction to a flora consisting entirely of Döderlein's vaginal bacillus associated with a highly acid reaction of the vaginal secretion. This change had been attributed by Miura, a Japanese worker, to the deposition of glycogen in the superficial vaginal epithelium when ovulation began, and the bacterial fermentation of the glycogen as glucose for the production of lactic acid in such concentration as to destroy all organisms save Döderlein's bacillus. Miura had also stated that in pregnant women there was an increased acidity of the vaginal secretion as pregnancy advanced.

The present investigation dealt with the vaginal flora of 200 pregnant women, a large proportion of whom attended at monthly intervals from the third month of pregnancy until term. Swabs were taken from the vaginal vault and smears and cultures made. The pH of the vaginal secretion which was collected at the same time with a long-handled spoon was estimated by the "capillator" method.

A classification into three grades of vaginal flora was made: Grade A, composed entirely of Döderlein's bacillus, the pH of the secretion varying only from 4.0-4.4; Grade B, containing a mixture of Döderlein's bacillus and diphtheroids, pH, 4.0-6.2; and Grade C, consisting of an abundant heterogeneous flora of diphtheroids, enterococci, staphylococci, and occasionally vibrios and coliform bacilli, pH, 4.8-6.8 with a more common range of 5.2-5.6. Large epithelial cells were particularly numerous in Grade A flora.

Of 200 pregnant women when first seen, 50 per cent. had Grade A flora, 10 per cent. Grade B, and 34 per cent. Grade C. Of the women who were followed throughout pregnancy there was found a remarkable constancy in the vaginal flora and in the pH of the vaginal secretion in those cases with Grade A flora. The women with Grade B or C flora were divided into those with pus cells in the vaginal smear and an indication of infection of the cervix of vagina—and a group with "idiopathic" Grade C flora, that is, an abundant group with the bacterial flora without pus cells. The flora in the former group remained Grade B or C throughout, but in the latter group the flora changed from Grade C to A in two-thirds of 21 cases followed to term, the improvement occurring usually about the sixth or seventh month of pregnancy.

The thesis was formed that there was some relation between the vaginal flora and ovarian activity, a Grade A flora being a reflex of actively functional ovaries whereas hypo-ovarianism was reflected in a Grade C flora. It was held that the association of an idiopathic Grade C flora with greater age and with a tendency to repeated abortion and the change-

over from a Grade C to A flora during pregnancy were findings which supported this view. No evidence has been found to indicate that a Grade C flora increased the susceptibility to puerperal sepsis, but the number of women examined was too small to allow of definite conclusions.

ASSOCIATION OF CLINICAL PATHOLOGISTS.

THE fourth summer meeting was held at the Cheltenham General and Eye Hospital on June 14th. Dr. J. B. Davey, pathologist to the hospital, occupied the chair.—Dr. T. C. Hunt described a combination of a water excretion and urea-concentration test for renal function.—Dr. S. C. Dyke gave a brief preliminary report upon the phosphate concentration test of Brain and Kay for estimation of renal function; he had found the test somewhat unwieldy for ordinary clinical use.—Dr. A. F. S. Sladden discussed the importance of the urinary acid-ammonia ratio as an index of renal health; he pointed out that this ratio is extremely constant, and that any departure from the normal in the absence of alkali therapy is an indication of disturbed renal function.—Dr. Dyke opened a discussion on the urea-concentration test in the course of which he asked at what stage of the test a specimen of blood for estimation of urea should be taken; opinion differed widely on this point. The speaker stated that inasmuch as he regarded the test as one of the concentrating power of the kidneys, it has been his custom always to take the blood at the third hour.—Dr. Davey reviewed the results of the urea-concentration test as an indication for complete prostatectomy. In the course of the afternoon session, demonstrations were given as follows: Dr. A. Renshaw, a self-filling burette for routine analytical work; a new type of chamber for counting the cells of the blood and other technical devices; Dr. Dyke, mice showing results of Zondek-Aeschheim test for pregnancy; Dr. A. L. Taylor, recent additions to the pathological museum of the Bristol General Hospital; Dr. E. N. Davey, pathological specimens from the Gloucester General Hospital, and an unusual type of typhoid bacillus isolated from a suppurating mesenteric cyst. Dr. J. R. Collins, senior physician to the Cheltenham Hospital, addressed the members on the "Sins of the Pathologist"; in the course of the evening a party of members was shown round the baths by Mr. T. Holmes, senior surgeon to the hospital.

ORTHOPEDIC HOSPITALS.—The fifth annual report of the Royal Cripples' Hospital, Birmingham, states that the work of co-ordination has gone steadily forward since the institution was formed by the amalgamation of the Birmingham Cripples' Union and the Royal Orthopaedic and Spinal Hospital in 1925. The Newhall-street Hospital has been closed and the patients transferred to Woodlands, where three new wards have been provided, together with an operating block and a nurses' home. Woodlands will now accommodate 60 adults and 130 children, and the cost of the improvements has been £17,000. The arrangements with the Birmingham health and education committees are working so smoothly that it is now practically impossible for any Birmingham child under 14 requiring orthopaedic treatment to be overlooked. It is hoped in the near future to open further extern clinics. During the past year a training centre and hostel for masscases, which has room for 20 resident students, was opened.—Last year the Shropshire Orthopaedic Hospital and Agnes Hunt Surgical Home, at Oswestry, treated 610 adults and 663 children in-patients; over 40,000 massage and gymnastic treatments were given, and 623 operations performed. The after-care scheme grows more important every year, and a closer link has been created between the hospital and various local societies and voluntary orthopaedic associations. In return for a payment of £1 per quarter the hospital undertakes to provide orthopaedic, surgical, and nursing attendance, to supply splints and appliances, and to alter boots surgically. With an income of £18,511, there was a credit balance on the year of £30.

Reviews and Notices of Books.

PSYCHIATRY.

La folie et la guerre de 1914-1918. By A. RODIET, Médecin-Chef de l'Asile de Ville-Evrard; and A. FRIBOURG-BLANC, Professeur au Val-de-Grâce. Paris: Felix Alcan. 1930. Pp. 194. Fr.30.

AFTER a brief historical comparison of the last war with that of 1870, the authors describe their efforts to collect statistics on the subject of the incidence of insanity in relation to the war of 1914-18. The few replies quoted show that this proved impossible, and they decided to confine their work to the adequate records kept of 25,000 cases which passed through Val-de-Grâce. Much space is wasted on ordinary descriptions of the different recognised forms of psychosis, and case-histories are given of samples of each. The one form supposed peculiar to war—"obusite," or shell-shock, is shown to include a variety of different conditions and no specific syndrome. The authors' general conclusion is that while most of the war cases would probably have had similar illnesses without the war, this did form an unusual stress which, to some extent, contributed to the mental breakdown, and even determined it in some who might have stood an easier life than that of a soldier. They differ from most observers in judging that cases recovered or improved can usefully be re-employed in the army. The question of pensionability is adequately discussed. The most interesting section in the book deals with experiments in suitable chronic and improved cases in village communities grouped round a central psychiatric unit and under proper supervision. This system has been tried with success in the Seine district, and is advocated in principle. Brief suggestions are made as to proper organisation of a psychiatric service for war conditions, and especially for the detection of psychopathic persons called up for service, with a view to placing them where they can perform useful service while avoiding such stress as might precipitate an acute breakdown. Malingering and simulation of insanity were found to be of relatively rare occurrence. The book would be much better if compressed to a quarter of its length, and if all matter not directly relating to war manifestations were rigorously excluded.

Manuel élémentaire de psychiatrie. By M. NATHAN, Ex-interne des Hôpitaux, Ancien Chef de clinique à la Faculté de Paris. Paris: Masson et Cie. 1930. Pp. 319. Fr.30.

THIS is an ordinary small text-book, giving general descriptions of the different types of psychosis and neurosis. After an introduction discussing modes of classification, the descriptions of syndromes are grouped into emotional and organic; in the former the author includes not only the neuroses and manic-depressive psychoses, but also schizophrenias, epilepsy, and confusional states, while all toxic psychoses including drug addiction are placed in the latter group. The final chapter on treatment is brief, and not likely to enlighten the student greatly; one section deals with tests using drugs affecting the autonomic nervous system, the idea being to use in treatment those which correct a "vago-tonie" or "sympathico-tonie." Another talks vaguely of acidity and blood pH, but advises only the administration of sod. bicarb. and calcium on the vaguest indications, while a general try-out of hormones is also advocated on no definite plan. The final chapter deals with methods of voluntary and certified admission, and the book ends with a prehistoric picture of the application of a variety of obsolete forms of mechanical restraint. Under psychotherapy is included a brief account of psycho-analysis, with no indication of the difficulty, if not impossibility, of its application to psychotic patients. It has to be remembered that

the author claims to have written only an elementary manual, for one would be sorry for him who fared forth into psychiatric practice with no other guide than this book provides.

Psychiatrie du médecin praticien. Second edition. By M. DIDE, Directeur Médecin de l'Asile de Braqueville; and P. GUIMAUD, Médecin-Chef des Asiles de la Seine. Paris: Masson et Cie. Pp. 466. Fr.45.

THIS is a thoroughly adequate and complete guide to psychiatry, beginning with general psychology and its disorders, then passing to a well-arranged description of the main psychoses and neuroses, their ætiology, clinical manifestations, differential diagnosis and treatment, and giving useful summaries and tables differentiating syndromes. A detailed account of the procedure for examination of a mental case and the possible procedure to be adopted for care and treatment follows, with particulars of the legal requirements. Next comes a most practical chapter on treatment, and the essential methods of pathological investigation of the cerebro-spinal fluid, which would be improved by the addition of exact instructions on doing a lumbar puncture. The book ends with an excellent summary of medico-legal questions relating to psychiatry, including criminal responsibility. A specially pleasing feature is the number of admirable reproductions of portraits of cases showing typical attitudes and facial expressions. In the almost complete absence of errors of printing we may note the misspelling of Schilder as Schilder, in the description of the periaxial encephalitis named after that authority.

Le traitement de la paralysie générale et du tabès par la malaria provoquée. By A. FRIBOURG-BLANC, Professeur agrégé au Val-de-Grâce. Paris: Masson et Cie. Pp. 120. Fr.15.

THIS little handbook sums up clearly the main points any practitioner will wish to know about this treatment. It gives the history of the method, evaluates its results, and provides full particulars of its application, with details of the dangers to be watched for and the means of meeting them. In the descriptions of methods of inoculation and preservation of blood for transport, no mention is made of the use of the mosquito for this purpose; the author gives evidence supporting the view that the induced strain of benign tertian cannot be transmitted through the mosquito, and states that the precautions against possible spread which are required in this country are wholly unnecessary. Full case-histories are given of typical cases, and the symptoms and signs which do and do not improve in those patients who derive general benefit are clearly set out. In tabes the author finds that subjective symptoms, notably visceral crises and lancinating pains, and also the general lack of muscle tone, are improved, while other manifestations show little change. The book is concise, while it leaves out nothing of real importance to anyone wishing to apply the treatment in practice.

A SYNOPSIS OF SURGERY.

Ninth edition. By ERNEST W. HEY GROVES, M.S., M.D. Lond., F.R.C.S. Eng., Surgeon to Bristol General Hospital, Professor of Surgery, Bristol University. Bristol: John Wright and Sons, Ltd. 1930. Pp. 670. 17s. 6d.

Prof. Hey Groves deserves congratulation on the thoroughness with which he has carried out the task of revision, since there is no statement to be found in the ninth edition of this popular book which is not in line with modern practice and teaching. To summarise the facts of surgical practice in 670 pages is no mean achievement, and when it is added that the summary is clear, full, and complete, and

further that it is illustrated, we can appreciate the difficulty of the task Mr. Hey Groves has ably fulfilled. Of the new inclusions the paragraph on radium on p. 75 is perhaps the least happy, in that it does not give a complete nor accurate account of modern radium therapy.

It is unnecessary to tell students that they will find this book of great help in revision, since this verdict has already been given by successive batches of students since 1908. Practitioners will find in it a useful and rapid means of refreshing their knowledge of any particular surgical problem.

GRAY'S ANATOMY.

Twenty-fourth edition. Edited by T. B. JOHNSTON, M.B., Ch.B., Professor of Anatomy, University of London, Guy's Hospital Medical School. London: Longmans, Green and Co., Ltd. 1930. Pp. 1466. 42s.

Prof. Howden, after more than a quarter of a century as editor of this famous text-book, resigned the onerous position last year. This edition, then, is the first which has appeared under the regis of Prof. Johnston, whose labours have met with great success. We are impressed by the evidence of careful and systematic revision which appear throughout the book. The frequent inclusion of very recent work in the general narrative is noteworthy, for this is not a common feature of text-books. The section on the central nervous system has been rewritten in large part, and many new figures have been added, so that this section is about half as long again as it was in previous issues. The new work has been very well done, as indeed are all the additions made by the editor. We notice a tendency to curtail the short paragraphs which were, in some sense, a feature of "Gray," under the name of applied anatomy, and this is, in our view, a move in the right direction. "Applied Anatomy" is only another name for medicine or surgery in one of their multiple spheres of activity, and its teaching, in the view of most anatomists, should be left to a later stage of the curriculum. While offering congratulations to Prof. Johnston we may add that, on grounds of sentiment, we rejoice to see this great work back in London, where it had its birth more than 70 years ago.

CHEMICAL METHODS IN CLINICAL MEDICINE.

Second edition. By G. A. HARRISON, B.A., M.D., B.Ch. Cantab., M.R.C.S. Eng., L.R.C.P. Lond., Reader in Chemical Pathology in the University of London; Chemical Pathologist to St. Bartholomew's Hospital. London: J. and A. Churchill. 1930. Pp. 534. 18s.

Of recent years the subject of chemical pathology has received a considerable amount of attention from publishers. Books dealing with the use of chemical methods in the diagnosis of medical and surgical conditions fall usually into two categories: (1) those intended mainly for the laboratory worker, and containing detailed accounts of the technique, and (2) those in which the actual technical consideration is not set out at length but where great attention is paid to the use and interpretation of the method. The latter are intended primarily for clinicians and form very useful additions to the literature. A number of books have appeared of recent years of both these types, among them this volume just published by Dr. G. A. Harrison stands out. Since the author is chemical pathologist to St. Bartholomew's Hospital, it follows that the experience behind the book must be extensive, and its lessons have been admirably assimilated. The scope of the book may be judged from the first paragraph of the preface, which contains samples of questions commonly asked by the student, the practitioner, and the laboratory worker, respectively. "Which book gives

the subjects dealt with in your classes?" "What is the meaning of these analytical results?" "How do you estimate such and such a substance?" The author has attempted to provide answers to all these and to similar questions. In other words, he has tried to write a book valuable to students, practitioners, and laboratory workers, and has succeeded.

The contents of the book cover the whole field of biochemistry as applied to medical and surgical diagnosis and treatment. After an introduction containing some very useful notes on solutions and apparatus, Dr. Harrison, in the following chapters, gives a detailed account of the routine tests on urine and tests for renal efficiency and for the presence of abnormal constituents in the urine, showing how these examinations can help the practitioner in the diagnosis and treatment of his cases. Blood analyses also are fully explained, and the final chapters deal with gastric analyses, determination of the basal metabolic rate, and methods of examining the cerebrospinal fluid. The chapter on investigations in diabetes mellitus and the control of insulin treatment is particularly good. In addition to the chemical details the book contains diets on Lawrence's well-known "line-ration" scheme; this is of great value to the clinician since it enables him to find in this one book all that he requires to know concerning the modern treatment of cases of diabetes.

TISSUE CULTURE.

Praktikum der Gewebepflege oder Explantation besonders der Gewebezüchtung. Second edition. By RHODA ERDMANN. Berlin: Julius Springer. 1930. Pp. 148. R.M.14.80.

THERE have been many advances in tissue culture during the eight years since the first edition of this book came out, and Prof. Erdmann has had much to add and amend. The result of her revision has been the production of an extremely valuable and up-to-date text-book on the subject. Prof. Erdmann uses excellent sketches to illustrate her technique in drawing blood from animals; these have the advantage over photographs in that no essential details can be missed. The methods used by A. Carrel and G. Fischer in maintaining sustained growth of tissue over long periods of time are fully described. The chapter on the growth in vitro of nervous tissue, muscle, epithelial and connective tissue is abundantly illustrated, and the much disputed subject of the production and cultivation of pure strains of cells is discussed at some length. The pathological aspect of tissue culture is dealt with in the concluding chapter where, among other subjects, the growth of malignant cells and the influence of invading bacteria are described.

This is a book that should be read by everyone interested in the cultivation and study of animal tissue in vitro; those unfamiliar with the German language would doubtless welcome a translation.

HANDBOOK OF THERAPEUTICS.

By DAVID CAMPBELL, M.C., M.A., B.Sc., M.D., "Pollok" Lecturer in Materia Medica and Pharmacology in the University of Glasgow; Assistant Physician to the Western Infirmary of Glasgow. Edinburgh: E. and S. Livingstone. 1930. Pp. 411. 12s. 6d.

This work is modestly termed a handbook, but it is much more than this. It is, indeed, a comprehensive treatise on therapeutics, full of up-to-date information given in a concise form. In the treatment of each separate condition Dr. Campbell has given us the results of a wide experience during which his critical outlook has remained keen, as the reader will admit when viewing therapy stripped of unnecessary frills. The work is well up to date; a paragraph notes on the uses of plasmochin in malignant tertian

malaria, while the value of ouabain, quinidine, and novarsural in special heart conditions, and the use of ephedrine in asthma are also assessed. In the paragraphs on coughs the author gives an interesting diagram representing the cough reflex. He reminds us that being a reflex a cough has a definite purpose, and therefore should not be suppressed without a careful consideration as to whether it is of benefit to the patient or not. According to him, analysis of patent cough mixtures shows that the majority contain some preparation of the alkaloids of opium; their efficacy in allaying cough is therefore measured in terms of their narcotic content. It is remarkable that in the treatment of acute and chronic nephritis jalap is recommended. Since jalap is now recognised to be a potent kidney irritant, and is even used experimentally on animals to affect the kidneys, its use in the treatment of nephritis would seem to be contra-indicated. In the section on blood diseases two interesting tables are given; one shows how the advance of polycythaemia vera can be controlled by short courses of acetylphenylhydrazine, and the other the remarkable effects of splenectomy on thrombocytopenic purpura. Especially good is the section on ductless glands, particularly the part dealing with diabetes; the table of caloric requirements for males and females for all ages should be of great assistance to those not accustomed to treating this disease. The paragraph headed "points in the training of patients" is well worth study. In discussing the uses of iodine in thyroid conditions, Dr. Campbell says: "It has at least the authority of antiquity, for well-authenticated Chinese writings about the years 1567 to 1573 show clearly that extracts of seaweed and burnt sponges (which contain considerable quantities of iodine) were regarded as specific in the treatment of goitre."

This book will be found of high value by practitioners and deserves a wide public.

BIOLOGICAL PRINCIPLES.

By J. H. WOODGER, B.Sc., Reader in Biology in the University of London. London: Kegan Paul, Trench, Trübner, and Co., Ltd. Pp. 498. 21s.

WHETHER working biologists are likely to possess the equipment for the digestion of Mr. Woodger's book may be doubted, but anyone who has had misgivings about the method of thinking, let alone the loose use of terms, will be grateful to the author for his profound and tenacious study of the logical basis of biological principles. Ordinary working biologists, even those who care to think upon the principles of evolution from the quasi-philosophical point of view, may be overwhelmed by the meta-physical introductory chapter and the long discussion of phenomenalism. But all who know the controversy which waged over the analysis of sensation since the time of Ernst Mach's famous book will realise that these epistemological discussions are necessary foundations for the establishment of a firm science of biological principles. Further, an analysis of things that happen is essential to an understanding of biological events; hence the chapter on Cause and Substance. Biological matters are only directly considered when the vitalistic and mechanistic theories are discussed, and this conducts the author into the analysis of the biological theory of organism, preformation, and epigenesis, and thence to teleology. In short, Mr. Woodger finds that the related matters of biology fall into groups: whole organisms; organic parts; environmental constituents; and the important types of relationship are: (1) spatio-temporal; (2) causal; (3) genetic; (4) organic or teleological. To all his long discussions the author brings acute critical powers which are admirably applied to an analysis of the important views of Whitehead and Schaxel, amongst the philosophic methodologists of the organism, and Wilson, amongst the pure biologists.

This work is a philosophic treatise of considerable length—perhaps of too great a length—but which no thoughtful biologist can afford to neglect if he cares for method as well as for collecting the bewildering facts of life.

THERAPEUTIQUE PHARMACOLOGIE ET MATIÈRE MÉDICALE.

Par le Dr. FRANÇOIS ARNAUD, Professeur honoraire à l'École de Médecine de Marseille, Médecin Consultant des Hôpitaux. Paris: Masson et Cie. 1930. Pp. 878. Fr.95.

Prof. Arnaud holds that the therapeutical equipment of the average young graduate is inadequate, and that there is room for considerable improvement in the teaching of therapeutics. This view is held by teachers in many other countries and is attributed to various causes; in France, according to Dr. Arnaud, it is due to the fact that there is no systematic teaching of pharmacology and therapeutics in the third or fourth year of medical study. He himself gives a course of instruction to senior students and on this course he has founded his book. In the first part he considers general principles, and deals with the absorption and elimination of drugs, the factors modifying their action, and prescription writing. The rest of the work is devoted to a discussion of the action and uses of individual drugs, which the author has classified into five groups. The first consists of those agents which modify infections, and includes immune sera, vaccines, general antiseptics, and specific medicaments, such as quinine, mercury, and the organic arsenical compounds. The second consists of agents which excite or depress the nervous system, while the third, fourth, and fifth deal respectively with drugs which act chiefly on the circulation, the secretions and excretions, and general nutrition. The classification is sound enough from the practical point of view though, as the author recognises, it is vulnerable on other grounds. The book as a whole provides a good account of pharmacology by one who has had great experience in the application of the subject to the practice of medicine.

New Inventions.

A MASTOID WOUND RETRACTOR.

THE illustration shows a simple self-retaining mastoid wound retractor which has proved itself most satisfactory in use. It is lightly but strongly

made, and is so curved that when the jaws are in position the shafts and handle lie conveniently against the head of the patient out of the way. It is fitted with a cam ratchet, which maintains the jaws at any desired width with delicacy and rigidity. The instrument, which can be taken apart at the joint, is made of stainless steel so as to withstand repeated sterilisations without damage.

The retractor was made to my design by Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E.

W. M. MOLLISON, M.Chir. Camb., F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, JUNE 28, 1930.

THE FOURTH DIMENSION IN NEUROLOGY.

THERE seems always to be a latent interval between the discovery of a new scientific principle and its passage into the general currency of thought. Both FREUD's psychological concepts and EINSTEIN's theories of relativity had been promulgated for a number of years before they suddenly became topics of dinner-table conversation. There is a summation of stimuli in the reception of ideas as in the perception of sensations. The principle of chronaxy, which as far as the medical world is concerned is still in its latent period, may prove to have a far-reaching influence upon neurological thought. Much interest therefore was aroused by a meeting of the Physiological Society last week at which Prof. L. LAPICQUE, the originator of the conception of chronaxy, Dr. GEORGES BOURGUIGNON, and some of their collaborators expounded their ideas and demonstrated their methods before an English audience. The conception of chronaxy, though at first sight somewhat complex, is based upon a fairly simple relationship between the duration and the intensity of a stimulus. Let us consider an electrical stimulus to a motor nerve. That such a stimulus must have a certain minimal intensity if it is to be effective seems obvious. It is less obvious but equally true that it must have a minimal duration. Stimuli shorter than this minimal duration are ineffective however intense they may be. As the duration of the stimulus is increased beyond its minimal length, the intensity required for its effectiveness diminishes. In other words, the shorter the stimulus the more intense it must be to produce a response. There is a limit, however, to the extent to which prolonging the stimulus enables its intensity to be reduced—that is, there is a minimal intensity below which no stimulus is effective however prolonged. Chronaxy is the measure of the relation between the duration and the intensity of a stimulus. It is taken as the minimal duration at which a current of double the minimal intensity is effective, the somewhat confusing doubling of the latter figure being necessary for technical reasons. An analogy may help to make the meaning of chronaxy clear. Let us picture the production of a response to a stimulus in a nerve as akin to the heaping of a certain quantity of earth in a sieve. To achieve this it is clearly necessary that the inflow shall exceed the outflow. If the time allowed be too short, the task cannot be carried out, however large the shovel, because there is not time to carry the shovel to the sieve. A minimal time is therefore necessary. The longer the time allowed, the smaller the shovel with which the task can be accomplished, but if the shovel be too small, no time will be long enough, because the outflow will exceed the inflow. There is therefore a minimal shovel. The chronaxy of this proceeding would be the least time in which the task could be carried out with a shovel twice the minimal size.

Let us turn now to the applications, actual and potential, of the principle of chronaxy. It has been found that there are differences of chronaxy between different nerves and between different muscles, and that chronaxy is modified by drugs and by pathological states. Normally a motor nerve and the muscles it supplies possess the same chronaxy, and this harmony or isochrony is necessary for the normal contraction of the muscles in response to impulses reaching them by way of the nerve. Curare increases the chronaxy of the muscles without influencing that of the nerves and muscular paralysis is the result. On the other hand, as BOURGUIGNON and HALDANE have shown, in tetany produced by hyperpnoea the chronaxy of the nerves is increased more than three times that of the muscles. Characteristic changes in the chronaxy of the muscles are found after lesions of the peripheral nerves and are of diagnostic and prognostic value. LAPICQUE claims that muscles differ in chronaxy according to their functions, and that muscles which contract synergically in effecting a movement always possess the same chronaxy. BOURGUIGNON believes that there exists a harmony between the chronaxy of the sensory and motor nerves supplying the same region of the body and has used this regional isochrony in the interpretation of reflex action. Thus he regards the normal flexor plantar reflex as due to the fact that the muscles which take part in it possess the same chronaxy as the nerves stimulated. Reflex action is thus akin to resonance. BOURGUIGNON also interprets in this way reflexes in which the motor response occurs in a region remote from that stimulated. An example is the palm-chin reflex of MARINESCO and RADOVIC, in which scratching the thenar eminence evokes a contraction of the muscles of the chin. The sensory and motor nerves and muscles concerned in this reflex possess the same chronaxy. The extensor plantar response is held to be associated with a breakdown of the isochrony upon which the normal flexor response depends, and the substitution of an abnormal isochrony linking the sensory fibres of the sciatic nerve with the extensors of the toes. This is at first sight a very different conception of reflex action from that which has been developed by English physiology and neurology, but the two views are not essentially incompatible. In living organisms there are many levels of explanation for the same phenomenon. We can consider reflex action in terms of the anatomical paths of the nerve-fibres concerned, in terms of their physiological relationships, and in terms of the biological purpose of the reflex for the organism. These explanations are mutually supplementary and not mutually exclusive. It may well be true that changes in reflexes are associated with alterations of chronaxy in the nerves and muscles concerned, but such metachronosis may be concomitant rather than causative. Moreover, the change of chronaxy which is held accountable for the extensor plantar response would be antagonistic to the extensor hypertonia which is the predominant reflex sequel of hemiplegia in the lower limb. This difficulty shows that the interpretation of changes of chronaxy is by no means easy and requires to take account of older and equally valid conceptions of neural activity.

When we transfer the conception of chronaxy from the peripheral nerve to the central nervous system we enter, as Prof. LAPICQUE admits, the realm of hypothesis. We cannot at present study directly the chronaxy of the intercalated neurones of the reflex arc. It may be freely admitted, however, that if, as seems probable, chronaxy is a property of all excitable tissue it may play an important part in the functions

of the central nervous system. For it renders possible what may be called a physiological resonance of the neurones which permits both a greater multiplicity and a greater delicacy of neuronal relationships than is conceivable on any purely anatomical basis. The assonance and variation of rhythms offer almost infinite possibilities of coördination with a limited structural linkage. Prof. LAPICQUE's hypothesis of chronaxy-switching may illuminate many problems of inhibition, excitation, and integration. It is worth while in conclusion to examine the deeper implications of the physiological doctrine that the duration of a stimulus is as important a factor in its effectiveness as its intensity. As we have seen, a more prolonged but less intense stimulus can produce the same effect as a less prolonged but more intense one—namely, a minimal excitation of the nerve. As far as we can judge, therefore, the peripheral nerve is within limits indifferent to the ratio of intensity and duration in the stimulus. In other words, at that elementary sensory level from which we derive the raw material of consciousness, time and space are, within limits, indistinguishable. To trace the implications of this fact would take us too far from our subject. It means, however, that all vital activity, including consciousness, is essentially four-dimensional. Current biological and physiological concepts are three-dimensional. The resulting discrepancy is responsible for many philosophical problems, especially in the realm of perception. Chronaxy foreshadows a four-dimensional philosophy of the organism.

A SURVEY OF MEDICAL EDUCATION IN EUROPE.

A GROUP of well-known American and Canadian authorities have been studying the pattern of medical education in Europe, or rather in certain European countries, and the various social problems related thereto. They have now made a report, for which Dr. WILLARD C. RAPLEYE, acting as "director of study" for an informal commission, is responsible, and it is a valuable document, which though partial in scope is impartial in judgment, and takes note of the things that matter. We obtain a detailed summary of the medical curriculum in this country, and a scrutiny of instructional courses in Germany and France which are not so full, but this is accounted for partly (and certainly) by the complicated story which British medical education presents, and partly (and probably) because an underlying sentiment of the commission is a desire for medical reciprocity between the English-speaking powers. Brief notes are added on the professional courses compulsory for medical students in Austria, Switzerland, the Netherlands, Denmark, and Sweden, and following these chapters we have a note on post-graduate education in Europe generally where the organisation in Denmark is fully treated. There is next an inquiry into the general aspects of medical practice in Europe in connexion with sickness insurance, which is succeeded by a valuable appendix where we find a list of the institutions and university faculties in the different countries which are able to grant medical qualifications. In the case of Great Britain the statistical information as to the average length of the curriculum, the broad results of examination, and the total expenditures by the schools upon the students is lucidly expressed and will furnish common ground for discussion between this country and America when questions of coöperation are on the tapis. All

this information is compressed into a readable document of some 200 pages, and such rigorous exclusion of all but necessary matter has been practised with due proportion under the various headings. The report, though intended for the information of American authorities, can be read with extreme advantage by all interested in the problems of medical education.

The position in Great Britain is put out with remarkable clearness in an essay which comprises rather more than a quarter of the volume. A correct historical résumé of the development of the medical schools notes their primary association with voluntary hospitals and their increasing connexion with universities. This is an important observation, being an indication of practical rapprochement between the educational system of this country and America, where the great medical schools practically represent the work of the medical faculty of a university, the hospitals thus being wholly, or partly, the workshops of that faculty—a bald but mainly accurate description. Follows an exposition of the duties and responsibilities of, and the services rendered to the public by, the General Medical Council; this would make instructive reading for many publicists in this country whose criticisms of the Council, both with voice and pen, are too often forcible in proportion to their inaccuracy. The facts here can be found in the prefatory reading attached to the Medical Register, in the volume recently published from this office, entitled the "Conduct of Practice," and, for the most part, in the yearly educational numbers of THE LANCET, but the running comments of Dr. RAPLEYE upon the career of the British student are informing to us all, inasmuch as he is led to stress certain aspects of the British medical curriculum which we take so much for granted that they seldom receive notice. Speaking of the elaborate system of examinations by which entrance to the medical profession is hedged about in this country, he alludes to the system as "a national industry"; and, drawing attention to the numbers of those who pass and those who fail at the numerous tests imposed by the qualifying bodies, he comments on the waste of time that is thus implied. He attributes these lamentable figures to two reasons, working throughout the course—namely, the absence of any arbitrary limitation to the number of students, followed by a similar absence of machinery under which a student can be removed from a medical school upon evidence of unfitness for the profession which he is striving to enter. Here, again, we have a reflection of fundamental importance to those who are working for an effective union between the medical professions of America and Great Britain.

It is with the possibility in view of such a union that this report becomes of topical interest to British educationists. The American "director of study," in scrupulously fair terms—indeed without a word of cavil—sets out the evils of examination; and those who know the framework of medical education in the best centres of the United States could point to the risks which are run by educational authorities when, in dispensing with external examiners, reliance is placed, for the standardisation of the medical students, upon the opinions of those engaged in teaching the candidates. The report finds in the British admission to the students' ranks of all and any who can comply with preliminary tests the cause of recurrent failures in examinations, and to some extent this is true. But those who are familiar with the drastic methods of weeding out that have to be practised in the medical schools in America so as to ensure that the classes of students, as they receive their training, present a common pattern of progress, will see no difference

in the plight of the rejected students; while the waste of time in dealing with unsuitable material has occurred before the sentences of banishment are pronounced. Progress lies between too much examination and too little examination—and this is alike the essential message of a clear and simple report, and a question of importance to America and Great Britain and to the other countries which have fallen under the notice of the commission. For those who regard union between the medical professions of each nation as a vital factor in the development of international amenities, it is satisfactory to hold that between the great English-speaking countries it is a matter not of principle but of degree, that calls for adjustment, when a fusion of interests can be secured.

PAPILLOMA AND CARCINOMA.

THERE are three main aspects of the cancer problem: a clinical or diagnostic, a surgical or therapeutic, and a biological, which concerns causation. It is for his work on the second of these that the name of **SAMPSON HANDLEY** will be lastingly remembered, since by his classical researches on the paths of dissemination he placed the surgical treatment of cancer upon a more scientific foundation—a foundation which is not likely to be shaken until we can dispense with mechanical methods of destroying malignant tumours. In the ninth of his Hunterian lectures, which we publish in our present issue, Mr. **HANDLEY** definitely passes to a consideration of aetiological factors and enunciates a new theory, which by reason of its extreme simplicity is bound to arouse universal interest and, as he has doubtless foreseen, not a little criticism. On page 1389 he says:—

"Any given consequence such as cancer springs from a chain of previous events stretching back to infinity, and not from a single cause. But if among those events one can be detected which for a given consequence is very frequently present, and has never been proved absent, the clue to the problem of causation has been obtained, and this event may be provisionally and loosely spoken of as the cause. In this sense I am bold enough to claim that lymphatic obstruction is the cause of cancer, though the labours of generations may be required to trace the intermediate steps."

The claim is, indeed, a bold one, and coming from any other pen might receive scant consideration. Examination of the steps that have led him to form the theory is not—at least at first sight—very convincing. It is claimed, for instance, that "papillomatosis precedes every variety of carcinoma," and when this quotation is taken out of its context it is one which the dermatologist—who has the most frequent opportunity of studying malignant neoplasms of all kinds in their earliest stages—will find it hard to accept. Quite early in the argument we are dogmatically informed that internal warts are much more common and much more important than those of cutaneous origin. The second assertion may be correct, but every skin department demonstrates the extreme frequency of verruca vulgaris among the dermatoses and infections of the epidermis and, what is of great importance in this connexion, their complete immunity, independent of their duration, from malignant change. What may possibly apply to papillomata in ducts cannot with any regard for truth be applied to the surface variety. Mr. **HANDLEY** might find the laryngologists equally opposed to the statement that "it is the rule for laryngeal cancer to begin as a papilloma." The Emperor Frederick's case which he quotes was the basis of an international inquiry, inaugurated by the *Central Blatt* in 1888, to determine

whether benign laryngeal growths could become malignant or be so converted by intralaryngeal operations. Of 2531 cases in the first category only 12 (one in 211) were asserted by their reporters to have become malignant, and in the second, which included no less than 8216 intralaryngeal operations, 33 (one in 249), were presumed to have taken on a cancerous tendency as a result of operative irritation. Though figures are notoriously misleading, the view that papillomatosis precedes every variety of carcinoma will not be readily accepted in face of such cumulative evidence.

If credence be given to the second part of the theory even greater difficulties seem likely to arise, for it is claimed that lymphatic obstruction—the first stage of, and quite possibly a factor in, the production of the duct papilloma—is the cause of cancer. In support of this contention the lecturer gives a detailed and interesting account of the lymphatic supply of the skin, and follows it with his observations on the origin of lupus carcinoma, from whose study originated his theory of lymphatic aetiology. The hypothesis is applied to the genesis of tar cancers, and even to those which have their origin in moles and naevi. But if lymphatic obstruction in its ordinary sense is a factor in the production of cancer, then why does not the disease arise more commonly from chronic ulcers of the leg, with which lymphatic obstruction is so often associated? And why are there no premonitory symptoms suggesting lymphatic obstruction in squamous epitheliomata and rodent ulcers originating in such delicate structures as the eyelid? It is curious, too, that Mr. **SAMPSON HANDLEY** passes so rapidly over the results of the experimental investigation of cancer. Here the "absences of the relationship between papilloma and carcinoma" on which Mr. **HANDLEY** relies finds a simple explanation. According to the published work the appearance of a carcinoma after tar painting is not necessarily preceded by that of a papilloma. When an area of skin is subjected to chronic irritation by tar painting a carcinoma may arise either alone or together with a papilloma, or a papilloma may appear first at the base of which a carcinoma arises subsequently. Papilloma and carcinoma have, therefore, a close relationship because they have the same aetiology of chronic irritation. The appearance in man of a papilloma in a tissue or organ indicates, therefore, that the tissue and organ may have been subjected to chronic irritation, and this in itself accounts for the subsequent appearance of a carcinoma.

These are some of the objections which are instinctively provoked by Mr. **HANDLEY**'s arguments, and in their turn are open to confutation. Meanwhile, his lecture should receive the careful consideration of those who have found their life-work in the study of cancer.

A COURSE IN RADIUM.

THERE have long been centres in this country at which individuals have done notable work with radium in one form or another, but hitherto students requiring a comprehensive course of study have resorted to Paris or Stockholm. The want is now to be filled by setting up a National Post-graduate School of Radiotherapy in London. Not long ago Mount Vernon Hospital obtained its enabling Act to investigate and treat cancer, and the Radium Commission, charged with the distribution of relatively large quantities of radium, encouraged the hospital and the Radium Institute to collaborate on a common basis

in the foundation of a school. Inasmuch as Mount Vernon is primarily a hospital for the treatment of cancer, the affiliation would become void should radiotherapy for cancer be abandoned. A scientific advisory committee, of which Sir Thomas Horder is chairman and Dr. Malcolm Donaldson honorary secretary, which was established to control treatment and research at Mount Vernon Hospital, has been accepted in that capacity by the Radium Institute; Sir Cuthbert Wallace will act as director of medical services for both places, and the school will be managed by a joint committee. Lectures will be delivered at the Institute in Ridinghouse-street, where the out-patient and follow-up departments will be located, together with a certain number of in-patients, but the bulk of the clinical teaching on in-patients will be done in the hospital at Northwood. At the instance of the Radium Commission, which is anxious that the teaching should be started as soon as possible, a course of one month's duration has been arranged to begin on Oct. 6th. This course will be given by the teachers in the two institutions and by others with special knowledge of radiotherapy. For example, Mr. Rock Carling will demonstrate the radium bomb at the Westminster Hospital annexe and the treatment of special regions will include demonstrations by Mr. W. D. Harmer on the larynx and antrum. On five mornings in each week of the course there will be attendance at out-patient practice. Later in the morning lectures and demonstrations will be given on the physical aspect of radium therapy, and on principles of treatment, including the methods of radiation and susceptibility of cells to different wave-lengths. Special teaching will be given by Sir Charles Gordon-Watson on the rectum, Mr. Stanford Cade on the tongue and pharynx, Mr. Geoffrey Keynes on the breast and œsophagus, Dr. Donaldson on the uterus, Prof. S. Russ on physics, Dr. J. C. Mottram on experimental pathology, and Dr. Philip Gosse and Dr. W. R. Ward on surface radiation. On three afternoons there will be ward rounds at Northwood. The details of the scheme will be circulated later and it is intended that the course itself shall be repeated periodically. Mount Vernon Hospital is appealing to the public for its assistance in equipping the hospital to be partner in a school of this magnitude. The new wing of the hospital, when complete, will bring up the number of beds from 150 to 250 and the projected X ray department will enable another form of treatment to be compared in efficiency with radium.

ROYAL MEDICAL BENEVOLENT FUND SOCIETY OF IRELAND.—The report of this Fund for 1929 presented at the annual meeting held last week in the Royal College of Surgeons, Dublin, shows that during the year a sum of £2104 was disbursed in grants to seven medical men, and 13 orphans and 63 widows of medical men, the average amount of grant being less than £24 10s. "Small as this grant is," writes our Dublin correspondent, "there is no doubt that in many cases it stands in the way of utter need. The subscriptions do not show any falling-off, but they are far less than they ought to be. Every medical practitioner in Ireland—some 4000—might readily subscribe £1 at least to the Fund. None knows to what needs he or his immediate dependents may be brought. From some counties a generous return comes, from others there is nothing, and from the whole City and County of Cork there is a single guinea! In each county there is a branch honorary secretary, but it would be fairer to the Fund and to its unfortunate beneficiaries if these secretaries who are unwilling to do any work would resign their offices and give the committees an opportunity of appointing more active workers."

Annotations.

"No quid nimis."

MEDICAL SERVICE IN INDIA.

THE absence of direct reference to medicine or to the health of India in the second volume¹ of the Simon Report, which appeared on Tuesday, can hardly fail to strike those who realise the part which the medical services have played, but there is a frank recognition that the problem of internal security is not a matter only of the preservation of law and order. The spread of epidemics, such as plague, in India is only prevented by constant vigilance on the part of the authorities, and it is laid down on an early page of the report that the life of millions in India depends literally on the existence of a thoroughly efficient administrative system. There must be in India a power which can step in and save the situation before it is too late. The principle, that during the period in which India is progressing on the road to complete self-government full provision must be made for the maintenance and efficiency of the fundamentals of government, applies with the utmost urgency to the securing of health. The Statutory Commission assumes that no change will be made in the position of existing members of any All-India services, and that the rights and privileges which they have at present will be safeguarded. The Commissioners see no reason why a career in the services should not under the new constitution provide ample interest and opportunity for men of brains and character, but, they add, "we cannot ensure this," and they recommend that retirement on proportionate pension should remain open without limit of time, although they believe that the majority of officers will be prepared to remain, providing this right is secured. At the present juncture India cannot afford to lose experienced men; it is recognised that European officers lay great stress on the continued provision for themselves and their families of medical treatment by European doctors. This the Commissioners regard as essential, and they recommend that no change should be made in the present rule (Devolution Rule 12) which gives the Secretary of State in Council power to prescribe the number of Indian Medical Service officers to be employed in the provinces, as well as the appointments and conditions under which they shall be employed. No effort, it is added, should be spared to secure an adequate number of European recruits for the Indian Medical Service to implement this fundamental obligation.

THE HUNTERIAN MUSEUM.

Sir Arthur Keith's annual report on the museum of the Royal College of Surgeons of England outlines a scheme of scientific research which will enable the museum to take its proper place in the advancement of science. Some of the rooms in the College have been converted into laboratories, and several new rooms have been built and equipped for research-work of a kind appropriate to the ordinary working of a museum. Through the efforts of its President, Lord Moynihan, the College is now in a position to award scholarships, three of which, bearing the names of Beaverbrook, Melchett, and Bernhard Baron, will be available at an early date, and will yield their holders £500 per annum. To a limited extent research has always been carried on at the Hunterian Museum, but it can hardly be said to have been recognised as one of its normal functions. The new scheme gives promise of fruitful investigations, the results of which will be embodied in the published transactions of the museum. Those who visit Lincoln's Inn between July 3rd and 26th, when the

¹ Report of the Indian Statutory Commission. Vol. II. Recommendations. H.M. Stationery Office. 3s.

additions to the museum will be on view, will have the opportunity of examining many instructive specimens, several of them of unusual interest. Details of these are given in the report of Mr. Cecil Beadles, the pathological curator; they include the series of tumours of the testicle, which formed the subject of the Jacksonian Prize for 1923, specimens of torsion of the testicle, chimney-sweep's cancer, cancer of the hand arising in a chronic tuberculous ulcer, unusual tumours of the brain and nerves, a remarkable specimen of congenital disease of the bones leading to hyperostosis and osteomata of various parts of the skeleton described by Dr. J. H. Sheldon,¹ an unusual form of calcifying sarcoma of bone presented by Mr. J. E. Schofield, and a unique specimen of multiple melanotic sarcomas in the liver of a child, the disease having been transmitted from a primary growth in the mother through deposits in the placenta. This specimen was presented by Dr. Parkes Weber, who is known to possess a particular genius for acquiring remarkable specimens; he has also presented a fine example of generalised osteosclerosis secondary to carcinoma of the prostate. Other notable specimens illustrate ossification in the scar tissue around a gastro-enterostomy opening, composite odontoma of the jaw, hookworm disease, and torsion of an appendix epiploica. Special mention should be made of a series of prehistoric Peruvian skulls with trephine openings, which demonstrate the very perfect results obtained by those primitive surgeons.

THE GERSON DIET FOR TUBERCULOSIS.

SOME months ago we gave a preliminary account² on the new Gerson diet for tuberculosis which is attracting much attention in Germany. Briefly it aims at: (1) limitation of mineral salts; (2) reduction of the proportion of carbohydrate in the diet; and (3) addition of raw foods containing vitamins. It is based on the theory that removal of salt from the food tends to dry up the tissues—a process which is considered to be essential to the healing of many so-called exudative processes. The carbohydrate components of food are reduced on the assumption that carbohydrates encourage catarrhal infections, while proteins, fats, and lipoids raise resistance. A total energy value of 3000 calories—derived from protein 90 g., fat 160 g., and carbohydrate 220 g.—is considered the standard. The treatment has been most extensively used by Prof. F. Sauerbruch and his assistant, Dr. A. Hermannsdorfer, chiefly in the treatment of lupus and of bone and joint tuberculosis, and the results in lupus are said to be exceptionally good. H. Rieckenburg,³ however, finds that the inconvenience of cooking in a private house, the expense, and possibly the monotony of the diet make it hard to persuade private patients to persevere. He also points out that the conditions of the Gerson diet are, to some extent, fulfilled in the feeding of cattle, but this does not result in their immunity from tuberculosis. C. Pöhlmann⁴ records a series of cases of pulmonary tuberculosis which were treated for three to four months on the Gerson diet; 33 cases were treated, all of them having open pulmonary lesions, and they showed an increase of weight over control cases. They also showed a slight improvement in physical signs, with less cough and sputum, and reduction of temperature, and, on the whole, offered a better prognosis than normally treated cases. In two papers by M. Gerson and A. Bacmeister⁵ the combination of the Gerson diet with phosphorised cod-liver oil in the treatment of tuberculosis is discussed. Gerson himself describes the dietary in detail, giving a long list of foods which may be used. E. Mayer and I. N. Kugelmass, in reporting⁶ a group

of 30 selected patients, give a sample diet for one day. This diet, which has a calorific value of 3500, is as follows:—

7 A.M.: Oatmeal, 1½ oz.; sugar, ½ oz.; cream, 1 oz. 8 A.M.: Br. tomatoes, 3½ oz.; stale bread, 1 oz.; sweet butter, ½ oz.; cream cheese, ½ oz.; honey, ½ oz.; milk, 8 oz. 11 A.M.: Lemon juice, 4 oz.; sugar, ½ oz.; egg yolk, ½ oz.; butter, ½ oz.; crackers, ½ oz. 1 P.M.: Veg. soup, ½ oz.; potato, 5 oz.; peas, 3½ oz.; carrots, 3½ oz.; lettuce, 1½ oz.; mayonnaise, ½ oz.; bread, 1 oz.; butter, ½ oz.; milk, 8 oz. 4 P.M.: Cocoa, 8 oz.; bread, 1 oz.; butter, ½ oz. 6 P.M.: Rice, 1 oz.; lettuce, 1½ oz.; cheese, ½ oz.; bread, 1 oz.; butter, ½ oz.; milk, 8 oz. 8 P.M.: Oatmeal, 1½ oz.; sugar, ½ oz.; cream, 1½ oz.; almonds, ½ oz. In addition, the patient receives one tablespoon of cod-liver oil three times daily, much fruit between meals, and about five grammes of meat weekly.

According to Gerson the foods which should be strictly avoided are: common salt, all kinds of preserves, smoked or spiced meat, smoked or salted fish, vegetable soup, cheese, vinegar, bacon, ham, sausage, cocoa, chocolate, cake, strong tea and coffee, and alcohol. The list raises doubt whether the good results reported may not be due to correction of national errors in diet. The difficulty of the treatment appears to be that special skill is required for cooking the salt-free diet, so that it can only be adequately provided in an institution. The fact that all foods must be fresh, and that salt must not be used in preparation, are no small drawbacks in these days of urban life, and in some German hospitals—e.g., in Berlin and Munich—special kitchens have now been installed.

SCIENCE AND PHILOSOPHY.

"A PHILOSOPHY," as Mr. Wilfred Trotter says in an interesting letter in the current number of *Nature*, "is an attempt to bring into harmony the verifiable truth of science and the intuitive truth of the mind." The philosophers recognise no bounds to the subjects with which they concern themselves. But scientists are divided more or less sharply into two groups by their views on the proper relationships between verifiable and intuitive truth. One group holds that science is concerned only with what is capable of objective proof and that therefore science and philosophy can have no profitable contact. The pursuit of natural knowledge by observation and experiment arose indeed as a protest against a general faith in the efficacy of tradition and intuition, and to admit intuition once again as a valid method of ascertaining truth is to betray the main position which natural science has slowly won for itself. Sir Peter Chalmers Mitchell in his Herbert Spencer lecture at Oxford recently put the case against imagination in science very strongly, and Mr. Morley Roberts in his layman's commentary on evolution and biological doctrine¹ speaks contemptuously of the attempts which are made "to raise futile hybrids from science and the verbal philosophies which are themselves the distorted offspring of orthodox religion": it might almost be the hard hitting with which T. H. Huxley supported the same cause. On the other hand, there is a group which frankly recognises what to the ordinary man in the street is an obvious fact—that life contains a subjective element as well as a material basis. People like Prof. A. S. Eddington on the physical side and Prof. A. Meek on the biological side say that "explanations" of the world which exclude mind must necessarily be wrong because they are manifestly incomplete. This way of thinking not only sees nothing improper in a contact between science and philosophy but looks to such co-operation as a necessary condition for further progress. The same point of view is urged by Prof. F. G. Donnan in a letter to *Nature* of June 7th. He says there is urgent need that philosophers, psychologists, and scientists should get together to discuss the nature and meaning of science and its relation to philosophy and to our ordinary

segment. This defect is, however, easily remedied. Radiologists will welcome a device which permits more nearly uniform irradiation and which ensures the treatment of the cornu in cases of cancer of the corpus. The difficulty of applying radium tubes with precision through the narrow cervical canal has long been recognised. Brown's paper does not give the results of cases treated by the method, and no physicist will accept his statement that it gives homogeneous irradiation to the entire uterus and ovaries and any pathological condition that may be present. Nevertheless the technique is of much interest.

ADRENALIN AND HYPOGLYCAEMIA.

THE symptoms which follow an overdose of insulin have never been satisfactorily explained. Hypoglycaemia alone cannot be regarded as wholly responsible, for in some patients, especially in diabetics with unusually marked hyperglycaemia, the blood-sugar may be barely subnormal during "reactions." It is well known that insulin and adrenalin, when injected, have opposite effects on the blood-sugar. Some experiments by A. Norsted, A. Norgaard, and T. E. H. Thaysen¹ suggest that insulin injections stimulate the suprarenal medulla to increased secretion, and that the symptoms of "hypoglycaemia" are partly due to adrenalin. During hypoglycaemia induced by intravenous injections of insulin, these authors observe a rise in the systolic and a fall in the diastolic blood pressure, accompanied by acceleration of the pulse; these circulatory changes, which are certainly suggestive of an increased output of adrenalin, are most evident when the blood-sugar has reached its lowest point, and is about to rise again. They quote other experiments supporting their hypothesis. C. G. Sundberg and others claim that, after excision of the suprarenal, animals become more sensitive to insulin, and W. B. Cannon and his associates find that insulin fails to accelerate the heart beat in such animals. B. A. Honesay, S. T. Lewis, and E. A. Molinelli have connected the suprarenal vein of one dog with the jugular of another and have found that an insulin injection into the first dog is followed by a rise in the blood-sugar of the second. Furthermore, in Addison's disease, the blood-sugar is often subnormal. It is, of course, unnecessary to attempt to ascribe all the various manifestations of "hypoglycaemia" to excess of adrenalin; diplopia, aphasia, coma, and hemiplegia cannot be so lightly dismissed. There seems, however, little doubt that insulin injections do provoke, either directly or otherwise, a compensatory increase in adrenalin output, which is probably responsible for some of the symptoms which characterise an overdose of the former hormone. Such a conception helps to explain why "hypoglycaemic" reactions may occur when a high blood-sugar falls sharply, but not to the point of actual hypoglycaemia, in the literal sense of the term. It also furnishes an argument for abandoning as misleading the word "hypoglycaemia," although an alternative is difficult to find. "Hyperinsulinism," while being less committal, is clumsy and has, in any case, already been applied to cases of spontaneous overactivity of the β cells.

SEDIMENTATION TEST IN LEPROSY.

PRESENT knowledge of the sedimentation of red blood cells dates from the observation of Fabraeus that suspension-stability is decreased in all kinds of infection, especially those accompanied by high fever. Puxeddu (1924) first studied this phenomenon in leprosy and with others noted that the rate of sedimentation is increased in active cases whereas in nerve leprosy there is little departure from the normal. An excellent résumé of the results obtained with Rubino's reaction reaches us from Malaya.² For

this test 1.0 c.cm. of leprosy serum is added to 1.0 c.cm. of specially prepared sheep cell suspension. The two are thoroughly mixed and then incubated for one hour at 37° C. With serum obtained from cases of leprosy, sedimentation is said to occur within half an hour, whereas many hours are needed to complete it with other sera. Marchoux and Caro reported 80 per cent. positive reactions in 800 lepers, using 0.2 c.cm. suspension in place of 1.0. Russell Amies employs an elaborate technique in the preparation of the sheep cell suspension, using a solution of 6 per cent. of formaldehyde at pH 7.4. The use of formalised sheep cells in place of the patient's own erythrocytes is a distinct advantage. The formaldehyde has the property of toughening the cell membrane, whilst the haemoglobin is changed into methaemoglobin. The theory that the suspension-stability of the blood depends upon its albumin and globulin content is thus borne out by experiment and the sedimentation-rate becomes the index of the proportion of these two protein factors in the blood. But as the albumin-globulin ratio is altered in many pathological conditions, it is obvious that a diagnostic test based upon this ratio cannot be very reliable. A positive reaction was obtained in 89 out of 353 leper sera examined, while 16 positive results were recorded in a series of 287 sera obtained from a mixed assortment of diseases. A more minute analysis shows that a positive reaction is given only in those cases of leprosy in which the disease is active. All workers on leprosy are familiar with the difficulty of deciding whether it is safe to press treatment or whether it is necessary to go slowly for fear of bringing on a reaction. Experience shows that some information can be got from the Rubino test; a number of positive reactions were given by lepers who at the time their blood was taken appeared to be fairly inactive cases, but who whilst receiving fairly large doses of Alepol shortly afterwards developed severe leprosy reactions. This suggested that a positive Rubino reaction contra-indicates intensive treatment with anti-leprotic drugs.

MEDICAL CONGRESS AT BRUSSELS.—On June 28th the King and Queen of the Belgians are opening the Journées Médicales de Bruxelles, which this year celebrate the centenary of national independence. The congress will end on July 2nd.

HOSPITALS CONFERENCE AT NEWCASTLE.—A joint conference of the British Hospitals Association and the Incorporated Association of Hospital Officers was held at the Royal Victoria Infirmary, Newcastle-on-Tyne, from Wednesday to Friday of last week. In the absence of the President, Sir Arthur Stanley, Lord Armstrong presided. On the first day the conference created a fund, on the lines of King Edward's Fund for London, for the benefit of the provincial hospitals. The terms of the resolution were as follows:—

Inasmuch as the benefits of King Edward's Hospital Fund for London are limited to hospitals within the London area, the British Hospitals Association, as the representative association of those hospitals in Great Britain and Northern Ireland which are under voluntary management, is prepared to accept donations and legacies for distribution at the discretion of the Council among voluntary hospitals outside the London area. Donations and legacies may be allocated for distribution among hospitals in any defined regional area outside London. The association is also prepared to accept donations and legacies for furthering such of the general objects of the association as the council may from time to time think fit.

The Royal Automobile Club has started the fund with a donation of £800, and a request that the money shall be distributed among hospitals which have been most called upon to deal with the victims of road accidents. Subsequently Sir Robert Bolam read a paper on the Relations of Contributory Schemes to Hospitals and their Staffs, in which he expressed the opinion that the area scheme in connexion with hospitals was the only rational and economical one. Lord Cozens-Hardy followed with a paper on Hospital Contributory Schemes and their Problems. He admitted that a scheme which covered the whole country might be ideal, but argued that it would lose the great advantages which accrue from local interest in local institutions.

LXXXVIII.

INTERPRETATION OF BLOOD FILMS.

PART II.—THE WHITE CELLS.

A DETAILED account of the varied white cell changes which may be present in the blood film is apt to be involved, but the diagnostic import of these changes can be assessed in a simple manner if they are considered mainly from the point of view of cell maturity. The white cell changes in the film can thus be considered a guide to the activity of the marrow and lymphoid tissues, and it becomes unnecessary to give a long list of disease syndromes with accounts of the blood changes which may accompany them. The red marrow and the lymphoid system can be regarded as tissues which respond to a variety of stimuli by passing out more or less mature cells into the circulation, the extent and nature of the transference varying directly with the extent of the stimulus. Thus in early acute inflammation the phagocytes of the peripheral blood are increased and tend to be less mature but otherwise normal cells. In myeloid leukemia a blood film resembles a marrow film in the proportions and immaturity of the cells present.

It is not necessary to consider any more elaborate scheme of derivation of the white cells than can be established from the examination of the blood film in disease or the red marrow in health. The primitive mononuclear non-granular myeloblast can be regarded as the parent cell of all the white cells except the lymphocytes. The myelocyte is the more mature and now granular myeloblast, the type of granule, whether large or small, oxyphil or basophil, determines the type of mature leucocyte produced. The round myelocytic nucleus becomes first notched, then lobulated to form the adult cell, and, generally speaking, the more mature the leucocyte the more distinct and numerous are the lobules of its nucleus. The origin of the phagocytic large hyaline or large mononuclear cells is uncertain, but according to one view they are derived from the granular myelocyte with notched nucleus, from the nucleus undergoing little further change and the neutrophil granules usually disappearing. The lymphocytes are derived from primitive lymphoblasts very similar in appearance to the myeloblasts, and develop into the small or large lymphocytes of the normal blood.

Differential Count.

The differential count of the white cells of the stained film gives one an approximate idea of the relative proportions of the various cells. The information is approximate, since it is unusual to count sufficient cells for an accurate ratio because of the considerable variations present in different normal individuals or in the same individual at different times. The normal percentages may be given as follows. The finely granular oxyphil or polymorphonuclear neutrophil 50-65, the eosinophil 1-3, the mast cell 0-1, the large hyaline or large mononuclear 3-6, the large and small lymphocytes 25-45. It should be observed that the polymorphonuclear neutrophils commonly comprise only about one-half the total number of white cells and that the small and large lymphocytes, taken together, may closely approach this proportion under normal conditions. In childhood the relative lymphocytosis often exceeds these figures. The high proportion of lymphocytes present in health is not so generally recognised as it might be, and figures within normal limits are often quoted as examples of a relative lymphocytosis.

Variations in the kind and in the relative numbers of the white cells afford valuable evidence in the stained film and may concern either the myelocytic or lymphocytic elements. Alterations in the total number of leucocytes can only be very approximately recognised in the film. The extreme leucopenia of aplastic anemia or the leucocytosis of the leukemias can, as a rule, be deduced with certainty from the number of white cells present per field of the microscope and from the proportion of white to red cells. The intermediate variations can only be hazarded, and any estimation of the actual number of leucocytes present is fallacious because of the uneven distribution of white and red cells in the great majority of film preparations.

Myelocytes.

Increase in the myelocytic white cells may be both absolute and relative, or less commonly only relative. It occurs in any inflammatory state associated with, or tending to be associated with, pus formation in any part of the body, and in these states the film usually provides more information than the total count. The blood picture varies in degree with the gravity of the clinical state. In the early stages of inflammation the phagocytic cells are absolutely and relatively increased, the polymorphonuclear neutrophils rising to 75 or 85 per cent. and the large lymphines to 5 or 10 per cent. The eosinophils are usually diminished or absent. If the condition progresses the changes become more pronounced and the cells affected tend to become less mature as shown by deficient lobulation of the nuclei, simple notching of the nucleus, the appearance of a few myelocytes, and even the occasional presence of a myeloblast. These changes, fluctuating with the clinical state, give some clue to the progress of the disease and can be estimated from the general appearance and description of the film.

Arnett Index: Granular Changes.

The nuclear immaturity of the polymorphonuclears can be numerically estimated and forms the basis of the Arnett index, obtained by counting the nuclear lobes. The so-called shift to the left of the index results from an increase in the immature cells with fewer lobes to their nuclei. Other but less evident changes in these cells have been observed in the granules, which in toxic or inflammatory conditions tend to become larger, more deeply staining, and less regularly distributed in the cell. This appearance is apparently the one which has attracted considerable notice in Germany recently and has tended to replace the Arnett index as a guide to the presence and progress of septic states and the granules in the cells have been considered to be fragmented bacteria or the debris of cells. Since a similar appearance is present in the few remaining polymorphonuclear neutrophil cells of an aplastic anemia case both these suppositions would appear to be unlikely and the altered size, distribution, and staining reaction of the granules may simply be indications of the extra work thrown upon the cellular ferments. More serious changes, of bad prognosis, are the relative increase of the phagocytes without a leucocytosis, or even with a fall in total number. Most serious is the complete or almost complete disappearance of the phagocytic cells, a blood picture to which the name of agranulocytosis has been given and which is usually associated with an intense and commonly fatal angina of the throat.

Blood Changes in Myeloid Leukemia.

One blood state may be mentioned in which an inflammatory leucocytosis is an almost constant feature—namely, primary erythraemia or Osler's disease. Films show crowded red cells with high hemoglobin content, occasional normoblasts, and many polymorphonuclear and large hyaline cells. Chronic myeloid leukemia provides in the film an exaggerated picture of the acute inflammatory state. Over 90 per cent. of the cells are myeloid, the majority being polymorphonuclear, myelocytes are numerous, and some 5-10 per cent. of myeloblasts are present. Mast

* Part I., on the Red Cells, appeared last week.

cells and to a less degree eosinophil cells are relatively and absolutely increased, and in addition red cell changes with normoblasts and megaloblasts are found. In acute myeloid leukaemia cellular development is arrested at the myeloblast stage, and as the fatal termination approaches the cell total falls until a state of actual leucopenia is reached. The eosinophil leucocyte requires special notice among the myeloid cells, since an increase above 5 per cent. has diagnostic significance. Eosinophilia is found in almost all widespread skin affections, including most of the specific fevers, in infection by animal parasites, and in certain other states of which spasmodic asthma is a well-known example. There is no general eosinophilia in Hodgkin's disease nor any blood changes of diagnostic value.

Changes following Carcinomatous Invasion of the Marrow.

It is probable that a leakage of marrow cells into the blood stream may occur under two other conditions which one may term mechanical. One of these has already been described—namely, the appearance of nucleated red cells and immature leucocytes in the film consequent upon carcinomatous invasion of the marrow. In the two last cases of proved myeloma at the London Hospital the blood films showed a normal picture with the addition of about 10 per cent. of large mononuclear non-granular cells of a primitive endothelial type which were thought to represent the actual marrow tumour cells.

Lymphocytes.

The lymphoid elements undergo alteration in the blood films in a degree somewhat similar to the myeloid. They are moderately increased in a variety of febrile states unaccompanied by suppuration as in the granulomata, tuberculosis, and syphilis, also in uncomplicated influenza and the enteric group of fevers. The increase is more relative than absolute, a decrease in the total number of leucocytes being usual and the more significant because the changes in the blood film are the exact opposite of those found in septic states. The lymphocytes are both relatively and absolutely increased in glandular fever and in certain infantile disorders, of which the most striking is whooping-cough, when the lymphocytosis is so extreme as to be of diagnostic importance. In glandular fever the lymphocytosis may be of short duration and may not appear until late in the disease. A relative increase of the lymphocytes accompanies a diminution of the myeloid elements in the early stages of aplastic anaemia, and in the final stages the few remaining leucocytes consist almost entirely of lymphocytes.

The greatest increase of lymphocytes met with occurs in the lymphatic leukaemias when the proportion of lymphoid to red cells equals that of the myeloid elements in myeloid leukaemia. The lymphocytes in leukaemia may be either large or small, the size of the cell having no prognostic significance, and are often atypical and occasionally difficult to distinguish from myeloblasts. The diagnosis of lymphatic leukaemia can in almost all cases be made from the film preparation alone.

Summary.

Leucocytic changes recognisable in the blood film are thus to be expected in some form or in some degree in almost every kind of diseased state; the nature of the change found in any morbid entity depends upon the kind of stimulus to the marrow and lymphoid tissues, the pyrogenic infections calling for phagocytes, the granulomata for lymphoid cells, the animal parasites for eosinophils. The response of the hæmatopoietic system will be stronger if the stimulus is prolonged or intensified, strongest—but still of the same category—in those states of unknown aetiology which appear to affect the marrow and lymph glands directly and which we call the leukaemias.

FIBROSITIS.

By E. B. CLAYTON, M.B. CAMB.,

DIRECTOR OF THE DEPARTMENT OF PHYSIOTHERAPY, KING'S
COLLEGE HOSPITAL;

AND

J. L. LIVINGSTONE, M.D., M.R.C.P. LOND.,

JUNIOR PHYSICIAN TO THE HOSPITAL.

FIBROSITIS is an inflammation of the fibrous sheath and supporting structure of muscles and nerves, the ligaments of joints, fascia, and tendons.

Thickenings have been removed and examined microscopically by Stockman. Essentially it is the white fibrous tissue that shows change. At first there is a sero-fibrinous exudate without much cellular reaction; no organisms have been demonstrated on culture. Later, the oedema is absorbed and there is fibroblastic proliferation; the veins and arteries show much endarteritis and nerve fibrils show thickening of their sheaths. The condition goes on to the formation of a small area of dense white fibrous tissue and the surrounding vessels are thickened. Similar lesions are produced by injecting various organisms intravenously into animals, and it is more than possible that the lesions in man are produced by circulating organisms becoming arrested in capillaries where the circulation is poor. Recent investigations show that bacteriæmia (e.g., *B. coli* or staphylococci) may occur without definite illness.

There is no specific cause, and the various aetiological factors are as follows.

1. *Focal Infection.*—Clinicians are well aware that acute fibrositis may follow acute tonsillitis, sinusitis, tooth abscess, colitis, prostatitis, influenza, and similar infective conditions; it is also well known that a certain proportion of cases recover permanently when a septic focus is suitably treated.

2. *Trauma and strain* are common antecedents of fibrositis; rupture of capillaries and muscle-fibres is followed by exudation and fibrosis. Many different forms of injury can either cause or light up quiescent fibrositis; a slight muscle strain in a person subject to fibrositis may cause an acute attack. A girl practising back-hand top-spin strokes at tennis frequently missed the ball; she developed a painful thickening in the supinator brevis muscle. The so-called "tennis elbow" has a tender spot over the origin of the extensor muscles of the wrist and fingers from the external condyle of the humerus. Many of these cases are due to fibrositis. But the same spot may become painful and tender from lifting heavy weights such as a full watering-can when gardening. Acute fibrositis can develop in the scar formed by the healing of a muscle or ligament which has been torn. This explains some of the cases of persistent pain after an injury to the back muscles or to a joint.

A fracture is occasionally the cause of fibrositis. Painful thickenings may develop round the shoulder-joint, in the palmar fascia, and on a flexor tendon of a finger after a Colles' fracture. Again, certain patients develop stiff joints after a fracture while others do not. Sometimes every joint in the limb is stiff though the fracture is through the shaft of the bone and the anatomical result is good. Full movements may not be recovered for several months and sometimes there is permanent limitation of movement, especially in the finger-joints, which become contracted. In many of these cases there is no sign of arthritis, and no effusion. It seems that there is probably fibrositis of the ligaments of the joints. This may be due to poor circulation in the arm in a patient with a septic focus, the poor circulation being caused by the injury and the lack of movement of the limb from the use of a splint.

The nerve-fibres are commonly not affected but paralysis of muscles and loss of sensation over the cutaneous districts may develop from pressure on the nerve. Local paralysis is a common example. The nerve trunk swells and is compressed in its course through the stylo mastoid foramen. Occasionally slight pressure on a nerve may cause a temporary paralysis with loss of sensation. This may occur on waking in the morning or after resting in a chair. Resting the arms on the sides of a chair may lead to

ulnar nerve paralysis. Usually this paralysis quickly disappears on moving the limb; also, as with symptoms of fibrositis, the nerve is only hypersensitive to pressure on certain days or with a change of weather. Occasionally the paralysis persists. The following cases are examples.

Foot-drop developed in one patient while kneeling to clean a grate, and in another while squatting when working in a garden. Wrist-drop was caused by lying with the hands behind the head for 15 minutes on a bale of paper. This last patient gave a history of numbness of the little finger at times, but not of complete ulnar nerve paralysis. Recovery-time varied between two and four months. There was no previous history of acute neuritis in any of these cases, but tender spots could be found along the course of the nerve.

This paralysis occurs from pressure at points where the nerve is comparatively superficial and is lying over bone. When the arm is rested on the side of a chair the ulnar nerve is pressed against the humerus just above the bend of the elbow. The musculospiral nerve can be compressed in the musculospiral groove on the back of the humerus when lying with the hands behind the head. The external popliteal nerve is compressed between the fibula and biceps femoris tendon when kneeling. If at the time there was an effusion into the sheath of the nerve, pressure paralysis would be likely to occur, since the nerve would be swollen and more liable to compression.

Fibrositis of a Joint.—The thickenings occur in the ligaments and, when the joint is superficial, can often be felt as small hard and tender nodules. In the acute stage the joint may be stiff and painful. But in the mild chronic stage there is often only a dull ache, which may be associated with creaking on movement. It is distinguished from arthritis by the absence of bony changes and synovial thickening. Also, since the inflammation only affects the ligaments, there is seldom much effusion into the joint.

Fibrositis of Fascia.—This may affect the superficial or deep fascia. Fibrositis of the superficial fascia is called panniculitis. There may be a subcutaneous thickening or a brawny mass adherent to the skin. It is often very difficult to decide whether the subcutaneous tissue is normal, since it varies very much in different individuals according to whether they are stout or thin. With panniculitis there will be aching pain and the thickening will be tender on pressure or gentle pinching. Fibrositis may occur in the deep fascia in the form of localised tender nodules. Sometimes there are no obvious thickenings, but there is creaking on applying friction-massage to the part. This is especially common with the deep fascia over the back muscles.

Fibrositis of Tendons.—This is relatively uncommon. As a rule the onset is acute, with severe pain and redness of the skin. The extensor tendons just above the wrist are most frequently affected and fine crepitus may be felt for three or four inches above the joint. The acute stage usually lasts from three to seven days, but the crepitus may persist for a month or more. In our experience it is uncommon to get adhesions, and complete resolution is the rule. Thickening of a tendon may come on insidiously, and crepitus, recognised by the patient, may be the first sign. Sometimes a well-defined nodule appears; one of these on the long flexor tendon of the hand is the cause of "snap-finger." The thickenings are tender on deep pressure and there may be pain on any movement which involves the use of the tendon.

Diagnosis.

Mistakes are usually due to insufficient examination. It is essential that the patient be properly stripped and lie down in such a way that the affected muscles are lax. A dusting powder should be applied to allow the examiner's fingers to slip easily over the skin. It often takes five minutes of careful kneading to localise the tender nodules and, unless these are accurately localised, treatment cannot be efficient. The average practitioner would never pronounce the lungs normal without an examination of at least

three minutes, and yet few will spend the same time in examining for fibrositis.

The second point to remember is that chronic lumbago and sciatica are unusual in young subjects, and the practitioner should be on the look-out for a tuberculous lesion of bone and have an X-ray taken if the pain lasts for several weeks.

Treatment of Acute Fibrositis.

General.—In all but the mildest types the patient should be put to bed. Continual application of mild dry heat is beneficial and can be supplied best by means of a 16 candle-power carbon bulb in a hand-lamp strapped to the inside of a bed-cradle. This keeps up a constant dry heat and can be regulated by the patient himself, as he can turn it off and on as required. At the onset a good hot bath, or better still a Turkish bath, will ease the pain, cause the skin to act, and generally make the patient more comfortable. The bowels should be well opened. The diet should consist of hot fluids only for the first 48 hours, with plenty of fruit juice and sugar; this ensures excretion by the skin and kidneys of toxins and metabolic products.

Drugs.—A Dover's powder at night gives a good night's rest; aspirin in big doses, grs. 15 6-hourly, relieves pain and is often almost a specific.

Local.—Of all forms of physiotherapy, heat is the most valuable in the acute stage. It may be given as moist heat, by the old-fashioned linseed and mustard poultice, or in a neater and more cleanly manner by Antiphlogistine. The applications must be kept really hot.

Heat.—Dry heat may be supplied by (1) a single carbon bulb of about 32 candle-power in a hand lamp; (2) a small radiant-heat bath; (3) a small electric radiator—the "bowl-fire type" is especially useful; or (4) a flat electrically heated pad. When available diathermy is especially valuable, since it differs from the above methods in that the deeper tissues are directly heated.

Massage.—Gentle effleurage, which consists in stroking the skin with the hand in the direction of the nearest lymphatic glands, should be employed from the beginning, since it tends to reduce the exudation and so relieve the pain. Friction-massage should be added as soon as the local tenderness is sufficiently diminished; the skin moving with the hand or finger is rubbed against the deeper tissues. This form of massage is applied to each thickening in turn and, unless the part is very tender, with heavy pressure.

Movements.—With fibrositis of muscle, very gentle active movements through a small range should be attempted even during the acute stage; these are gradually increased in range with the object of relaxing the muscle spasm. A hand pressed over the muscle, but not over the tender area, will often ease the pain on movement.

Counter-irritants.—The heat can be followed by local application of ultra-violet rays to cause a second or third degree erythema, or by the constant current; the effect of both is probably simply counter-irritation. They are preferable to other counter-irritants such as mustard, iodine, and vesicants, as they do not cause injury to the skin, which might prevent further massage.

Dry-cupping.—This old-fashioned treatment is easily applied anywhere and deserves further recognition, as it frequently relieves pain in a remarkable way.

Acupuncture.—If these other methods fail to relieve the pain in three or four days acupuncture should be given a trial. For this the skin is purified and a fairly wide area of skin and subcutaneous tissues infiltrated with 1 per cent. novocain by means of a fine hypodermic needle. Then a large needle from a 20 c.cm. syringe is passed through the skin and thrust slowly through the affected muscles in several different directions. As a rule a single skin puncture suffices to needle a fairly wide area of muscle.

Treatment of Chronic Fibrositis.

Septic Foci.—A thorough and careful search should be made for foci of sepsis. If the usual physical examination reveals nothing, radiograms should be taken of the teeth and nasal sinuses and a culture of the urine should be made in all doubtful cases. Any vaginal or nural discharge should be investigated and, if these prove negative, the stools should be examined bacteriologically. In cases in which nothing is found a course of Plombière's treatment is well worth a trial. The bowels should be opened twice a day. It is advisable to keep the patient on a diet that is mainly vegetarian for a week or two at least; plenty of fluids should be taken and a four-mile walk a day is an excellent rule. In adipose persons attempts should be made to reduce weight to the average figure.

Drugs.—There is no specific drug and medicines do not play a large part in treatment. Iodine in some form is undoubtedly valuable, especially Lugol's iodine solution; M.v. twice daily is an average dose. A course of thyroid extract is useful and probably promotes a better metabolism of the skin tissues. It should be given in moderate doses—e.g., grs. 5 daily.

With the idea of increasing general immunity colloidal manganese can be given intramuscularly and extra vitamins may be given in the form of radiostoleum. Intestinal antiseptics such as dimol or guaiacol are worth a trial in suitable cases.

Massage.—The application of heat is continued to ease the pain, but massage, consisting of effleurage and frictions, is the essential treatment. Each thickening must be treated in turn with a few minutes' massage and this must be persevered with daily. The majority of thickenings will disappear with this treatment, the more recent ones requiring a shorter course. The patient should be warned that massage is likely to increase the pain for the first few days.

Movements.—The muscles and joints are worked through their full range of movement, special attention being paid to the stretching of structures such as muscles, ligaments, or nerves, which are likely to become shortened by the contraction of the newly formed fibrous tissue. In the later stages of the course of treatment, exercises and the faradic current are employed to develop the wasted muscles.

When fibrositis is associated with obesity it is very important to reduce the weight with special diet and exercises. General faradism to the muscles, applied by the Bergonié method, is often very effective; it should be employed in those cases in which it is difficult to persuade the patient to perform the exercises with sufficient vigour and regularity.

Counter-irritants.—These may be used in cases of fibrositis in which the pain persists in spite of treatment; they are also of value in cases of perineuritis which are not amenable to treatment by massage.

Some Special Points in the Treatment of Perineuritis.—Heat is applied in the acute stage, either by means of radiant heat baths or by diathermy. The diathermy current can be used in two ways. It can be passed along the limb in strength only sufficient to cause mild heating (since a greater degree frequently increases the pain); or it may be given locally to the increases at the tender points. In cases of facial paralysis the diathermy current or the constant galvanic current is applied to the region of the stylo-mastoid foramen to improve the circulation and reduce the swelling of the nerve. In the subacute and chronic stages of perineuritis, effleurage and frictions are used along the course of the nerve. The frictions are given with considerable pressure to superficial such as the sciatic, but with less pressure to deeper nerves, especially at points where they lie over bone. With certain nerves the massage is followed by nerve stretching. At first this is performed gently, but with increased force as the pain diminishes. Massage, exercises, and the faradic current are utilised to develop the wasted muscles.

With pressure-paralysis special splints should be worn for wrist or foot-drop. Commonly the faradic reaction is only slightly reduced, so that this current can be used for muscle stimulation. But for facial paralysis the galvanic current is more comfortable because the muscles are usually hyperexcitable to this current and painless contractions can be obtained with about 1 ma., while the faradic current is very painful on the face. As soon as any active movement returns to the paralysed muscles it is carefully re-educated with graduated exercises.

Surgical.—Localised chronic painful nodules which do not improve with medical treatment in a few weeks should be excised under a local anæsthetic. The definite tender thickenings which can be felt in the nerve in sciatica should be incised under general anæsthesia and the nerve should then be forcibly stretched. Distension of the sciatic sheath by means of injection of 100 c.cm. of normal saline or 1 per cent. quinine urea-hydrochloride has met with a few excellent results in our hands, but on the whole has been disappointing.

The rather more diffuse thickenings that occur in the lumbar and scapular regions may be infiltrated with an oily solution known as A.B.A. (Allen and Hanburys). This is slowly absorbed and produces analgesia for one to three weeks; during this time rather more drastic massage may be given, with complete cure in some cases. This solution usually causes a burning sensation for a few minutes.

In conclusion, we would point out that we do not claim that any of this treatment is original; our object in writing this article was to set out the forms of treatment that we have found most useful and to emphasise the importance of accurate diagnosis.

MEDICINE AND THE LAW.

MARRIAGE UNAWARES.

EARLIER in this month the Divorce Court had to deal with a petition for nullity of marriage presented by a petitioner who claimed that the marriage was invalid owing to his mental incapacity due to prolonged and persistent confusional psychosis. In December, 1915, he had been wounded at Gallipoli in the arms, legs, and possibly head. On his way to England he was examined by a nerve specialist who thought him a bad case. The petitioner contended that he did not know or appreciate what he was doing when he was married. The judge did not accept the contention. The petitioner had himself signed the marriage register. His friend, a minister, described him as having acted like a normal man. He had bought clothes and a ring for the wedding. There was a suggestion that he was not normal because he engaged different flats in different names. There was not, however, said Mr. Justice Bateson, such "confusional psychosis" as could be interpreted as unsoundness of mind at the time of the marriage.

A lunatic so found cannot enter into a valid contract of marriage. This is the purport of the Marriage of Lunatics Act of 1817, which replaced an Act of 1742 said to have been passed after a scandal associated with a natural son of the Earl of Bradford to whom his father left a large fortune. Apart from the Act of 1817 there is nothing to prevent a person of weak or unsound mind from validly contracting a marriage unless it is afterwards proved that he or she did not understand or consent to the contract. The cases on this subject have been interwoven with allegations of fraud, undue influence, and other elements; but the law as laid down by Sir James Hannen in *Durham v. Durham* in 1885 is reasonably clear. The contract of marriage, said Sir James, is a very simple one which does not require a high degree of intelligence to comprehend. A mere comprehension of the words of the promises might not be enough. The mind of one of the parties might

be capable of such comprehension but yet might be affected by such delusions or other symptoms of insanity as might satisfy the court that there was not a real appreciation of the engagement apparently entered into. In *Durham v. Durham* Sir William Gull gave evidence that Lady Durham was depressed in health but showed no trace of mental disease. Three medical witnesses who had examined her at a particular date observed none of the mental symptoms alleged to exist. The judge held that any change in her condition from sound to unsound mind had occurred after marriage; there was no proof of mental unsoundness at the date of the marriage. The husband's petition for nullity, based on the wife's insanity, was therefore dismissed. In the same year the same judge, in *Hunter v. Edney*, pronounced a decree on the ground that the wife had not been able to know and appreciate the act she was doing in being married but "took an entirely morbid and diseased view of it." This last case was followed in 1908 by *Bargrave Deane J. in Jackson v. Jackson*, where the respondent was certified insane and was in confinement in an asylum. The question, said the judge, was not merely whether she had been aware that she was going through the ceremony of marriage but whether she was capable of understanding the nature of the contract she was entering into, free from the influence of morbid delusions on the subject.

As will have been gathered from these decisions the vital date at which it is material for this purpose to know the mental condition of the party alleged to be mentally unsound is the date of the marriage. Insanity supervening later is for this purpose immaterial, though, as is well known, the advocates of divorce law reform desire to see the law changed so that the subsequent insanity of husband or wife can be made a ground for dissolving the marriage tie. The decisions also make it clear that husband and wife can petition on the ground of either their own or their spouse's insanity at the time of the marriage. The burden of proof is on the party alleging the invalidity of the marriage contract, for everything is presumed in favour of a marriage validly solemnised. In the recent case before Mr. Justice Bateson the proof was inadequate. Incidentally the case showed the characteristic reaction of the common sense legal view to the suggestion of "confusional psychosis." "Medical evidence," said the judge, "as to a dual ego, personality or individuality would lead to strange results if the same man in one personality—which might be called the unreal—could contract a marriage and the same man in another capacity—which might be called the real—could, when it revived, escape from such marriage."

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Recognition of Medical Degrees.

THE question continues to attract general attention. Comment for the most part is coloured by the feeling natural under present political conditions, and much of the criticism shows no attempt at a fair estimate of the situation. Here and there one notices more moderate statements, such as that of the Vice-Chancellor of Bombay University in addressing a conference of the medical faculties of all the Indian universities. This conference met in Bombay in May to consider the situation arising from the withdrawal, by the General Medical Council, of its recognition of the Indian universities for the purpose of registration, and to suggest measures for safeguarding the interests of Indian medical students and graduates. In his address the Vice-Chancellor outlined the course of events which led up to the crisis, pointing out the influence of the Montague-Chelmsford reforms and the transference to popular control of medicine,

amongst other subjects, in bringing it about. The conference resolved to recommend the Government of India to appoint a joint university medical board, with the Director-General I.M.S. as its president, to regulate medical studies and to arrange for several medical inspectors to take the place of the single inspector whose appointment was asked for by the General Medical Council, pending the establishment of an All-India medical council. This recommendation when it was put forward by the Government of India to the General Medical Council was, it will be remembered, not accepted. An encouraging feature is that opinion is crystallising in favour of an All-India council. The *Antiseptic*, a medical paper published in Madras, recalls the attitude of the provincial ministers who opposed the proposal originally, and urges their conversion at any cost, while the *Sind Medical Journal*, in the midst of suggestions for measures of retaliation, also stresses the importance of the early formation of such a council. This may, indeed, be the only way out of the impasse.

The Supply of Quinine.

The Royal Commission on Agriculture recommended that the production of cinchona should be centralised under the Government of India. Madras has had its own cinchona department for the last 70 years, but the supply has never equalled the demand, and the present position is that India depends for at least 60 per cent. of its quinine on Java-grown bark. Clearly much remains to be done before India becomes self-supporting. The Royal Commission urged the Government to take energetic action in opening new areas under cinchona, and if a plentiful supply is to be assured, this will have to be done. But an extensive programme of planting will entail large expenditure which those in charge of the undertaking will desire to cover by some guarantee of purchase on the part of the provinces concerned. Apparently this has not yet been obtained. As long as the supply is dependent on outside sources it seems impossible to obtain quinine or the other cinchona alkaloids at a reasonable price. The world has been for some time increasingly dependent on the island of Java for these drugs, which are now a virtual monopoly of the Dutch.

Priestcraft.

A curious movement has been started in Bombay by an eminent physician, one or two prominent politicians, and some theosophists, backed, it is stated in the *Times of India*, by a large number of Congressmen and other influential persons representative of castes, creeds, and religions all over India. A society called the Anti-Priestcraft Association has been formed, with the object of combating all religious and social beliefs, customs, and institutions which cannot stand the test of reason. It is emphasised that the association is not anti-religious, but is intended to fight superstitions which have been imposed by interested persons. The chairman of the inaugural meeting remarked that all religions were good in the beginning, but tended to become priest-ridden and to degenerate with the passage of time. Another speaker stated that their object was to intellectualise religion, and to accustom men and women to make reason their supreme guide in all their affairs. It is hardly surprising that orthodox religious leaders of all communities have held aloof from the movement, but in India, as in all eastern countries (and perhaps elsewhere), it would be easy to substantiate the contention that no real advance is possible until the fetters forged by the priestly caste are broken. In medicine and other scientific subjects this is particularly true.

ELLESMERE PORT AND DISTRICT HOSPITAL.—This institution, simultaneously with being enlarged, has dropped the word "Cottage" from its name. The extension consists of two wards with 28 beds, bringing the total number of beds to 50. The cost has been £4000.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

Ministries and Medicine.

THE *Praxis Medici* reports that the Government is going to amalgamate the ministry of health with the ministry of labour, and it is widely felt that this step would be bad both for the public health and the medical profession. It is noteworthy, not only in Rumania but in other countries, that ministers of health are not medical men. In the cabinet which left office a fortnight ago, when Prince Carol returned to take up his throne, two physicians held portfolios, one as minister for home affairs and the other for agriculture. While all the other professions in Rumania get powerful support from any of their members who enter the Government, medical men who reach the pedestal of ministry deny all community with their past and with professional obligations attaching to it. Vajda or Dobrescu, although doctors, have never taken the remotest part in any medical cause or movements. They never even proposed that Prof. Moldovan should be made minister of health, although he is the obvious man for the post. He has become ministerial secretary of health in the Government formed by Maniu on June 14th. Again, in the Government of Bratianu there were two medical ministers, Angelescu and Lupu, and it was characteristic of Prof. Angelescu, who has twice been minister of education, that during his ministry he did not want to hear anything about medical affairs, while now that he is out of office he seems to feel himself a physician again. If our medical ministers had cared more for the affairs of the profession there would have been no proposal to abolish the ministry of health—that is the general opinion of Rumanian doctors. The name suggested for the new combination is the Ministry of Welfare.

Restriction of Cremation in Rumania.

A few years ago the council of the city of Bucharest set up a crematorium, disregarding the energetic protests of the clerical party, which has a big influence in Rumania. The crematorium started work about two years ago, and bodies were burnt without adequate safeguards and regulations. Recently a man was cremated who was regarded as a suicide, and a few days afterwards the suspicion arose that he had been murdered. Prof. Mina Minovici, who had a large share in creating the crematorium, has asked the minister of justice to forbid further cremation until regulations have been drawn up. For the time being, only bodies which have been examined post mortem may be burnt.

A Private Medical Clinic.

Under the title of "Clinica Medicilor Asociati, S.A." (Clinic of Associated Physicians Co., Ltd.) a company has been formed and duly registered in one of the districts of Bucharest. It starts with whole-page advertisements in the daily papers, and announces that the clinic is under the management of university professors, lecturers, present and late assistants, and hospital senior and junior physicians. It has 12 sections, and besides the attending physicians there is also a scientific committee, consisting of university professors, at the service of patients. The advertisements do not fail to point out that the chiefs of the sections are specialists who have been trained at Paris, Rome, Vienna, Bucharest, and Budapest, and have acted as assistants to the most celebrated teachers. Furthermore, it is to be noted that there are 10 auxiliary doctors and 15 "out-doctors." Besides sections for dermatology and syphilology there is also one for venereal diseases. The radiological section includes X rays, ultra-violet rays, diathermy, electrotherapy, and also hydrotherapy. The twelfth section is the "Plaja artificiala," or artificial swimming

pool, which is under the control of a committee of specialists.

The clinic calls itself a preventive medical institution organised according to the pattern of the American Life Institute. Every member, including those who are healthy, receives a health sheet, whereon radioscopic and laboratory reports are recorded. The clinic endeavours to prevent disease or nip it in the bud. If a member falls ill he is to receive medical attention and drugs without stint. Patients will pay no extra fees for calling the doctors to their own houses. Dental treatment is free, and even the first two salvarsan courses are given free to those needing it—all these privileges being included in the membership fee, which is 200 lei monthly (5s.) for single men or women, and 300 leis (7s. 6d.) for those who are married.

The profession in this country is unanimously against this commercialisation of the medical sciences. They say that now, when we are carrying on a keen fight against the socialisation of medical practice, when even the "free choice" system of insurance is regarded as a method to be rejected, when already voices are heard saying that the over-increasing number of hospitals cripple the physician, then it is but natural that practitioners should be righteously indignant about the enterprise of the 18 "apostles," as they call them, who want to embrace everybody, without exception, be he rich or poor. Those who say this forget that in Bucharest, apart from the insurance offices, there are sick clubs for every large enterprise; every ministry employs a doctor for medical attendance on its staff, while small employers have their own insurance clubs. What, then, remains for the poor practitioner? Public officials and commercial employees are not paid so well that they can enrol in this new insurance club if they are unsatisfied with those prescribed by law. Thus nothing but the middle-class remains to be exploited by the new association. But this is the stratum of the community which has been left for private practice and which assures his daily bread, though scarcely anything more, to the practitioner. So far the Rumanian Medical Association has taken no notice of the new enterprise, but the matter is likely to come up for discussion at the annual congress, and the institution will probably have to be closed.

Open Coffins.

The new public health Bill now being drafted in Bulgaria puts an end to an old oriental custom which has made a bad impression on many foreigners who have had the bad luck to see a burial there. It is the rule in Sofia, the capital, and in several other towns, to carry the dead from the mourning house to the church and from there to the cemetery in open coffins. Every spectator or follower has the right to see the body. The health authorities of Bulgaria hold that this is not a spectacle which fits in with the noisy traffic of streets, and if the Bill becomes a law the coffins will have to be closed in the morning house.

Abortion in Russia.

A Bucharest doctor, just returned from Russia, says that since abortion was legalised in Russia the number of abortions has neither increased nor decreased. A happy consequence of the law, however, has been a great reduction in the number of criminal abortions. As abortion has to be notified by the practitioner, the statistics are fairly reliable; only those miscarriages are kept secret in which the obvious misconduct of a girl or wife demands discretion, and even then it is very rare for them to be hushed up, for the penalty imposed on the reluctant doctor is too heavy to be risked. In Leningrad the majority of aborting women are married multiparae who do household work for their own family. Tuberculosis is the most common indication for interrupting pregnancy, the next being social and economic indications. Since the legalisation of artificial

miscarriage, perforation of the uterus and infections following curettage are much less common, because the operations are performed with asepsis. Even so, chronic disease of the genital tract is met with, according to Levit, in 20 per cent. of curettages performed in the out-patient departments of the clinics. Bronnikowa at the State clinic in Moscow observes that the more often a woman aborts the less is the weight of her child. The conclusion may be drawn that even if abortion passes off normally and without apparent complications in a healthy woman, the uterus is, nevertheless, made somewhat less fit for further child-bearing.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Evacuation of St. Kilda.

AN annotation in your issue of May 24th (p. 1139) mentioned the possibility that the islanders could be induced to leave St. Kilda. Mr. Tom Johnston, M.P., the Under Secretary of State for Scotland, has visited the island and reports that the number of people concerned is about 36. Among these there are only eight able-bodied men and these are not enough to maintain the life even of this small community. Careful inquiry has been made into the conditions of each family; relatives on the mainland have been traced out; possibilities of residence in different mainland areas have been explored, and it is said that the difficulties of accommodating the remnant in the County of Inverness, to which the island belongs, will not be serious. At present, apparently, members of the community are unanimous in their desire to leave; but this does not exclude the certainty that they will suffer badly from nostalgia. As the islands seem to have 1500 acres of grazing land and a smaller portion of arable land, it is possible that some industrial use might well be made of it. A geologist who recently spent some time there suggests that, apart from sheep and crops, the rock offers facilities for the creation of good quarries. The question of a meteorological station or a wireless station has been discussed; but St. Kilda apparently has no advantage in this respect over the places already in use.

Dundee Maternity Hospital.

A new maternity hospital in association with Dundee Royal Infirmary was opened by Mrs. F. B. Sharp on Friday last. It is a ferro-concrete building of three storeys, and incorporates departments for the care of in- and ante-natal patients, district room and inquiry office, students' room, and lecture theatre suite. There are two wards each of 12 beds, and wards of two beds each. Suitable and separate accommodation has been provided for the delivery and after-care of "failed forceps" and other potentially septic patients—the admission of these women being safeguarded by their passing through two admission departments. Rooms are set apart for babies, for premature infants, for women suffering from eclampsia and for those in the first stage of labour. A large flat roof, suitably screened from the wind, is served by the lift. Some special features are adequate provision for the sterilisation of bedpans, soiled linen chutes, emergency lighting at all strategic positions, X ray and electrocardiograph plugs. Adjoining the delivery room and its adjuncts is the new gynaecological operation theatre complete with surgeon's room with spray bath, wash-up, sterilising and instrument rooms, and students' gallery; the newest type of scialytic light affords very satisfactory illumination during perineal operations. Doors and woodwork are made of teak, furnishings are in oak, and floors laid in terrazzo and oak blocks. The hospital is separate from the main building of the Royal Infirmary to which it is connected by a short bridge at the level of the first floor.

The late Mr. Skirving.

By the death of Mr. Scot Skirving, at the age of 61, the Edinburgh school loses another favourite surgeon. He relinquished the position of senior surgeon at the Royal Infirmary about two years ago. A great grandson, it is said, of Adam Skirving, the author of "Hi! Johnny Cope," one of the most famous of the Jacobite songs, he was educated at Edinburgh Academy, Cheltenham College, and Edinburgh University. He was house surgeon to the late Prof. Chiene, and went with him to the South African War, being attached to the Imperial Yeomanry Field Hospital. For his services he received the C.M.G. On his return, he became a surgeon at Leith Hospital and afterwards at the Edinburgh Royal Infirmary. In the late war he served for a year in France, and for the rest of the time he was attached to Bangour Hospital. At Edinburgh he took an interest in University affairs, and became senior president of the Students' Representative Council. He was a sound teacher, and had published a text-book "Applied Anatomy and Operative Surgery," as well as many surgical papers. He drops out of the race at a comparatively early age; but he has left a reputation of careful and solid work, and many friends will miss his cheerful greeting.

Public Health Services.

SCHOOL MEDICAL SERVICE.

	No. on roll.	Average attendance.	Routine inspection.	Special reinspection.	Per cent. of defects.
Sheffield ..	77,067	69,506	26,551	128,461	15.89
Warwick-shire ..	36,650	32,849	11,865	7,862	22.7
Ilford ..	15,562	—	6,254	9,573	23.7

Sheffield.

Dr. T. Chetwood remarks of medical inspection, which has now been in force for rather more than 20 years, that, although its primary purpose was to fit children to receive full benefit from the education provided, its value can only be fully recognised if regarded as an essential factor in the national health. Medical and dental inspections are now so much a part of the educational system that the setting apart of a special room for this purpose may well be looked for in all new schools; in Sheffield these rooms have been made to serve the wider purposes of branch clinics. The scheme of clinics in the city is very extensive and the attendances this year and last year (289,688 and 307,055) are without precedent, which shows that the resources of the service are by no means exhausted. No doubt as the parents become better acquainted with the benefits of the system, they become more and more ready to avail themselves of its opportunities. The percentage of parents attending medical inspections was 69.86, a remarkable figure. Close association is kept up with staffs of hospitals and with private practitioners, and Dr. Chetwood expresses appreciation of their help in providing for the children's needs. Much of the treatment is given by them; the clinics were established to deal with such minor ailments and other conditions as did not lend themselves to effective treatment elsewhere. Of this orthopaedic treatment is a good example, and Sheffield doctors have not been slow to utilise the facilities provided by the local authority. The scheme includes a surgical consultant, Mr. W. J. Lytle, F.R.C.S., hospital treatment, massage, and electrical treatment at the Edgar Allen Institute, and schools for the physically defective. The type of child admitted to these schools shows a change during recent years; there are fewer cripples, 48 per

cent. instead of 74 in 1920, and more children of rheumatic type. It might be fair to deduce from Dr. Chetwood's statement that these P.D. schools are likely to become less of homes for incurables and more a part of a general scheme of treatment and prevention. Dental work is developing steadily, and before long the service will be sufficient to secure for the school population a condition of dental soundness. A special investigation by Mr. E. A. Reeve shows the advantage of dental treatment at regular intervals during school life. Sheffield has a nursery school with 100 places; its activities include the care of the difficult and nervous child, and Dr. Annie Sykes aims at eliciting the co-operation of parents so as to prolong the good physical and mental environment of the pupils after they have left school. Among the parental mistakes are cited overclothing, unwise punishment, and indiscriminate drugging.

Warwickshire.

Dr. A. Hamilton Wood reports progress but evidently suffers from shortage of staff. Difficulty was experienced in completing routine medical inspections and it has been impossible to make reinspections for following up. It is not always realised as it should be what demands are now made on the time of school medical officers, who, over and above the ordinary medical inspections with following up, have to deal with special examinations, refractions, visits to cases referred by attendance officers, visits to secondary schools, work at the clinics, health lectures, and even attendance at police-courts. The appointment of another assistant would allow of the provision of further minor ailment clinics in the county; a second could undertake the supervision of children between the ages of 2 and 5, so strongly recommended nowadays. The present senior assistant would then have leisure to deputise for the county officer. The care of the pre-school child, recommended in Circular 1054, will involve extension of treatment facilities and more health visitors; last year only two visits were paid to each school for cleanliness surveys. Some relief is expected from the appointment of three "dental attendants"; in the past the health visitors in addition to their other duties have assisted the dentists. The number of operations for adenoids has fallen from 64.3 per cent. last year to 58 this; the facilities provided are very complete for a county area and the low percentage is the result of inadequate following up. Mr. P. R. Marsh, organiser of physical training, describes the different conceptions of physical training which are held. To some it is merely drill more or less military; to others a means of attaining strength. The value to health and education is, however, increasingly recognised, the children becoming more intelligent, responsive, and self-reliant. Orthopaedic treatment is given to large numbers of children, many of them of pre-school age; a clinic at Solihull will complete the scheme.

Ilford.

Dr. A. H. G. Burton compares the figures for his borough with the averages for the country. The incidence of various defects found at inspections is about the average, as is also the percentage of defective children. But Ilford has 74.6 per 1000 (compared with 80.8 for the whole country) with defective vision, and 1.8 (compared with 8.0) with squint. There is no obvious explanation for the lower rate in Ilford as the standard described in Dr. Burton's analysis seems rather a high one. Again he contrasts the incidence rate of defects, physical and mental; here too the differences are slight, except in regard to crippled children, 1.7 in Ilford compared with 9.1 per 1000 in the whole country. Here the explanation is that the Ilford definition is a stringent one including only those children who are so crippled as to require instruction at a cripple school; it appears to exclude all those who can attend elementary schools with special precautions. A third table contrasts the causes of death, at all ages and at school age, over the whole country and in Ilford.

On this subject some of Dr. Burton's comments are:—

(1) That there were more deaths from all causes in school-children in Ilford is partly but, not altogether, explained by its large child population.

(2) That tuberculosis is specially high in school-children in the borough, a reason for satisfaction at the recent establishment of an open-air school.

(3) The relatively high number of deaths from measles and whooping-cough in children reflects perhaps the lack of hospital accommodation for these childish fevers.

(4) Similarly, the high figures for heart disease might be associated with the non-existence in the borough of any rheumatic clinic or special department for children suffering from subacute rheumatism causing heart disease.

The last comment provides an argument for a special P.D. school which would accept all the cripples and children with severe heart disease, including those at present attending elementary schools with special precaution. There is need of a special M.D. school for mentally defective children, but Ilford is in advance of many towns of its size in having an open-air school at Benton, which was opened in January, 1929, with accommodation for 60 pupils and is giving excellent results, physical and mental; the latter is shown by an increase of the "mental age" by one and three-quarter years in the 12 months. The high average percentage of attendance (87.3) may be attributable in part to the fact that the pupils are brought to the school by ambulance, but it also reflects the enthusiasm and interest which the school has aroused in children and parents. The percentage of dental treatment at Benton is 100, whereas in some other schools it is little over 10. Apart from the lack of a special P.D. school, the orthopaedic scheme established towards the end of the year is complete, including an orthopaedic consultant, Mr. J. B. Barnett, F.R.C.S., an orthopaedic clinic with a qualified orthopaedic nurse-masseuse, and three beds in the Royal National Hospital. A further extension of the scheme may be seen in the work of the instructor of physical training whose duties include the arrangement of special home exercises, in consultation with the school medical officer, for a number of cases of minor physical defects.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

JUNE 14TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 266 (last week 237); scarlet fever, 1430; diphtheria, 988; enteric fever, 52; pneumonia, 842; puerperal fever, 41; puerperal pyrexia, 76; cerebro-spinal fever, 12; acute poliomyelitis, 2; acute polio-encephalitis, 2; encephalitis lethargica, 17; continued fever, 2; dysentery, 5; ophthalmia neonatorum, 103. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 17th-18th was as follows:—Small-pox, 460 under treatment, 11 under observation (last week 434 and 25 respectively); scarlet fever, 1089; diphtheria, 2104; enteric fever, 20; measles, 616; whooping-cough, 70; puerperal fever, 24 (plus 13 babies); encephalitis lethargica, 122; poliomyelitis, 1; "other diseases," 18. At St. Margaret's Hospital there were 18 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 43 (6) from measles, 7 (3) from scarlet fever, 11 (0) from whooping-cough, 21 (3) from diphtheria, 43 (8) from diarrhoea and enteritis under two years, and 20 (3) from influenza. The figures in parentheses are those for London itself.

Seven fatal cases of measles were reported from Liverpool, 3 each from Southampton and Birmingham. Liverpool reported 9 deaths from diarrhoea and Manchester 3. Six deaths were attributed to influenza at Manchester.

The number of stillbirths notified during the week was 287 (corresponding to a rate of 47 per 1000 births), including 54 in London.

representation made by the medical officer of the county to the County Council, and forwarded by them to the town council of the burgh.

Mr. JOHNSTON (Under Secretary for State for Scotland) said there was a considerable body of opinion in all parts of the Committee which hesitated at accepting these words in Subsection (1), and the suggestion that the Government were prepared to make as a way out of the difficulty was that the words "to the County Council and forwarded by them to the town council of the burgh" should be deleted, and that there should be inserted in their place the words "and forwarded by him to the medical officer of health of the burgh." He said the object was that where there might be a difference of opinion between the medical officer of health of the burgh and the medical officer of health of the county regarding housing or health affairs in the small burgh on some matter which the county medical officer of health had discovered in the course of his investigations inside the burgh, he should not be compelled to report, so to speak, over the head of a medical officer of health for the small burgh, or appear in any way to interfere with the housing rights and duties of the small burgh. The suggestion he made to meet the difficulty was that the county medical officer of health should not make his report to the Department of Health, or to the town council of the small burgh, but that he should make his report to the medical officer of health of the small burgh. He trusted that this proposal for the solution of the difficulty would be generally accepted in all parts of the Committee.

Mr. DUNCAN MILLAR said that the Under Secretary for Scotland had treated this matter as if it related purely to the question of the transferred public health services, but this Bill dealt with slum clearance and improvement schemes in relation to housing, which was a matter over which the burghs had complete control. The issues which the Under Secretary had raised was a separate issue which would be dealt with by a local committee, but Mr. Johnston had not met the point that the local authority in the burgh ought to have complete contact with and control over its own officials, who ought to be directly responsible to it in the matter of official representation. According to the words proposed by the Under Secretary the medical officer of health of the county would make the representation, and the representation would be forwarded by him to the medical officer of health of the burgh.

Mr. JOHNSTON said Mr. Millar was entirely mistaken. Where a burgh appointed a medical officer of health it was the clear duty of that medical officer to report to the burgh, and only to the burgh. Where, however, the medical officer of health to the burgh had not made such a report to his town council, or had been remiss in his duty, and the county medical officer of health discovered some housing matter affecting public health, not only in the burgh but also in the county, it was proposed that it should be the duty of the county medical officer to bring such representations as he might make to the notice of the burghal medical officer of health; but in no sense was it proposed to interfere with the statutory duty of the burghal medical officer to report to his own council in the matter.

Mr. MACROBERT: Is it the position that the medical officer of health of the burgh is in supreme command?

Mr. JOHNSTON: Undoubtedly, in the burgh.

Mr. MACROBERT: And if he gets a representation from the medical officer of health for the county he can veto it? I should not so construe the clause.

Mr. JOHNSTON said that the Government had been legally advised to that effect.

Mr. MACROBERT asked if it was intended that the medical officer of health for the burgh could suppress a representation from the medical officer of health for the county, and not send it to the local authority? If that were so, it was not really an official representation at all; it was, worthless unless the medical officer of health for the burgh passed it on.

Dr. HUNTER said that if the Under Secretary for State meant that the county medical officer should report the circumstances of the unsatisfactory houses to the burghal medical officer of health he would be satisfied, but if the Under Secretary meant that the official representation was passed on to the burghal medical officer, and that it should be his duty to hand it over to the town council as if it were a mandate or order from the county medical officer he would not be satisfied. He thought the duty of a county medical officer ended when he discovered unsatisfactory housing and reported the matter.

The LORD ADVOCATE (Mr. CRAIGIE AITCHISON) said he hoped the Committee would accept the suggestion of the Government. What the clause, if amended as suggested, would provide was that the medical officer of health for the county in the appropriate case would make a representation and forward it to the medical officer of health for the small burgh, and there the matter would end. It was for the burgh medical officer of health to say whether he regarded the representation made to him as having

substance or not, and whether he proposed to act on it or upon a view of his own. If they did not leave the matter there the result would be an interference with the powers of the medical officer for the burgh, which was the very thing he understood the Committee were anxious to avoid.

Mr. MACROBERT said that if the representation were not passed on it would be of no avail and would be useless.

The LORD ADVOCATE said in the case where a representation was not passed on there was nothing in the Bill to prevent the town council of the burgh calling for that representation, and it was very difficult to conceive that such a representation would simply be pigeon-holed. The town council would not be bound to act upon the view of the burgh medical officer; if it chose it could accept the view of the county medical officer.

After further discussion,

Mr. JOHNSTON said it must be apparent to every member of the Committee that there was a difficulty here, and they were not getting nearer to a solution. It was quite clear that the form of words which he had suggested still left untouched the difficulty about "official representation." When a complaint was made by four local government electors it was provided under the clause that it should then be the duty of the medical officer to inspect a house and report to his local authority. The question arose whether a way out of the difficulty could not be found by putting the county medical officer of health on the same footing towards the burgh medical officer of health as the four ratepayers. If such a suggestion met the wishes of the Committee he would give an undertaking on behalf of the Government that the proper form of words should be introduced on the Report stage. In the meantime he was prepared to accept Mr. Millar's amendment on the clear understanding that qualifying words should be inserted at a later stage.

Mr. DUNCAN MILLAR said he was the first to acknowledge the effort which the Under Secretary had made to meet the views of the Committee. He would not like to commit himself to the suggestion that the powers of the burghs should be limited in any respect with regard to housing.

Mr. DUNCAN MILLAR's amendment was then agreed to.

Mr. JOHNSTON moved an amendment to insert a new subsection, providing as follows:—

"Before making an official representation (other than such a representation for the purpose of section eleven or section thirteen of this Act) the medical officer of health of a local authority shall consult with, or obtain a report from, the sanitary inspector of the authority."

The amendment was agreed to, and Clause 29, as amended, was ordered to stand part of the Bill.

The Committee adjourned.

HOURS OF SHOP ASSISTANTS.

The Select Committee of the House of Commons on the Hours of Shop Assistants heard evidence on June 18th from Mr. J. R. LESLIE, General Secretary of the National Amalgamated Union of Shop Assistants, Warehousemen and Clerks. He said that so far there had been only two measures limiting the working hours of assistants. Long hours behind the counter, worked often in a vitiated atmosphere, had a decidedly detrimental effect on the health of those employed. Over 40 years ago, Dr. Richardson stated that in his opinion eight hours daily was the maximum time during which labour ought to be carried on in shops. Two years ago an ex-army doctor was so impressed by the tired appearance of girls in shops in the south of England that he made personal investigations and approached the Union to see if anything could be done to stop what he considered a blot on our civilisation. At a subsequent demonstration he vigorously denounced the long hours that shop assistants had to endure as being detrimental to their health, and extremely dangerous to young women whose health would probably be impaired for life through long hours of standing. In the recent debate on shop hours in the House of Commons, Dr. Bentham, speaking as a medical practitioner, declared that the health of shop assistants compared extremely badly with that of people in almost every other trade. The Shop Acts made no provision for sanitation, ventilation or other health safeguards as did the Factory and Workshops Acts. In large numbers of cases shop assistants stood almost elbow to elbow behind their counters. Ventilation on any scientific plan was often non-existent, and in thousands of cases no regard was paid to keeping up a reasonable temperature. During winter months the sick benefit paid by the Union's approved society to its members was greatly increased, and was distinctly traceable in great part to the chilling effect of unheated shops. In February of last year, during an extremely cold spell of weather, the sickness ratio rose to the highest peak that their approved society had experienced. In a large number of shops there

were no sanitary conveniences at all. Women were sometimes called on to lift weights which were liable to cause injury. He asked that the Factory and Workshops Acts should be extended to include shops, warehouses and offices, and that the standard set by the Home Office in the case of sanitary conveniences should apply to shops.

The Committee adjourned.

HOUSE OF LORDS.

WEDNESDAY, JUNE 18TH.

FOOD VALUE OF CONDENSED SKIMMED MILK.

LORD CRANWORTH drew attention to the increased import and consumption of dried and tinned skim milk to the detriment of the market for British-produced whole milk, and asked, in view of its grave effect on the health and physique of the nation, what steps the Government proposed to take in the matter, and moved for Papers. He said that in 1921 the imports of unsweetened whole milk were 612,000 cwt. in round figures, and in 1929 they were 405,000 cwt. The imports of sweetened whole milk in 1921 were 601,000 cwt., and in 1929 253,000 cwt. In 1921 the imports of separated or skimmed tinned milk were 873,000 cwt., and in 1929, 1,988,000 cwt. The figures showed an increase in regular sequence every year, and so far from the position being changed this year there was every reason to believe that at the end of 1930 the imports would exceed 100,000 tons. The production of milk in this country was governed by various milk and dairy orders, which imposed an increasingly rigorous demand on the farmer for a higher and better production of milk. He thought that was right, but was it fair that the British farmer should be saddled with this increased cost of production unless his foreign competitors were saddled with the same cost? As regarded the detriment of these foreign milk imports to the health of the nation, that was, in his view, by far the most important point they had to consider. There was nothing which caused greater anxiety to-day than the deterioration of the national physique. Figures given by the Secretary of State for War in the House of Commons on this matter were very illuminating. Mr. Shaw had stated that out of 72,268 recruits who presented themselves for the line, 61 per cent. were rejected (91 per cent. of them on medical grounds), although in December, 1923, the standard for infantry of the line was reduced to 5 ft. 2 ins., and in the same year the dental standard was lowered. That was a very serious state of affairs. It would, of course, be absurd to suggest that this deterioration in physique was due to the fact that the people of this country consumed tinned skimmed milk in such quantities. The life of the nation had changed. The ancestors of the men of whom he spoke had plenty of regular work, perhaps too much. They did wholesome food; perhaps not enough of it. But they did not live as so many of the population did now, on cheap cigarettes, canned food, and appliances. His contention was that with the new conditions of life to-day, whatever Government was in power ought to see that everything possible was done to preserve the health of the nation. If the Government took account of what was put into the heads of the children to-day, were they to take no responsibility for what those children put into their stomachs? He held in his hand a tin of what he understood was the most popular brand of tinned skimmed milk. On the front of it were the words "Unfit for babies." If they placed in a children, let them note, but for babies. If they placed in the tumbler of water, pure or impure, three teaspoons of the contents of the tin, they got a substance which looked remarkably like milk, and which cost 3d., and three teaspoons of milk as such cost 1d. It would probably last good for a fortnight. Was it surprising that the temptation to use such milk was too great for practically any poor person to overcome? He had an analysis of this substance by a first-rate London analyst, which had not been challenged. It was: asph. 2.6 g.; fat, .86; milk sugar, 13.7; case solid matter, 45.1; 72.6; spec. 1.034; water, 27.6; total solid matter, 72.6; ash, 2.8 g.; fat, .86; milk sugar, 13.7; case solid matter, 45.1. Therefore he did not say that the mixture was poisonous, or even that it was valueless for certain purposes. But it had no right to be labelled "milk," and it was a monstrous thing that three-quarters of the children of this country should be brought up on this product. It was dangerous that any Government should countenance such a thing. If he had proved his three points he contended that it was for the Government to suggest a remedy.

LORD HASTINGS said he thought Lord Cranworth had made out an abundant case for investigation from the standpoint of the Ministry of Health.

LORD MARLEY (Under Secretary of State for War) said that the Government had a great deal of sympathy with the case as stated by Lord Cranworth. The Government considered that the use of milk was of immense importance

for the maintenance and improvement of the health of the people. They were also in agreement with the object of improving the market for British milk. They recognised that condensed skimmed milk was inferior to whole milk, and might be classified as a second-class food. But he did not think that it was possible to prohibit the import of a food merely because it was second class.

LORD CANSON: But is this substance we are talking about milk? I understood Lord Cranworth to point out that it was not milk at all.

LORD MARLEY said that condensed skimmed milk was whole milk from which the fat had been removed as well as part of the water, and to the remainder sugar was added. The composition of an ordinary tin of milk was 20 per cent. of milk solids, 46 per cent. or thereabouts of cane sugar, and 34 to 20 per cent. of water. The sugar, of course, was an addition. The dried milk to which reference had been made was milk from which not only all the fat, but practically all the water, had been removed, and it consisted of 95 per cent. of milk solids and a very small residuum of water. The milk solids consisted of non-fatty solids of considerable biological value. They included lactose—i.e., milk sugar—mineral matter and other substances. A Commission was sent to Holland and Denmark to ascertain the conditions of production, and they had reported that the conditions of production were at least as good as the conditions in this country. They also found that the cowsheds in Holland were in many cases better than the cowsheds in England. The only dietetic objection to condensed skimmed milk was that there was an absence of fat products, and the same objection applied to many other foods. Adequate steps had been taken to guard against the danger of the use of this condensed skimmed milk by ignorant people in the belief that they were using whole milk. It was a curious fact that while the consumption of condensed skimmed milk had increased, at the same time the general health of the nation had improved. The annual death-rate, which averaged 15.4 per 1000 from 1901 to 1910, had been reduced to 14.3 per 1000 from 1911 to 1920, and was further reduced to 12.2 from 1921 to 1929. But what was still more important was that the infant mortality rate had improved enormously. It averaged 128 per 1000 from 1901 to 1910, was reduced to 100 per 1000 from 1911 to 1920; and was further reduced to 73 per 1000 in the period from 1921 to 1929. Furthermore, recently, owing to the extension of the school medical service it had been found that the general health of school children—their weight, their measurements, their height—had shown a steady improvement during the last ten years. From experiments carried out by the Scottish Board of Health, in which they took a number of groups of children of various ages, and added to their normal diet certain additional diets of various kinds of milk, it had been found that although, in the case of six-year-old children, whole milk was significantly superior to skimmed milk, yet skimmed milk itself was an extremely valuable food. In children above six there was no significant difference between those children who received whole milk and those children who received skimmed milk. Dried skimmed milk, when reconstituted with water, was practically the same as boiled skimmed milk had about the same food value as that dried skimmed milk. It might be said that condensed skimmed milk was better than badly produced unsound skimmed milk. He entirely agreed that if infants were going to suffer they must do more than they had done, but the words "Unfit for babies" were very clearly printed on all the tins. There was very little evidence that this substance was used for the feeding of infants. The main reasons for using this kind of milk were undoubtedly ignorance and poverty, and perhaps, therefore, the best check on the misuse of this milk was an attack on the price and bad housing. He did not pretend for a moment that whole milk was not far better as a food than condensed skimmed milk. This country consumed far too little whole milk. The consumption in England was 4 of a pint per head per day; in the United States the figure was 1 pint a day; in Norway, 1.1 pints; in Denmark, 1.2 pints; and in Switzerland, 1.8 pints. The Government were giving full support to the work of the National Milk Publicity Council. That Council devoted itself to the advertising of whole fresh milk, and had conducted a scheme which this year was estimated to supply 4,000,000 gallons of fresh milk to school children. Many local education authorities were advertising milk and supplying it. In Scotland the Empire Marketing Board was feeding thousands of school children on milk. He would like to see a large extension of the supply, and advertising of whole milk by local education authorities, child welfare centres, and nursery schools. The prohibition of importation as a means of helping agriculture was a policy which had not been adopted by previous Governments, and could not be adopted by the present Government. It would have the effect of raising prices, and might very well

commented. Therefore, however, they might differ from him, as he certainly did, in thinking that an ordinary degree of skill is necessary for a surgeon who undertakes to perform surgical operations, and although he thought that a surgeon would be liable for *crassa ignorantia* and would be justly responsible for damages for having rashly adventured upon the exercise of a profession without the ordinary qualification of skill to the injury of the patient, yet the question did not arise upon the evidence in this case, for no want of skill was imputed to the defendant, and therefore the opinion of the learned judge who tried the case in the first instance upon that point did not affect the merits of the verdict. The other judges concurred, and the new trial was not granted.

In this case Mr. Justice Heath held that unskillfulness without neglect would not maintain the action. He himself however seemed doubtful whether this rather remarkable opinion was sound. At the trial negligence and carelessness were alone imputed, but the evidence showed that the dislocation was properly reduced and there was no gross negligence proved. He advised the jury not to convict and this advice was followed. Lord Ellenborough disagreed with Mr. Justice Heath, but held that in this case want of skill had not been proved and therefore he would not grant a new trial. His colleagues on the bench concurred in this judgment. There can be no doubt, I think, that as regards the first point (that unskillfulness without neglect would not maintain an action), Lord Ellenborough was right and Mr. Justice Heath wrong.

HOLIDAYS FOR WORKING WOMEN.

To the Editor of THE LANCET.

SIR,—May we once more, through the columns of your paper, plead the cause of the working women of London, and thereby secure for some of them, at least, the chance of a fortnight's respite from the toil and dull monotony of their daily lives? We want more help to enable us to lighten the burden of the mother of a large family, whose work is never ended, and who hardly knows what recreation means, of the lonely woman who, dependent upon her own modest earnings for her livelihood, carries on patiently, year in, year out, the dull struggle for existence, haunted by the fear of one day losing even that small income. The Women's Holiday Fund is striving to give to as many as possible of these tired and overburdened women the happiness and rest which a holiday should always bring. Away from the noise and dinginess of the London streets, and freed for a time from the worries of their homes, they are given a glimpse of a larger life. Jarred nerves are soothed by the fresh country or sea air, and hope and cheerfulness come back, when health is restored by good food and rest. The constant recurrence of such phrases as "living just like a lady," "all your meals got ready for you," in the letters of the women who write to thank for happy holidays, shows how much it means to those who are always ministering to others to find all arrangements specially made for their comfort. The applicants contribute what they can, according to their circumstances. Some indeed, having once tasted the joy of a holiday, begin saving up for the next year directly they return home.

A sum of £2 will pay for a fortnight's holiday for one woman. Donations for this sum and smaller amounts will be most gratefully received by The Secretary, Women's Holiday Fund, 76, Denison House, Vauxhall Bridge-road, S.W.1.—We are, Sir, yours faithfully,

A. F. LONDON,

J. SCOTT LIDGETT,

MANUEL J. BIDWELL, HELEN A. POWNALL,

Chairman of Executive Committee.

June 17th, 1930.

"UNE PLÉTHORE MÉDICALE."

ACCORDING to an article in our lively contemporary, the *Siccle Médical*, the medical profession in France is in danger from its very popularity. Prof. G. Carrière, of Lille, states that the total number of entrants to the medical schools this year is double what it was last year, and he fears that with a swollen entry list the quality of the instruction must deteriorate. It seems that there are not enough cadavers and microscopes to go round, and the attendance at out-patients is so heavy that most of the students only see a few patients from a considerable distance and hear little or nothing of the items of instruction that the master bestows on them. The senior physician finds it a physical impossibility to go his rounds followed by the multitude who should accompany him, 40 or 50 students, and sometimes more. A few of the senior students, Prof. Carrière writes, can see the patient, and sometimes perhaps percuss and auscultate him; the remainder converse in a low tone on matters unconnected with medicine. The result is that candidates may qualify without knowing how to do a venesection or write a prescription, for, incredible though it may sound, in France there are no rejections at

the hand of the examiners. Everyone who qualifies sooner or later. In 30 years, Prof. Carrière has never known a student, no matter how he fails to secure the parchment which gives him power or death over his fellow-men. The aspirant who fails his first attempt waits a few months and then comes another and more lenient jury. The candidate who fails is not required to repeat any courses of instruction; he is obliged neither to attend lectures in the university nor to keep posts; he lives—as Prof. Carrière puts it, a serene life of an annuitant, without the slightest obligation, and, if he has been signed up for the required number of posts (or even sometimes if he has not), by a little money by doing locums for sick or absent colleagues. In some other professions the situation is quite other. Veterinary science is taught in schools, entrance to which is by competitive examination for a limited number of places, only candidates with University degrees allowed to compete. Progress is checked by severe examinations, and a failure two years runs below a certain standard, means dismissal. Prof. Carrière reports the farewell remark of one of the teachers of a batch of students who were being expelled in this "This does not matter very much, does it? I shall see you all next year on the benches of the Faculty of Medicine. The remedies for which Prof. Carrière vehemently is are the restriction of entries to a certain number every year calculated on the requirements of the profession, with an adequate entrance qualification and drastic thinning of the curriculum and examinations, the latter conducted by teachers from another medical school. The provincial examiner is afraid that severity will pre-empt him in the future, that students when they are quizzed will remember it against him and refuse to call him for consultation or send him patients. There is, of course, in France no statutory tribunal of medical education and ethics, but if a tithe of what Dr. Carrière relates is introduced and taken seriously, even the most intemperate criticism of our General Medical Council may be given pause.

THE MEDICINE OF AVICENNA.

WE recently reviewed a treatise on the Canon of Avicenna by Dr. O. Cameron Gruner in which there was incorporated a translation of the first book. In that review we expressed the opinion that in the Islamic revolt from Christianity the line of progress of medicine was to be found through

long period of the development of our science. We received from Teheran an eloquent letter of protest, the authorship of which we have been unable to trace. The gist of the protest was to the effect that Islamic teaching was no revolt from Christianity but an imperfect revival of Christianity. Here the arguments were not of great interest, though their historical backing was excellent. But a photograph was enclosed which appeared to show the entrance to a tomb, and in case any of our readers are interested in the structure we should be glad to be informed at
